The proposed space-borne laser interferometric gravitational wave (GW) observatory TianQin adopts a geocentric orbit for its nearly equilateral triangular constellation formed by three identical drag-free satellites. The geocentric distance of each satellite is $\approx 1.0 \times 10^5$ km, which makes the armlengths of the interferometer be $\approx 1.73 \times 10^5$ km. It is aimed to detect the GWs in 0.1 mHz–1 Hz. For space-borne detectors, the armlengths are unequal and change continuously which results in that the laser frequency noise is nearly 7–8 orders of magnitude higher than the secondary noises (such as acceleration noise, optical path noise, etc.). The time delay interferometry (TDI) that synthesizes virtual interferometers from time-delayed one-way frequency measurements has been proposed to suppress the laser frequency noise to the level that is comparable or below the secondary noises. In this work, we evaluate the performance of various data combinations for both first- and second-generation TDI based on the five-year numerically optimized orbits of the TianQin's satellites which exhibit the actual rotating and flexing of the constellation. We find that the time differences of symmetric interference paths of the data combinations are $\sim 10^{-8}$ s for the first-generation TDI and $\sim 10^{-12}$ s for the second-generation TDI, respectively. While the second-generation TDI is guaranteed to be valid for TianQin, the first-generation TDI is possible to be competent for GW signal detection with improved stabilization of the laser frequency noise in the concerned GW frequencies.

I. INTRODUCTION

The detection of gravitational waves (GWs) from the coalescence of a stellar-mass black hole binary (GW150914) by advanced LIGO detectors [1] has opened up the era of observational GW astronomy. During the first two observing runs (O1 and O2) [2] and the first half of O3 [3] of advanced LIGO and advanced Virgo, more than 50 compact binary coalescences, including the first observation of binary neutron star inspiral (GW170817) [4], have been detected. Both advanced LIGO and advanced Virgo will reach their design sensitivities in the coming years which can boost the detection of GW events to higher rate. In addition, the underground cryogenic GW telescope KAGRA [5] has recently joined in the advanced ground-based detector network.

The observational window of GW astronomy will be broadened to millihertz range (0.1 mHz–1 Hz) by the proposed space-borne laser interferometers, such as Laser Interferometer Space Antenna (LISA) [6], TianQin [7], DECIGO [8], ASTROD-GW [9], gLISA [10], Taiji (ALIA descoped) [11] and BBO [12]. Among these, LISA has been comprehensively studied and developed for more than three decades [13]. In 2017, it has been selected as ESA’s L-3 mission Cosmic Vision programme with the theme of “the Gravitational Universe”. LISA is scheduled for launch in early 2030s and will be operated concurrently with ESA’s next generation Advanced Telescope for High ENergy Astrophysics (Athena). The latter will tremendously enhance the follow-up X-ray observation of the electromagnetic counterparts of LISA’s GW source candidates [14]. The successful flight of LISA Pathfinder has demonstrated the feasibility of the key technologies, such as gravity reference system and space laser interferometry, to be implemented in LISA [15, 16]. The recent GRACE Follow-on mission has demonstrated the technologies to be used in the laser ranging interferometer (LRI) of LISA [17].

Similar to LISA, TianQin is comprised of three identical drag-free satellites that form a nearly equilateral triangular constellation [7]. Each pair of satellites is linked by two one-way infrared laser beams which can be used, together with the intra-satellite laser links, to synthesize up to three Michelson interferometers. Distinct from LISA, TianQin adopts a geocentric orbit with an altitude of 10^5 km from the geocenter, hence the armlength of each side of the triangle is approximately 1.73×10^5 km. The detector plane formed by the three satellites faces to the galactic white dwarf binary RX J0806+1527 [18] (see Fig. 1). The guiding center of the constellation coincides with the geocenter, and the period of each satellite orbiting around the Earth is 3.65 days. Analytic approximation of the orbit coordinates for each satellite and the strain output of a Michelson interferometer for arbitrary incoming GWs are studied in [19]. A series of study on TianQin’s orbit and constellation, including constellation stability optimization [20], orbital orientation and radius selection [21], eclipse avoidance [22], and the Earth-Moon’s gravity disturbance evaluation [23], have been conducted. The recent progresses in the investigations of both science case and technological realization for TianQin can be found in [24–34]. A brief summary can be found in [35].

The GW sources in the mHz frequency regime are rich, which include coalescing supermassive black hole binaries (SMBHBs), ultracompact binaries in the Galaxy, extreme mass ratio inspirals (EMRIs), stochastic GW background, etc [36, 37]. For TianQin, preliminary studies on the detection rate of the SMBHBs [25], the associated parameter estimation accuracy based on the inspiral signals [24], and testing the no-hair theorem [26] and constraining the modified gravity [27] with the post-merger ringdown signals have been carried out. The prospects for detecting galactic double white dwarfs [30], EMRIs [29] and stellar-mass black hole binaries [28] with TianQin have been investigated.

Unlike the ground-based interferometers, the armlengths of a space-borne interferometer are unequal and varying in time. Therefore, the common mode laser frequency (or phase) noise, which is 7–8 orders of magnitude higher than the secondary noises (such as optical path noise and acceleration noise), cannot be canceled out at the phasemeter where the delay lines from different paths are interfered. The time delay interferometry (TDI) has been proposed to suppress the laser frequency noise for space-borne interferometers to the level that is comparable or below the secondary noises, while conserving the GW content in the data stream, by synthesizing virtual interferometers with time-delayed one-way frequency measurements [38–46]. The first-generation TDI is devised to remove the laser frequency noise in a static detector configuration. Multiple data combinations have been found which include the six-pulse combinations ($\alpha, \beta, \gamma, \zeta$), the eight-pulse combinations, such as unequal-arm Michelson (X, Y, Z), Relay (U, V, W), Monitor (E, F, G) and Beacon (P, Q, R) (see examples in Fig. 4) [39, 47], and the optimal combinations (A, E, T) [48].

All data combinations are aimed to make the lengths of the two symmetric interference paths in the synthesized interferometric measurements nearly equal. However, in the reality, this equality cannot be exactly satisfied due to the orbital dynamics of each satellite. The second-generation TDI has been proposed to further account for the rotation of the constellation and the linear variation of armlengths [44, 45, 49], which improves the length equality by judiciously splicing the first-generation interference paths [50]. This results in more data combinations than the first-generation TDI.

The result from *Synthetic LISA*, based on the analytic approximation of LISA spacecraft’s orbits [51], shows that the time differences of the symmetric interference paths are 10^{-6} s and 10^{-10} s for the first- and second-generation TDI, hence the latter must be adopted in LISA data analysis to comfortably cancel out the laser phase noises [52].

This is further confirmed by the detailed numerical simulations, based on the orbits optimized with CGC 2.7 ephemeris [53], of various first- and second-generation TDI data combinations for (e)LISA [54, 55]. Similar investigations have also been conducted for ASTROD-GW [56, 57] and Taiji [58].

