Heisenberg-limited ground state energy estimation for early fault-tolerant quantum computers

February 24, 2021

Abstract

Under suitable assumptions, the quantum phase estimation (QPE) algorithm is able to achieve Heisenberg-limited precision scaling in estimating the ground state energy. However, QPE requires a large number of ancilla qubits and large circuit depth, as well as the ability to perform inverse quantum Fourier transform, making it expensive to implement on an early fault-tolerant quantum computer. We propose an alternative method to estimate the ground state energy of a Hamiltonian with Heisenberg-limited precision scaling, which employs a simple quantum circuit with one ancilla qubit, and a classical post-processing procedure. Besides the ground state energy, our algorithm also produces an approximate cumulative distribution function of the spectral measure, which can be used to compute other spectral properties of the Hamiltonian.

1 Introduction

Estimating the ground state energy of a quantum Hamiltonian is of immense importance in condensed matter physics, quantum chemistry, and quantum information. The problem can be described as follows: we have a Hamiltonian $H$, acting on $n$ qubits, with the eigendecomposition

$$H = \sum_{k=0}^{K} \lambda_k \Pi_k,$$

where $\Pi_k$ is the projection operator into the $\lambda_k$-eigensubspace, and $\lambda_k$'s are increasingly ordered. Each eigenvalue may be degenerate, i.e. the rank of $\Pi_k$ can be more than one. We assume we can access the Hamiltonian $H$ through the time evolution operator $e^{-i\tau H}$ for some fixed $\tau$. Our goal is to estimate the ground state energy $\lambda_0$ to within additive error $\epsilon$.

Some assumptions are needed as otherwise this problem is QMA-complete [2, 24, 26, 37]. We assume we are given a state described by its density matrix $\rho$. Let $p_k = \text{Tr}[\rho \Pi_k]$. Then if $p_0$ (i.e. the overlap between the initial state and the ground state) is reasonably large we can solve the ground state energy estimation problem efficiently. This assumption is reasonable in many practical settings. For example, in the quantum chemistry setting, the Hartree-Fock method usually yields an approximate ground state that is easy to prepare on a quantum computer, and for atoms or molecules that are not too large there is usually a significant overlap between this approximate ground state and the exact one. Therefore we can use the Hartree-Fock solution as $\rho$ in this setting.

The computational complexity of this task depends on the desired precision $\epsilon$. Even in the ideal case where the exact ground state is given, this dependence cannot be better than linear in $\epsilon^{-1}$.

for generic Hamiltonians [5]. This limit is called the Heisenberg limit [19, 20, 52, 53] in quantum metrology. This notion is closely related to the time energy uncertainty principle [3, 4, 5, 14]. This optimal scaling can be achieved using the quantum phase estimation (QPE) algorithm [25], which we will discuss in detail later.

Much work has been done to develop the algorithms for ground state energy estimation both for near-term quantum devices [23, 33, 38, 40], and fully fault-tolerant quantum computers [1, 16, 29, 41]. Relatively little work has been done for early fault-tolerant quantum computers, which we expect to be able to accomplish much more complicated tasks than current and near-term devices, but still place significant limitations on the suitable algorithms. Refs. [11, 27] carried out careful resource cost estimation of performing QPE for the Hubbard model using surface code to perform quantum error correction. These are to our best knowledge the only works that addressed ground state energy estimation in the context of early fault-tolerant quantum computers.

We expect such early fault-tolerant quantum computers to have the following characteristics: (1) The number of logical qubits are limited. (2) It is undesirable to have a large number of controlled operations. (3) It is a priority to reduce the circuit depth, e.g. it is better to run a circuit of depth $O(D)$ for $O(M)$ times than to run a circuit of depth $O(DM)$ for a constant number of times, even if using the shorter circuit entails some additional poly-logarithmic factors in the total runtime.

In this context, the textbook version of QPE (see e.g. Ref. [36]), which uses multiple ancilla qubits to store the phase and relies on inverse quantum Fourier transform (QFT), is not suitable for early fault-tolerant quantum computers. Some variants of QPE have been developed to achieve high confidence level [28, 35, 42], which can be important in many applications. However, such modifications require even more ancilla qubits to store multiple estimates of the phase and an additional coherent circuit to take perform logical operations.