In this work, we simulate the time differences of the symmetric interference paths of various TDI data combinations for TianQin. The optical paths are evaluated based on the numerical orbits of TianQin's satellites that have been optimized to meet the orbital stability requirements imposed by the long range space laser interferometry. Four types of the first-generation TDI data combinations show time differences of $\sim 10^{-8}$ s which makes them competent for GW signal detection for the frequencies $\lesssim 10^{-3}$ Hz and $\gtrsim 10^{-1}$ Hz given the stabilization of the laser frequency noise of $10 \text{ Hz}/\sqrt{\text{Hz}}$ in concerned frequency range. With an ample margin, the second-generation TDI data combinations with time differences of $\sim 10^{-12}$ s are warranted to reduce the laser frequency noise well below the secondary noises.

The rest of the paper is organized as follows. In section II, we discuss the orbit optimization for TianQin's satellites. The resulting numerical orbits interpolated by Chebyshev polynomials are subsequently used in the simulations of the time differences of the symmetric interference paths for various first- and second-generation TDI data combinations in section III A and III B, respectively. The paper is concluded in section IV.

II. CONSTELLATION OPTIMIZATION FOR TIANQIN

The orbit of each satellite is primarily determined by the monopole gravitational field of the Earth. Besides, the perturbation from the multipole terms and relativistic post-Newtonian correction of the Earth gravitational field, the monopole gravitational field of the Moon, the Sun, the major planets in the solar system, Pluto and large asteroids will also contribute. Dispersion from the Earth atmosphere and solar radiation are ignored due to the implementation of the drag-free control for the satellite platform. The minor eccentricity of the nominal Keplerian orbit along with time-dependent perturbation forces will induce variation of the armlengths, and flexing and breathing of the triangular constellation. On the other hand, the high precision space laser interferometry imposes requirements on the stability of the triangular constellation [7, 20]: (a) the armlength variation less than $0.5\% \times (\sqrt{3} \times 10^5) \text{ km}$; (b) the breathing angle (subtended by two arms) variation less than 0.1° during the first two years and less than 0.2° during the five years mission lifetime; (c) the relative range rate (Doppler velocity) less than 5 m/s during the first two years and less than 10 m/s in five years.

A. Calculation of the satellite orbits

In this work, the geocentric ecliptic coordinate system (x, y, z) shown in Fig. 1 has been adopted in the calculation and optimization of the orbits for TianQin's satellites. This choice is different from [19] in which, for the sake of calculating the antenna response of TianQin to GWs, the heliocentric ecliptic coordinate system is used. The gravitational field of the Earth is described in the Earth-fixed reference coordinate system WGS84 [59].

From the six initial Keplerian elements $\sigma_0 = (a_k, e_k, i_k, \Omega, \omega, M_k)$ of the k -th ($k \in \{1, 2, 3\}$) satellite, we can obtain the initial Cartesian coordinates in the geocentric ecliptic coordinate system as follows [60]:

$$\begin{aligned} x_k &= l_1 a_k (\cos E_k - e_k) + l_2 a_k \sqrt{1 - e_k^2} \sin E_k, \\ y_k &= m_1 a_k (\cos E_k - e_k) + m_2 a_k \sqrt{1 - e_k^2} \sin E_k, \\ z_k &= n_1 a_k (\cos E_k - e_k) + n_2 a_k \sqrt{1 - e_k^2} \sin E_k. \end{aligned} \quad (1)$$

Here $a_k \approx 1.0 \times 10^5 \text{ km}$ is the semi-major axis, and $e_k \approx 0$ is the orbit eccentricity. The eccentric anomaly E_k can be obtained by the Newton's iteration method [61]:

$$E_{n+1,k} = E_{n,k} + \frac{M_k - E_{n,k} + e_k \sin E_{n,k}}{1 - e_k \cos E_{n,k}}, \quad (n = 0, 1, 2, \dots), \quad (2)$$

where n is the index of the iteration and $E_{0,k} = M_k$. We set the mean anomaly $M_k = \varpi_k(t - t_0) + 120^\circ \times (k - 1) + 60^\circ$ in order to arrange the three satellites into a nearly equilateral triangle constellation. $\varpi_k = \sqrt{GM_\oplus/a_k^3}$ represents the angular velocity of the satellite, where M_\oplus is the Earth mass. The surrogate variables $(l_{1,2}, m_{1,2}, n_{1,2})$ in Eq. 1

are defined as follows:

$$\begin{aligned}
 l_1 &= \cos \Omega \cos \omega - \sin \Omega \sin \omega \cos i_k, \\
 m_1 &= \sin \Omega \cos \omega + \cos \Omega \sin \omega \cos i_k, \\
 n_1 &= \sin \omega \sin i_k; \\
 l_2 &= -\cos \Omega \sin \omega - \sin \Omega \cos \omega \cos i_k, \\
 m_2 &= -\sin \Omega \sin \omega + \cos \Omega \cos \omega \cos i_k, \\
 n_2 &= \cos \omega \sin i_k.
 \end{aligned} \tag{3}$$

Here we set the argument of periapsis (the angle between ascending node and perigee) $\omega = 0$. The three satellites form a detector plane (subtended by x' and y' axes in Fig. 1), the normal of which (z' axis) points toward the reference source RX J0806+1527. It thus indicates that the inclination of the detector plane $i_k = 94.7^\circ$ and the longitude of the ascending node (the angle between x axis and x' axis) $\Omega = 210.5^\circ$.

Finally, through coordinate transformation, we obtain the expression for the initial positions of the satellites in geocentric equatorial coordinates. Here we choose obliquity of the ecliptic $\varepsilon = 23^\circ 26''$.

FIG. 1. (x, y, z) represents the geocentric ecliptic coordinate system, x axis points toward the mean equinox of J2000. (x', y', z') represents the orbit coordinate system of the detector, x' axis points toward the ascending node of the satellites and z' axis points toward the reference source RX J0806+1527. Ω is the angle between x and x' , i is the inclination of the detector plane.

The subsequent evolution of the satellites' orbits, after setting up the initial condition, is determined by the dynamic equation [59] (for clarity we ignore the satellite index k hereafter),

$$\ddot{\mathbf{r}} = \ddot{\mathbf{r}}_{\text{NB}} + \ddot{\mathbf{r}}_{\text{NS}} + \ddot{\mathbf{r}}_{\text{PN}}, \tag{4}$$

where \mathbf{r} represents the position vector of the satellite relative to the geocenter. The Newtonian body term is

$$\ddot{\mathbf{r}}_{\text{NB}} = -GM_{\oplus}\mathbf{r}/r^3 - \sum_{i=1}^{10} Gm_i(\Delta_i/\Delta_i^3 + \mathbf{r}_i/r_i^3), \quad (i = 1, 2, 3, \dots, 10). \tag{5}$$

Here G is the gravitational constant. m_i , in the ascending order of i , denotes the masses of the seven major planets, Pluto, the Sun and the Moon. \mathbf{r}_i and $\Delta_i = \mathbf{r} - \mathbf{r}_i$ are the position vectors of the i -th perturbing body relative to the geocenter and the satellite, respectively. $r_i = |\mathbf{r}_i|$ and $\Delta_i = |\Delta_i|$. The positions of the planets, the Sun, the Moon are extracted from the ephemeris DE421 [62]. $\ddot{\mathbf{r}}_{\text{NS}}$ includes the sectorial and tesseral harmonic terms of the Earth's non-spherical gravitational perturbation, respectively. The first-order post-Newtonian correction term [63–65] is

$$\ddot{\mathbf{r}}_{\text{PN}} = \frac{GM_{\oplus}}{c^2 r^2} \left[(4GM_{\oplus}/r - v^2) (\mathbf{r}/r) + 4(\mathbf{r} \cdot \dot{\mathbf{r}}) (\dot{\mathbf{r}}/r) \right], \tag{6}$$

TABLE I. The values of the elements of the optimized orbit $\bar{\sigma}_0^*$ for the three satellites at the initial epoch $t_0 = \text{MJD } 64104.5$.

	Semi-major axis a (km)	Inclination i ($^\circ$)	Eccentricity e
S1	99995.0717	94.7473	2.8483×10^{-4}
S2	100010.8914	95.7094	0
S3	99992.5623	94.6469	2.0876×10^{-4}

where $v = |\dot{\mathbf{r}}|$, and c is the speed of light.

Once set the orbit elements at an initial epoch, for example $t_0 = \text{MJD } 64104.5$ (May 22 2034 12:00:00 TDB), we can numerically integrate Eq. 4 by Runge-Kutta 7(8) method to obtain \mathbf{r} and $\dot{\mathbf{r}}$ at subsequent time stamps t_i ($i = 1, 2, \dots, N$), where $N = T/\Delta t$ and $T = 5$ yr. The integration time stepsize $\Delta t = 1$ hr, which is chosen such that the total computational error (combining the accumulated round-off error from arithmetic operations of double-precision float number and the truncation error of Runge-Kutta algorithm) approaches its minimum.

B. The constellation optimization

In order to fulfill the aforementioned requirements on orbit stability, we try to find a set of initial orbit elements in the vicinity of the fiducial ones such that during the mission lifetime the armlength variation measured by the sum of squared length differences of the three arms reaches a global minimum in the parameter space. It has been proved effective in practice to only search in the nine dimensional parameter space spanned by $\bar{\sigma}_0 = (a_k, i_k, e_k)$, $k \in \{1, 2, 3\}$ [66]. Thus, the constellation optimization problem can be formulated as follows,

$$\bar{\sigma}_0^* = \arg \min_{\bar{\sigma}_0 \in \mathbb{D}} \mathcal{O}(\bar{\sigma}_0) = \arg \min_{\bar{\sigma}_0 \in \mathbb{D}} \sum_{k=1}^3 \sum_{i=1}^N (L_{k,i} - L_{k,0})^2, \quad (7)$$

where $L_{k,i}$ represents the length of the arm opposite to the k -th satellite at time t_i , and $L_{k,0}$ is the armlength at the initial epoch. \mathbb{D} is the *search space* of the optimization with the ranges: $a_k \in [0.999, 1.001] \times 10^5$ km, $e_k \in [0, 1 \times 10^{-3}]$, $i_k \in [93.2^\circ, 96.2^\circ]$.

The *objective* function $\mathcal{O}(\bar{\sigma}_0)$ may have a highly multi-modal landscape owning a forest of local minima. Therefore any deterministic local optimizer would locate a suboptimal solution. On the other hand, a direct grid search will be computationally prohibitive due to the high dimension ($\dim(\mathbb{D}) = 9$). Instead, the optimization methods including some randomness can be used to effectively pinpoint the global minimizer in $\mathcal{O}(\bar{\sigma}_0)$. In this work, we use one of the stochastic optimization methods based on emulating biological groups, namely the particle swarm optimization (PSO) [67]. PSO has been applied in many fields [68], including gravitational wave data analysis for detecting and estimating compact binary coalescence signals in a network of ground-based laser interferometers [69, 70] and continuous waves in pulsar timing arrays [71, 72].

The resulting $\bar{\sigma}_0^*$ for each satellite is listed in Table I. The variations of the armlengths, the variations of breathing angles, Doppler velocities and pointing deviation (from the direction of RX J0806+1527) of the satellite constellation during 5-yr mission lifetime are shown in Fig. 2. We can see that the optimized orbits satisfy the aforementioned requirements on the constellation stability with some margins. Note that, although the constellation optimization method is different from the three-step scheme adopted in [20], the results, in terms of the initial elements and performance of constellation optimization is virtually consistent (see Fig. 1 in [20]).

C. Interpolation of the orbit

The orbit coordinates of the satellites can be represented as finite sequences with sampling interval of Δt . As it will become more clear in Sec. III, the orbit positions and velocities at arbitrary time points within (t_i, t_{i+1}) are needed in generating the TDI data combinations. In this case, we use Chebyshev polynomials to approximate the orbit of each satellite at $t \in (t_i, t_{i+1})$. This method is stable and has been widely used in high precision ephemeris interpolation, such as the DE series ephemerides developed by Jet Propulsion Laboratory (JPL) [73]. Here, Chebyshev polynomials up to 15 orders are adopted and the sampling interval of the fitted data is 0.5 day with interpolation precision of $\sim 10^{-10}$ km. The weight of position and velocity is 1 : 0.4, which turns out to be the optimal choice to calculate the positions of the planets in the solar system [73]. The function approximation algorithm finds the best-fit coefficients of Chebyshev polynomials by minimizing the variance of the residuals between the data and the model [74].