Due to the above considerations, we focus on the variants of QPE that use only very few ancilla qubits (in fact, all algorithms below use only one ancilla qubit). Kitaev’s algorithm (see e.g. [26]) uses a simple quantum circuit with one control qubit to determine each bit of the phase individually. However this method, together with many other algorithms based on it [49, 50, 51], are designed for phase estimation with an eigenstate given exactly, which is different from our goal. The semi-classical Fourier transform [21] can simulate QFT+measurement (meaning all qubits are measured in the end) with only one-qubit gates, classical control and post-processing, thus trading the expensive quantum resource for inexpensive classical operations. One can replace the inverse QFT with the semi-classical Fourier transform, and this results in a phase estimation algorithm that uses only one ancilla qubit [6, 22]. This approach can be seen as a simulation of the multiple-ancilla qubit version of QPE, and is therefore applicable to the case when $\rho$ is not exactly the ground state. Because of these attractive features this is the version of QPE used in Refs. [11, 27]. However, as we will explain below in Section 1.1 this type of QPE requires running coherent time evolution for time $O(p_0^{-1} \epsilon^{-1})$. This leads to large circuit depth when $p_0$ is small.

In this work, the complexity is measured by the time for which we need to perform time evolution with the target Hamiltonian $H$. We will use two metrics: (1) the maximal evolution time, which is the maximum length of time for which we need to perform (controlled) coherent time evolution, and (2) the total evolution time, which is the sum of all the lengths of time we need to perform (controlled) coherent time evolution. They describe respectively the circuit depth and the total runtime. We present an algorithm that achieves the following goals:

1. Achieves Heisenberg-limited precision scaling, i.e. the total time for which we run time evolution depends linearly (up to a poly-logarithmic factor) on $\epsilon^{-1}$;
2. Uses only one ancilla qubit;
3. The maximal evolution time is at most $O(\epsilon^{-1} \text{polylog}(\epsilon^{-1} p_0^{-1}))$.

To our best knowledge our algorithm is the first to satisfy all three requirements. In our algorithm, we sample from a simple quantum circuit, and use the samples to approximately reconstruct the
Figure 1: Comparing the performance of the textbook version QPE (blue dashed-dotted line) and the method in this work (red solid line) in ground state energy estimation with a fixed maximal evolution time (300 steps of time evolution with $H$) and decreasing initial overlap $p_0$. The results are benchmarked against QPE with maximal evolution time proportional to $p_0^{-1}$ (green dashed line). To use QPE, either with fixed or $O(p_0^{-1})$ maximal evolution time, to estimate the ground state energy, we run QPE for $O(p_0^{-1})$ times and take the minimum in energy measurement outcomes as the ground state energy estimate. The error is averaged over multiple runs, and the failure rate is the percentage of runs that yield an estimate with error larger than the tolerance $0.04$. The Hamiltonian $H$ is the Hubbard Hamiltonian defined in Eq. (37) with $U = 10$, and the overlap $p_0$ is artificially tuned.

cumulative distribution function (CDF) of the spectral measure associated with the Hamiltonian. We then use classical post-processing to estimate the ground state energy with high confidence. Besides the ground state energy, our algorithm also produces the approximate CDF, which may be of independent interest.

1.1 Related works

We first briefly analyze the cost of the textbook version of QPE using multiple ancilla qubits. Although this method is not suitable for early fault-tolerant quantum computers, this analysis will nevertheless be helpful for understanding the cost of other variants of QPE. For simplicity we assume $\rho = |\phi\rangle \langle \phi|$ is a pure state, and the ground state $|\psi_0\rangle$ is non-degenerate. Approximately, the QPE performs a projective measurement in the eigenbasis of $H$. With probability $p_0$, $|\phi\rangle$ will collapse to the ground state $|\psi_0\rangle$. If this happens the energy register will then give the ground state energy $\lambda_0$ to precision $\epsilon$. Therefore we run phase estimation for a total of $O(p_0^{-1})$ times, and take the instance with the minimum value in the energy register. With high probability this value will be close to $\lambda_0$. Each single run takes time $O(\epsilon^{-1})$. The total runtime cost is therefore $O(p_0^{-1} \epsilon^{-1})$. For simplicity here we do not consider the runtime needed to prepare $|\phi\rangle$.