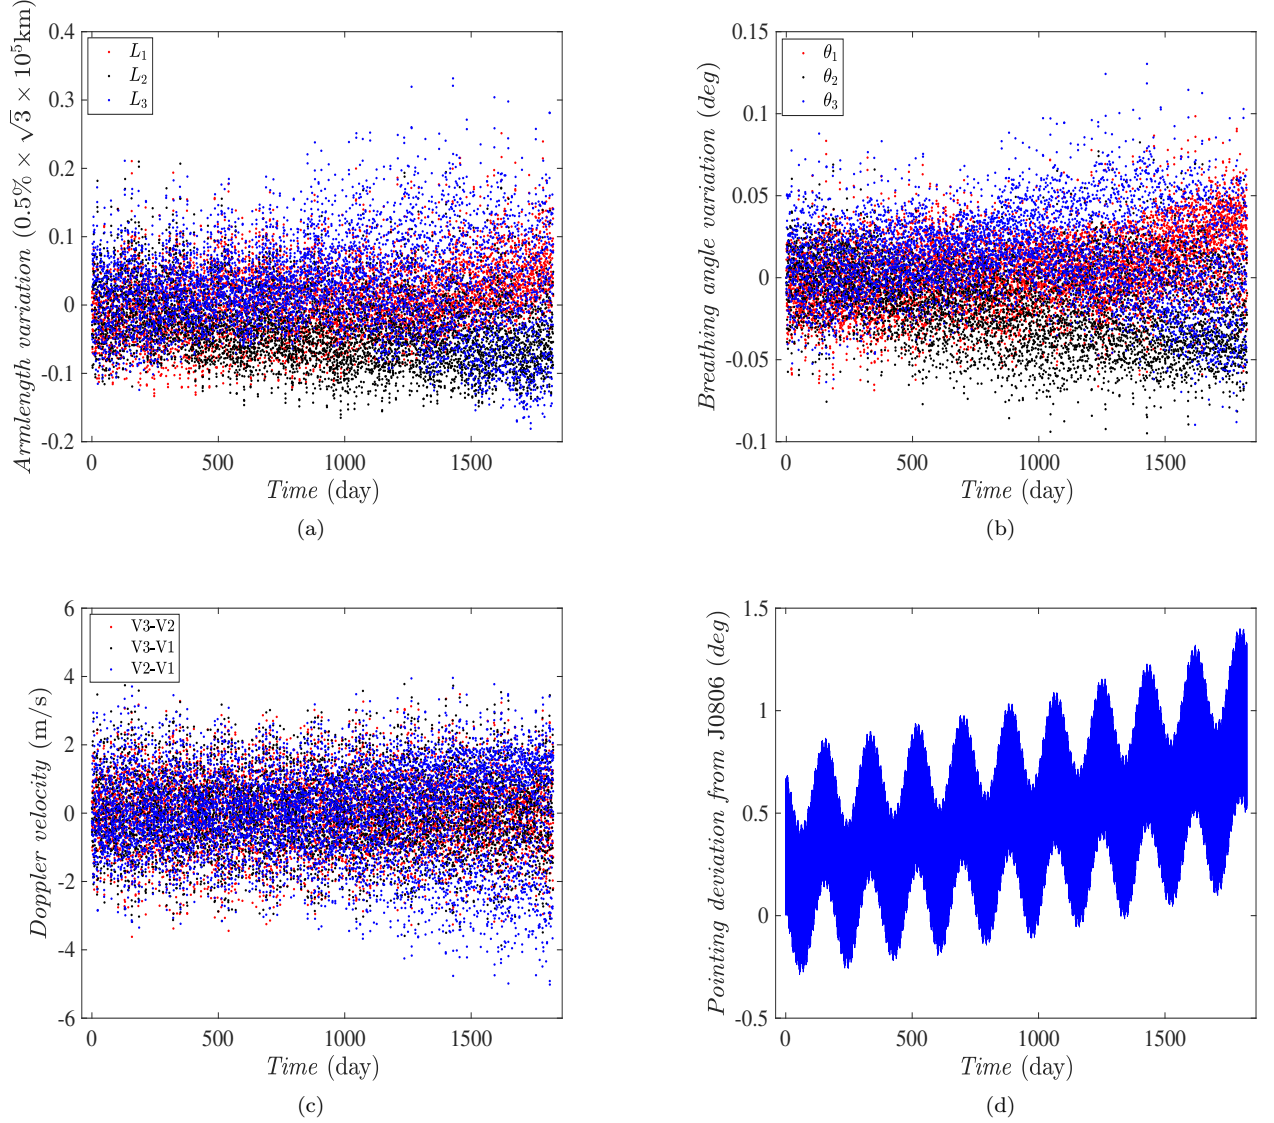

FIG. 2. (a) The variations of armlengths; (b) The variations of breathing angles; (c) Doppler velocities; (d) Pointing deviation from J0806+1527 during 5-yr mission lifetime.

III. SIMULATION OF TIME DIFFERENCES FOR TDI DATA COMBINATIONS

In this work, we assume that the lasers on the two optical benches housed in a satellite are locked in phase, so we only consider the inter-satellite fractional frequency measurements ‘ y ’ which account for the cancellation of the laser frequency noise. Following [47], the naming convention of the interference arms is shown in Fig. 3.

A. Time differences for the first-generation TDI

The first-generation TDI has 15 interference data combinations, namely (α, β, γ) , (X, Y, Z) , (U, V, W) , (E, F, G) , and (P, Q, R) . Five representative combinations are shown in Fig. 4. The other subtypes are different in the starting satellite of light paths and their combinations can be obtained by cyclic permutation of the indices for satellites: $1 \rightarrow 2 \rightarrow 3 \rightarrow 1$. As an example, the Doppler data for the Sagnac-type α combination is as follows:

$$\alpha = y_{23,13} + y_{12,3} + y_{31} - y_{21} - y_{13,2'} - y_{32,1'2'} , \quad (8)$$

FIG. 3. The labels of the satellites and the interference arms.

FIG. 4. Schematic diagram of the first-generation TDI combinations.

where ‘,’ marks the time delay of the laser beam traveling along an arm. $y_{23,13} = y_{23}(t - L_1 - L_3)$, which represents the time-delayed fractional frequency fluctuation time series measured at reception by S3 with transmission from S1 along arm 2. Here and hereafter, we set $c = 1$. As in Fig. 4, the clockwise (1-2-3-1) and the counter clockwise (1-3-2-1) light paths interfere at S1 at time t . While, their initial times of emission at S1 are $t - L_{3'} - L_{1'} - L_{2'}$ and $t - L_2 - L_1 - L_3$, respectively. Inserting the fractional frequency fluctuation $C_i(t)$ of the laser on Si into Eq. 8, we obtain:

$$\begin{aligned}
 \delta C_\alpha(t) = & [C_1(t - L_2 - L_1 - L_3) - C_3(t - L_1 - L_3)] + [C_3(t - L_1 - L_3) - C_2(t - L_3)] \\
 & + [C_2(t - L_3) - C_1(t)] - [C_3(t - L_{2'}) - C_1(t)] \\
 & - [C_2(t - L_{1'} - L_{2'}) - C_3(t - L_{2'})] \\
 & - [C_1(t - L_{3'} - L_{1'} - L_{2'}) - C_2(t - L_{1'} - L_{2'})] \\
 = & C_1(t - L_2 - L_1 - L_3) - C_1(t - L_{3'} - L_{1'} - L_{2'}).
 \end{aligned} \tag{9}$$

The first-generation TDI assumes a fixed detector constellation in space and the armlengths are unequal but constant, thus Eq. 9 can be canceled out exactly. However, in reality, the armlengths are time varying due to the actual rotating and flexing of the constellation. To the first order of $L_i(t)$, Eq. 9 can be expanded as:

$$\begin{aligned}
 \delta C_\alpha(t) \simeq & \dot{C}_1(t)[-L_2 + \dot{L}_2(L_1 + L_3) - L_1 + \dot{L}_1 L_3 - L_3 \\
 & + L_{3'} - \dot{L}_{3'}(L_{1'} + L_{2'}) + L_{1'} - \dot{L}_{1'}(L_{2'}) + L_{2'}]
 \end{aligned} \tag{10}$$

where both L_l and \dot{L}_l are evaluated at time t . When only the zero order of $L_l(t)$ is concerned, as in the first-generation TDI, Eq. 10 vanishes. The data combinations that have this nature are called *L-closed* [50]. Therefore, the level of laser frequency noise cancellation is determined by how well we can synthesize equal-length virtual paths, such as the two paths for the α combination, in the construction of virtual interferometers. In other words, from Eq. 9, we can see that the magnitude of the residual laser noise can be measured by the time difference of the two interference paths, which, for the α combination, is

$$\Delta t_\alpha = L_{2,13} + L_{1,3} + L_3 - L_{2'} - L_{1',2'} - L_{3',1'2'} . \quad (11)$$

Here, $L_{2,13} = L_2(t - L_1(t) - L_3(t))$ is the length of L_2 at time $t - L_1(t) - L_3(t)$. Through the armlengths obtained in Sec. II B, we can calculate the time differences of interference paths, which can be used to analyze the level of the laser frequency noise cancellation. Fig. 5 presents the result for the α combination in the five years mission lifetime. We can see the net time difference of the two opposite paths induced by the Sagnac effect $\Delta t_{\text{Sag}} = 4\vec{\Omega} \cdot \vec{A}$ [49, 75]. With the area $|\vec{A}| = \sqrt{3}L^2/4$ ($L \simeq \sqrt{3} \times 10^5$ km) and the angular velocity of the constellation $|\vec{\Omega}| = 1/3.65$ cycle/day for TianQin, $\Delta t_{\text{Sag}} \simeq 1.15 \times 10^{-5}$ s. Therefore, the result of this data combination is about three orders of magnitude worse than the other first-generation data combinations below.