The above analysis, however, is overly optimistic. Since we need to repeat the phase estimation procedure for a total of $O(p_0^{-1})$ times, for an event that only has $O(p_0)$ probability of happening in a single run, the probability of this event occurring at least once in the total $O(p_0^{-1})$ repetitions is now $O(1)$. Moreover, suppose the maximal evolution time is $T$, then each time we measure the energy register there is a $O(T^{-1} \epsilon^{-1})$ probability that the output will be smaller than $\lambda_0 - \epsilon'$. If we choose $T = O(\epsilon^{-1})$ as discussed above, and we let $\epsilon' = \epsilon/p_0$, then the probability of the minimum of the $O(p_0^{-1})$ energy register measurement outputs being smaller than $\lambda_0 - \epsilon/p_0$ is $O(1)$. This means there is a high probability that the ground state energy error we get in the end will be of order $\epsilon/p_0$. 

instead of $\epsilon$. For a more formal analysis see \cite{10} Appendix A. We demonstrate this numerically in Figure \ref{fig:1} in which we show the error increases as $p_0$ decreases and there is a larger probability of the estimate deviating beyond a prescribed tolerance if the maximal evolution time, or equivalently the circuit depth, for QPE is fixed.

To avoid this, one can instead choose the maximal evolution time to be $T = O\left(p_0^{-1} \epsilon^{-1}\right)$. After repeating $O\left(p_0^{-1}\right)$ times, the total runtime then becomes $O\left(p_0^{-2} \epsilon^{-1}\right)$. The increase in maximal evolution time can prevent the increase of error (see Figure \ref{fig:1}). However, the extra $p_0^{-1}$ factor increases the circuit depth and is undesirable. Since the semi-classical Fourier transform \cite{21} simulates the QFT in a classical manner, the QPE using single ancilla qubit and semi-classical Fourier transform has the same scaling in terms of the maximal evolution time and the total evolution time.

In order to improve the dependence on $p_0$, we may use the high-confidence versions of the phase estimation algorithm \cite{28,35,42}. In this method, the maximal evolution time required can be reduced to $O\left(\epsilon^{-1} \log(p_0^{-1})\right)$, through taking the median of several copies of the energy register in a coherent manner. However, this requires using multiple copies of the energy register, together with an additional quantum circuit to compute the medians coherently that can be difficult to implement. Note that semi-classical Fourier transform can only simulate the measurement outcome and does not preserve coherence, and therefore to our knowledge, the high-confidence version of phase estimation cannot be modified to use only a single qubit. In Ref. \cite{10}, the authors used a method called minimum label finding to improve the runtime to $O\left(p_0^{-3/2} \epsilon^{-1}\right)$, but the implementation of the minimum label finding with limited quantum resources is again difficult.

Besides these algorithms based on phase estimation, several other algorithms have been developed to solve the ground state energy problem. Ref. \cite{10} proposed a method based on the linear combination of unitaries (LCU) technique that requires running time evolution for duration $\tilde{O}(p_0^{-1/2} \epsilon^{-3/2})$ and preparing the initial state $\tilde{O}(p_0^{-1/2} \epsilon^{-1/2})$ times. Assuming the Hamiltonian $H$ is available in its block-encoding \cite{12,32}, Ref. \cite{29} uses quantum signal processing \cite{18,31} with a binary search procedure, which queries the block-encoding $\tilde{O}(p_0^{-1/2} \epsilon^{-1})$ times and prepares the initial state $\tilde{O}(p_0^{-1/2} \log(\epsilon^{-1}))$ times. To our knowledge, this is the best complexity that has been achieved. However the block-encoding of a quantum Hamiltonian of interest, LCU, and amplitude estimation techniques (used in \cite{29}) are expensive in terms of the number of ancilla qubits, controlled operations, and logical operations needed.