FIG. 5. Simulation of the time difference for the first-generation TDI α combination.

Following the same procedure, the time differences for the other types can be written as:

$$\begin{aligned} \Delta t_X &= L_{3',322'} + L_{3,22'} + L_{2,2'} + L_{2'} - L_3 - L_{3',3} - L_{2',3'3} - L_{2,2'3'3} , \\ \Delta t_U &= L_{2',3'1'1} + L_{3',1'1} + L_{1',1} + L_1 - L_{3'} - L_{2',3'} - L_{1',2'3'} - L_{1,1'2'3'} , \\ \Delta t_P &= L_{3',1'12} + L_{1',12} + L_{1,2} - L_{3',2} + L_{2,3'} - L_{1',3'} - L_{1,1'3'} - L_{2,11'3'} , \\ \Delta t_E &= L_{1',13} + L_{1,3} + L_3 - L_{2'} - L_{1',2'} - L_{1,1'2'} + L_{2',1'1} - L_{3,11'} . \end{aligned} \quad (12)$$

The corresponding results are shown in Fig. 6. The time differences for the first-generation TDI X , U , P and E data combinations are $\sim 10^{-8}$ s.

The TDI data combinations can be considered effective when, taking the α combination as an example, $|\delta\tilde{C}_\alpha(f)|^2 \leq S_\alpha(f)$. Here,

$$|\delta\tilde{C}_\alpha(f)|^2 = 4\pi^2 f^2 |\tilde{C}_1|^2 \delta t_\alpha^2 , \quad (13)$$

which can be obtained by using the derivative theorem of Fourier transform for Eq. 9 [52]. $\delta t_\alpha \equiv \sup\{|\Delta t_\alpha(t)|\}$. $S_\alpha(f) = [4\sin^2(3\pi fL) + 24\sin^2(\pi fL)]S_y^{\text{accel}} + 6S_y^{\text{opt}}$ is the secondary noise power spectral density (PSD) for the α combination [39], where $S_y^{\text{accel}} = 2.8 \times 10^{-49} (f/1 \text{ Hz})^{-2} \text{ Hz}^{-1}$ and $S_y^{\text{opt}} = 4.4 \times 10^{-40} (f/1 \text{ Hz})^2 \text{ Hz}^{-1}$ are the PSDs of the acceleration noise and the optical path noise [39] assuming the one-sided amplitude spectra of the acceleration noise and the optical path noise of a single link are $1 \times 10^{-15} \text{ m s}^{-2}/\sqrt{\text{Hz}}$ and $1 \text{ pm}/\sqrt{\text{Hz}}$, respectively, for TianQin [7, 19]. $|\tilde{C}_1|^2 = 1.26 \times 10^{-27} \text{ Hz}^{-1}$ is the fractional laser frequency fluctuation (corresponding to the raw laser frequency noise of $10 \text{ Hz}/\sqrt{\text{Hz}}$) [7, 39], which is assumed to be white in the concerned frequency range. Then, we find that the required time difference $\delta t_\alpha \leq 2.3 \times 10^{-7}$ s.

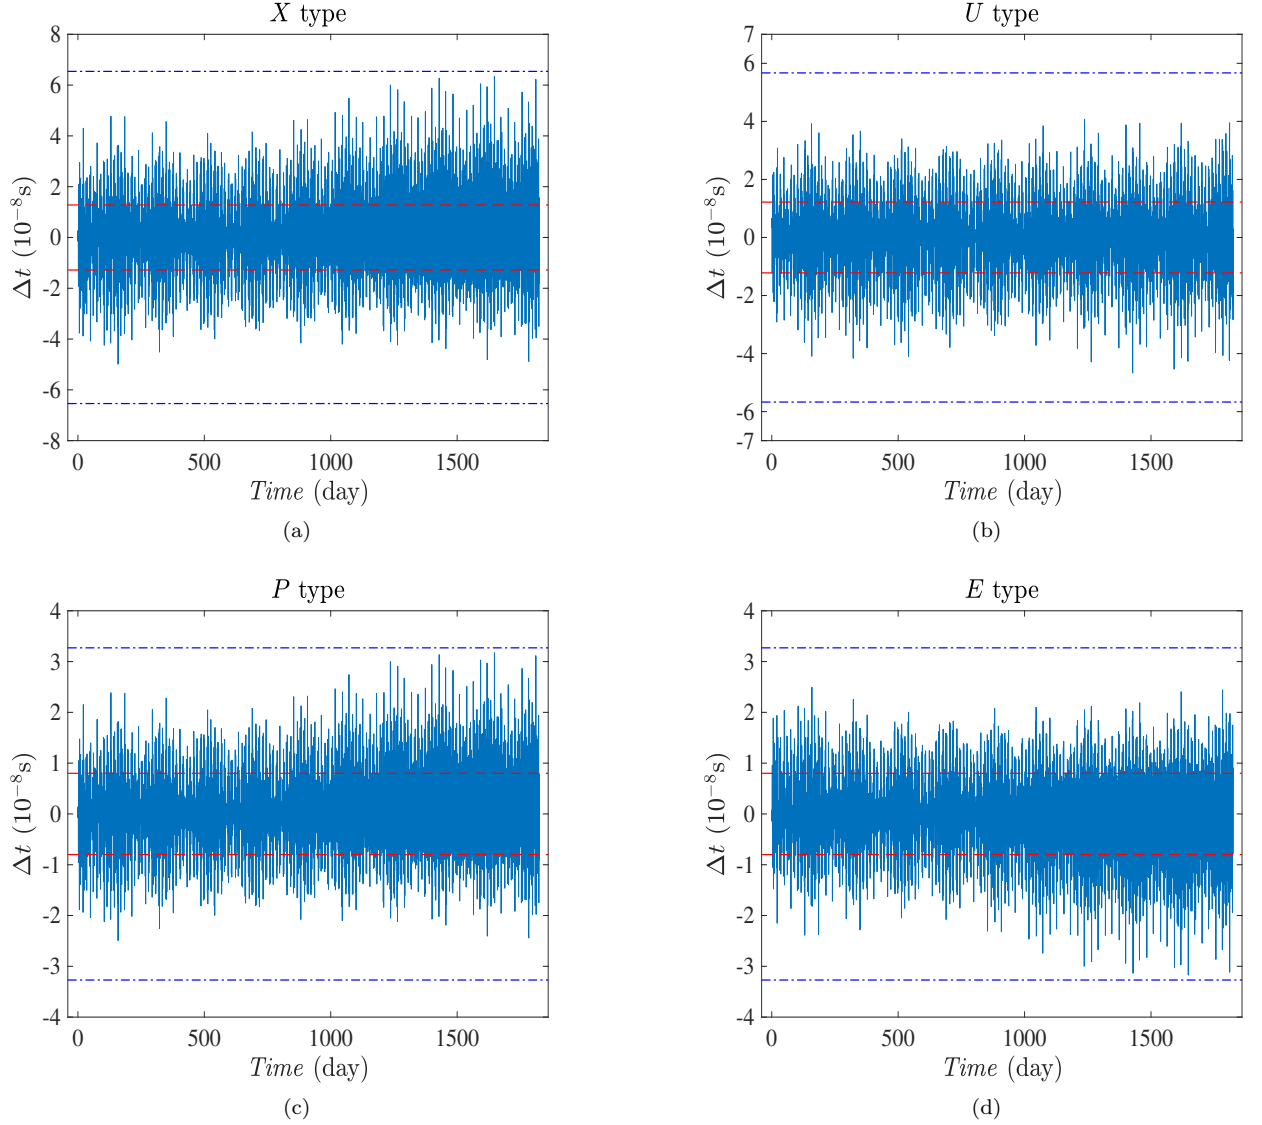

FIG. 6. Simulation of the time differences for the first-generation TDI X , U , P and E combinations (blue solid line). In each panel, the red dash lines represent the lowest required time differences for each combinations at $f \approx 10^{-2.2}$ Hz (c.f. right panel of Fig. 7). For comparison, the blue dash-dot lines represent the ones at $f = 10^{-3}$ Hz.

Similarly, for the X , U , P , and E combinations with the corresponding secondary noise PSDs as follows,

$$S_X(f) = [4 \sin^2(4\pi fL) + 32 \sin^2(2\pi fL)]S_y^{\text{accel}} + 16 \sin^2(2\pi fL)S_y^{\text{opt}}, \quad (14)$$

$$S_U(f) = [8 \sin^2(3\pi fL) + 12 \sin^2(2\pi fL) + 24 \sin^2(\pi fL)]S_y^{\text{accel}} + [4 \sin^2(3\pi fL) + 8 \sin^2(2\pi fL) + 4 \sin^2(\pi fL)]S_y^{\text{opt}}, \quad (15)$$

$$S_P(f) = [4 \sin^2(2\pi fL) + 32 \sin^2(\pi fL)]S_y^{\text{accel}} + [8 \sin^2(2\pi fL) + 8 \sin^2(\pi fL)]S_y^{\text{opt}}, \quad (16)$$

$$S_E(f) = S_P(f). \quad (17)$$

The required time differences are shown in the right panel of Fig. 7.

The PSDs of the secondary noises and the residual laser frequency noises for the X , U , P , and E combinations are shown in the left panel of Fig. 7. For the latter, the actual time differences δt from Fig. 6 are used. We can see that the first-generation TDI data combinations cannot suppress the laser frequency noises below the secondary noises for $10^{-3} \lesssim f \lesssim 10^{-1}$ Hz; while they are effective at the frequencies $f \lesssim 10^{-3}$ Hz and $f \gtrsim 10^{-1}$ Hz.

FIG. 7. Left panel shows the secondary noise (solid line) and the residual laser frequency noise (dotted line) for the first-generation X , U , P and E combinations. The lines for P and E are overlapped, only the ones for P are shown. Right panel shows the required time differences for the corresponding combinations.

B. Time differences for the second-generation TDI

The second-generation TDI can suppress the laser frequency noise further by canceling the L_l and $L_l\dot{L}_m$ terms in Eq. 10. The data combinations that have this nature are called \dot{L} -closed, for which the interference paths can be found through splicing the first-generation interference paths [44]. Taking the α combination as an example, a new path 1 (1-3-2-1-2-3-1) can be synthesized by splicing the path 1 (1-3-2-1) and path 2 (1-2-3-1) of the first-generation α ; a new path 2 (1-2-3-1-3-2-1) is in a reversed order of the satellites. Specifically, this process can be expressed as:

$$\begin{aligned} \overrightarrow{1231231} \overleftarrow{1231231} + \overrightarrow{1321321} \overleftarrow{1321321} &\Rightarrow \overrightarrow{213[3'1'2']312} \overleftarrow{213[3'1'2']312} \quad (\alpha_{12} - 1) \\ &= y_{23;133'1'2'} + y_{12;33'1'2'} + y_{31;3'1'2'} + y_{32;1'2'} + y_{13;2'} + y_{21} \\ &\quad - y_{31} - y_{12;3} - y_{23;13} - y_{21;213} - y_{13;2'213} - y_{32;1'2'213}. \end{aligned} \quad (18)$$

Here, $y_{23;13} = y_{23}(t - L_1(t - L_3(t)) - L_3(t))$. Note that we use ‘;’ here to represent the time delay in the second generation. Two laser beams passing along ‘ \rightarrow ’ and ‘ \leftarrow ’ interfere at time t . The numbers below each arrow represent the interference arms, the subscripts on the left hand side represent the indices of satellites. On the right hand side, $\overrightarrow{2133'1'2'}$ represents a laser beam passing along the arms from left to right; while, $\overleftarrow{3122'1'3'}$ from right to left. $\alpha_1 : \overrightarrow{1231231} \overleftarrow{1231231}$ represents the paths of two laser beams for the first-generation TDI, then by reversing we obtain $\alpha_2 : \overrightarrow{1321321} \overleftarrow{1321321}$. The path α_1 is spliced with the path α_2 and result in the path $\alpha_{12} - 1$. Here, ‘[]’ indicates where we insert α_2 into α_1 [50].

From Eq. 18, we can write the time difference of the combination $\alpha_{12} - 1$ as:

$$\begin{aligned} \Delta t_{\alpha_{12}-1} &= L_{2;133'1'2'} + L_{1;33'1'2'} + L_{3;3'1'2'} + L_{3';1'2'} + L_{1';2'} + L_{2'} \\ &\quad - L_3 - L_{1;3} - L_{2;13} - L_{2';213} - L_{1';2'213} - L_{3';1'2'213}. \end{aligned} \quad (19)$$

Similarly, the path $\alpha_2 : \overrightarrow{1321321} \overleftarrow{1321321}$ can be split at the position of ‘ \uparrow ’. This results in a new path $\overrightarrow{213'2'1'} \overleftarrow{3121321} \overrightarrow{132}$, which makes S2 as the starting and ending satellite. Stitching it with α_1 , we can obtain a new combination:

$$\begin{aligned} \overrightarrow{1231231} \overleftarrow{1231231} + \overrightarrow{213'2'1'} \overleftarrow{3121321} \overrightarrow{132} &\Rightarrow \overrightarrow{21[1'2']312} \overleftarrow{21[1'2']312} \overleftarrow{32'1'3'} \quad (\alpha_{12} - 2) \\ &= y_{23;11'2'31} + y_{12;1'2'31} + y_{13;2'31} + y_{21;31} - y_{31;31} - y_{12;1} \\ &\quad - y_{23} + y_{32;3'2} + y_{31;33'2} - y_{21;33'2} - y_{13;2'33'2} - y_{32;1'2'33'2}. \end{aligned} \quad (20)$$

Here, following the advancement rule introduced in [50], we adopt the advancement indices \bar{l} . For example,

$$y_{32, \overline{3}2} = y_{32}(t + L_{3'}(t - L_2(t)) - L_2(t)). \quad (21)$$

In addition, the path α_2 can be split to make S3 as the starting and ending satellite, which gives:

$$\overrightarrow{1231231} \overleftarrow{12'31'3'_1} + \overrightarrow{321} \overleftarrow{1321321} \overrightarrow{13'_21'_3} \Rightarrow \overrightarrow{2[2'3123'1']132'1'3'} \quad (\alpha12 - 3). \quad (22)$$

Fig. 8 gives the smallest (right panel) and the largest (left panel) time differences for the second-generation α -type combinations.

FIG. 8. The time differences for the second-generation α -type combinations.

For the other second-generation TDI combinations, the results are:

$$\begin{aligned} X : & \overrightarrow{13'_23_1232'_1} \overleftarrow{13_23'_12'_32_1} + \overrightarrow{12_32'_13'_23_1} \overleftarrow{12'_32_13_23'_1} \\ \Rightarrow & \begin{cases} \overrightarrow{3'322'[22'3'3]2'233'} \overleftarrow{33'2'2} & (X16 - 1), \\ \overrightarrow{3'322'[3'3]2'233'} \overleftarrow{22'} \overleftarrow{33'2'2} & (X16 - 2), \\ \overrightarrow{22'3'3[22']33'2'2} \overleftarrow{3'3} \overleftarrow{2'233'} & (X16 - 3). \end{cases} \end{aligned} \quad (23)$$

The path $X_1 : \overrightarrow{13'_23_1232'_1} \overleftarrow{13_23'_12'_32_1}$ is spliced with its reversed version $X_2 : \overrightarrow{12_32'_13'_23_1} \overleftarrow{12'_32_13_23'_1}$, resulting in the path $X16 - 1$. Also, the path $X_1 : \overrightarrow{13'_23_1 \uparrow 232'_1} \overleftarrow{13_23'_12'_32_1}$ can be split at the position of \uparrow , and generate the new path $X_3 : \overrightarrow{22'} \overleftarrow{33'2'2} \overleftarrow{3'3}$, which is spliced with the path X_2 to form the path $X16 - 3$. The path X_2 can generate the new path $X_4 : \overrightarrow{3'3} \overleftarrow{2'233'} \overleftarrow{22'}$, which is spliced with the path X_1 to form the path $X16 - 2$. Among these three combinations, $X16 - 1$ uses four directional arms which form a two-beam interferometers; While, $X16 - 2$ and $X16 - 3$ are four-beam interferometers.

Similar to Eq. 18 and Eq. 19, we can calculate the time differences for the second-generation X combinations for TianQin. The smallest (right) and largest (left) time differences are shown in Fig. 9. As we will see below, the time differences of X combinations are the largest comparing with in the α , U , P and E combinations. This is because when inserting the frequency noise $C_i(t)$ into the combinations of ' y ' for the X (the expression similar to Eq. 18) and expanding in L_l further than the canceled L_l and $L_l \dot{L}_m$ terms, the next leading terms read $L^2 \ddot{L}_m$ and the sums of these terms for the X combinations are larger than the other combinations.

FIG. 9. The time differences for the second-generation X -type combinations.

$$\begin{aligned}
 U : & \overrightarrow{3'2'1'3'1_2} \overleftarrow{2'3'1'2'1_3} + \overrightarrow{3'1_21'3'2'_2} \overleftarrow{2'1_31'2'3'_2} \\
 \Rightarrow & \begin{cases} \overrightarrow{2'3'1'1} \overleftarrow{3'2'1'[3'2']} \overrightarrow{11'2'3'} \overleftarrow{11'1} & (U16-1), \\ \overrightarrow{2'3'1'1} \overleftarrow{3'2'} \overrightarrow{[11'2'3']} \overleftarrow{11'3'2'} \overrightarrow{1'1} & (U16-2), \\ \overrightarrow{2'3'1'1[1'2'3']} \overleftarrow{11'3'2'} \overrightarrow{1} \overleftarrow{3'2'1'1} & (U16-3). \end{cases}
 \end{aligned} \tag{24}$$

The path $U_1 : \overrightarrow{3'2'1'3'1_2} \overleftarrow{2'3'1'2'1_3}$ is spliced with its reversed version $U_2 : \overrightarrow{3'1_21'3'2'_2} \overleftarrow{2'1_31'2'3'_2}$, resulting in the path $U16-2$. Also, the path $U_2 : \overrightarrow{3'1_21'3'2'_2} \overleftarrow{2'1_31'2'3'_2}$ can be split at the position of \uparrow , and generate the new path $U_3 : \overrightarrow{1'2'3'} \overleftarrow{11'3'2'} \overrightarrow{1}$ and $U_4 : \overleftarrow{3'2'} \overrightarrow{11'2'3'} \overleftarrow{11'}$. U_3 is spliced with the path U_1 to form the path $U16-3$. $U16-1$ is obtained by U_1 and U_4 . All the U -type combinations are four-beam interferometers. Here, four directional arms $2', 3', 1', 1$ are used. Fig. 10 gives the smallest (right panel) and the largest (left panel) time differences for the second-generation U -type combinations.

$$\begin{aligned}
 P : & \overrightarrow{1'3'2'1'3'1_2} \overleftarrow{2'3'_1} \overrightarrow{1'2'_3} \overleftarrow{3'1'_21'3'2'_1} + \overrightarrow{1'2'_31'3'2'_1} \overleftarrow{3'2'_1} \overrightarrow{1'3'_2} \overleftarrow{2'1'_31'2'3'_1} \\
 \Rightarrow & \begin{cases} \overrightarrow{3'1'1[1]} \overleftarrow{2} \overrightarrow{3'} \overleftarrow{11'3'} \overrightarrow{21} \overleftarrow{3'} \overrightarrow{2} \overleftarrow{1'12} & (P16-1), \\ \overrightarrow{211'[1]} \overleftarrow{3'} \overrightarrow{2} \overleftarrow{1'12} \overrightarrow{3'1'} \overleftarrow{2} \overrightarrow{3'} \overleftarrow{11'3'} & (P16-2), \\ \overrightarrow{211'} \overleftarrow{2} \overrightarrow{[3'1'1]} \overleftarrow{3'} \overrightarrow{2} \overleftarrow{1'12} \overrightarrow{3'} \overleftarrow{11'3'} & (P16-3). \end{cases}
 \end{aligned} \tag{25}$$

The path $P_1 : \overrightarrow{1'3'2'1'3'1_2} \overleftarrow{2'3'_1} \overrightarrow{1'2'_3} \overleftarrow{3'1'_21'3'2'_1}$ is spliced with its reversed version $P_2 : \overrightarrow{1'2'_31'3'2'_1} \overleftarrow{3'2'_1} \overrightarrow{1'3'_2} \overleftarrow{2'1'_31'2'3'_1}$, resulting in the path $P16-3$. Also, the path $P_2 : \overrightarrow{1'2'_31'3'2'_1} \overleftarrow{3'2'_1} \overrightarrow{1'3'_2} \overleftarrow{2'1'_31'2'3'_1}$ can be split at the position of \uparrow , and generate the new path $P_3 : \overrightarrow{1} \overleftarrow{2} \overrightarrow{3'} \overleftarrow{11'3'} \overrightarrow{21}$, which is spliced with the path P_1 to form $P16-1$. From P_1 we can derive $P_4 : \overrightarrow{1} \overleftarrow{3'} \overrightarrow{2} \overleftarrow{1'12} \overrightarrow{3'1'}$, which is spliced with the path P_2 to form $P16-2$. Fig. 11 gives the smallest (right panel) and the largest (left panel) time differences for the second-generation P -type combinations.

FIG. 10. The time differences for the second-generation *U*-type combinations.FIG. 11. The time differences for the second-generation *P*-type combinations.

$$\begin{aligned}
 E : & \overrightarrow{21'_3 1_2 3_1} \overleftarrow{12'_3 1'_2 1_3} \overrightarrow{32'_1} \overleftarrow{13_2} + \overrightarrow{23_1} \overleftarrow{12'_3} \overrightarrow{31_2 1'_3 2'_1} \overleftarrow{13_2 1_3 1'_2} \\
 \Rightarrow & \begin{cases} \overrightarrow{1[1'13} \overleftarrow{2'1'1} \overrightarrow{2'} \overleftarrow{3]} \overrightarrow{1'2'} \overleftarrow{311'} \overrightarrow{3} \overleftarrow{2'} & (E16-1), \\ \overrightarrow{1'[11'2'} \overleftarrow{311'} \overrightarrow{3} \overleftarrow{2']} \overrightarrow{13} \overleftarrow{2'1'1} \overrightarrow{2'} \overleftarrow{3} & (E16-2), \\ \overrightarrow{11'2'} \overleftarrow{3} \overrightarrow{1'13} \overleftarrow{2'1'1} \overrightarrow{2'} \overleftarrow{311'} \overrightarrow{3} \overleftarrow{2'} & (E16-3). \end{cases}
 \end{aligned} \tag{26}$$

By reversing the interference arm of $E_1 : \overrightarrow{21'_3 1_2 3_1} \overleftarrow{12'_3 1'_2 1_3} \overrightarrow{32'_1} \overleftarrow{13_2}$, we can obtain $E_2 : \overrightarrow{23_1} \overleftarrow{12'_3} \overrightarrow{31_2 1'_3 2'_1} \overleftarrow{13_2 1_3 1'_2}$. $E_2 : \overrightarrow{23_1} \overleftarrow{12'_3} \overrightarrow{31_2 1'_3 2'_1} \overleftarrow{13_2 1_3 1'_2}$ can be split at the position of \uparrow , and generate the new path $E_3 : \overrightarrow{11'2'} \overleftarrow{311'} \overrightarrow{3} \overleftarrow{2'}$, which is spliced with the path E_1 to form the path of $E16-1$ and $E16-2$. Also, the path E_1 can generate the new path of $E_4 : \overleftarrow{3} \overrightarrow{1'13} \overleftarrow{2'1'1} \overrightarrow{2'}$, which is spliced with the path of E_3 to form the path $E16-3$. The combinations of *E*-type and *P*-type both form eight-beam interferometers. Fig. 12 gives the smallest (right panel) and the largest (left panel)

time differences for the second-generation E -type combinations.

FIG. 12. The time differences for the second-generation E -type combinations.

As we can see from the results above, the eight-beam interferometers are better than the other second-generation TDI combinations. The time differences of all the second-generation TDI data combinations are below 5×10^{-12} s. Similar to Fig. 7, the results for the second-generation combinations, taking $\alpha 12-1$ and $X16-1$ as examples, are shown in Fig. 13. Here, the secondary noise PSDs $S_{\alpha 12-1}(f) = 4 \sin^2(3\pi fL)S_\alpha(f)$ and $S_{X16-1}(f) = 4 \sin^2(4\pi fL)S_X(f)$ [76] are adopted. We can see that the time differences of the second-generation data combinations ($\sim 10^{-12}$ s) are substantially lower than the requirements ($> 10^{-10}$ s), thus they are guaranteed to suppress the laser frequency noise well below the secondary noises for TianQin in the concerned frequencies.

FIG. 13. Left panel shows the secondary noise (solid line) and the residual laser frequency noise (dotted line) for the second-generation $\alpha 12-1$ and $X16-1$ combinations. Right panel shows the required time differences for the corresponding combinations.

IV. CONCLUSION AND DISCUSSIONS

Using the numerically optimized orbit that shows realistic features of the satellite constellation, we investigated the time differences of the symmetric interference paths, as a measure of residual laser frequency noise, of various first- and second-generation TDI data combinations for TianQin. We found that while the second-generation TDI with a typical time differences of 10^{-12} s is guaranteed to be valid for laser frequency noise suppression, the first-generation TDI is possible to be competent for GW signals at frequencies $\lesssim 10^{-3}$ Hz and $\gtrsim 10^{-1}$ Hz (given the raw laser frequency noise of $10 \text{ Hz}/\sqrt{\text{Hz}}$), which cover the coalescence of the SMBHB with a redshifted total mass $> 10^6 M_\odot$ [24] for the former or the inspiral of the stellar-mass black hole binary (e.g., GW150914) $\lesssim 1$ yr before its final merger [28] for the latter. The first-generation TDI combinations will become fully useful with improved stabilization of the raw laser frequency noise down to $\approx 1 \text{ Hz}/\sqrt{\text{Hz}}$ in $10^{-3} - 10^{-2}$ Hz. This further stabilization of laser frequency can be possibly achieved through suppressing the fluctuation of the Pound-Drever-Hall error signal offset, thermal stabilization at the zero-crossing temperature of the optical bench coefficient of thermal expansion, upgrading the automatic functions of the digital controller, etc. [77–79]. The first-generation TDI combinations, when implemented, will simplify the data analysis procedure and reduce the computational cost, since they employ half of the single-link data than the corresponding second-generation ones.

The current work serves as our first step towards building an end-to-end TDI simulation for TianQin. Here, we only discussed the inter-satellite measurements ‘ y ’. In reality, when each laser on the two optical benches housed in a satellite are unlocked or the acceleration noises of the optical benches are concerned, the intra-satellite measurements ‘ z ’ need to be included in the simulation, although which are not subjected to the orbital effects of the satellites discussed here. The simulated TDI data combinations, realistic noises from various subsystems, interplanetary and relativistic effects on the optical path, etc. will be taken as the input of subsequent GW data analysis for various astrophysical sources. These will be investigated in our future study.