A very different type of algorithms for ground state energy estimation is the variational quantum eigensolver (VQE) \cite{33,35,40}, which are near-term algorithms and have been demonstrated on real quantum computers. The accuracy of VQE is limited both by the representation power of the variational ansatz, and the capabilities of classical optimization algorithms for the associated non-convex optimization problem. Hence unlike aforementioned algorithms, there is no provable performance guarantees for VQE-type methods. In fact some recent results show solving the non-convex optimization problem can be NP-hard \cite{9}. Furthermore, each evaluation of the energy expectation value to precision $\epsilon$ requires $O(\epsilon^{-2})$ samples due to Monte Carlo sampling. This can to some extent be remedied using the methods in \cite{28,49} at the expense of larger circuit depth requirement.

There are also a few options that can be viewed to be in-between VQE and QPE. The quantum imaginary time evolution (QITE) algorithm \cite{34} uses state tomography turning an imaginary time evolution into a series of real time Hamiltonian evolution problem. Inspired by the classical Krylov subspace method, Refs. \cite{23,39,46} propose to solve the ground state energy problem by restricting the Hilbert space to a low dimension space spanned by some eigenstates that are accessible with time evolution. Similar to VQE, no provable complexity upper bound is known for these algorithms, and all algorithms suffer from the $\epsilon^{-2}$ scaling due to the Monte Carlo sampling. In fact, the stability of these algorithms remains unclear in the presence of sampling errors.

A more ambitious goal than ground state energy estimation is to estimate the distribution of
all eigenvalues weighted by a given initial state $\rho$. Using a quantum circuit similar to that in Kitaev’s algorithm as well as classical post-processing, Ref. [45] proposed an algorithm to solve the quantum eigenvalue estimation problem (QEEP). We henceforth refer to this algorithm as the quantum eigenvalue estimation algorithm (QEEA). Suppose $\|H\| \leq 1/2$, and the interval $[-\pi, \pi]$ is divided into $M$ bins of equal size denoted by $B_j = [-1/2 + j/M, -1/2 + (j + 1)/M]$. Then QEEA estimates the quantities $q_j = \sum_{k:\lambda_k \in B_j} p_k$. Although QEEA was not designed for ground state energy estimation, one can use this algorithm to find the leftmost bin in which $q_j \geq p_0/2$, and thereby locate the ground state energy within a bin of size $M^{-1}$. While the maximal evolution time required scales as $O(\epsilon^{-1})$, the total evolution time of the original QEEA scales as $O(\epsilon^{-6})$. We analyze the cost of QEEA in Appendix C and show that the total runtime can be reduced to $O(\epsilon^{-4})$ for the ground state energy estimation in a straightforward way, yet this is still costly if high precision is required.

To the extent of our knowledge, none of the existing algorithms achieves all three goals listed on Page 2. Some can have better maximal evolution time or total evolution time requirement, but the advantage always comes at the expense of some other aspects. In Table 1 we compare the maximal evolution time, the number of repetitions (the number of times we need to run the quantum circuit), and the total evolution time needed, using the three qubit-efficient methods that require only one ancilla qubit.

Table 1: Comparison of the maximal evolution time, the number of repetitions (the number of times we need to run the quantum circuit), and the total evolution time needed for estimating the ground state energy to within error $\epsilon$, using the three methods that require only one ancilla qubit: the method in this work, QPE with semi-classical Fourier transform that uses only one ancilla qubit, and the QEEA in Ref. [45]. The overlap between the initial state and the ground state is assumed to be $p_0$. The number of repetitions is also the number of times we need to prepare the initial state. An analysis of the QEEA in Ref. [45] can be found in Appendix C. For clarity we have omitted all poly-logarithmic dependence on $\epsilon^{-1}$ and $p_0^{-1}$.

Finally, in a gate-based setting, the exact relations between the maximal evolution time and the circuit depth, and between the total evolution time and the total runtime, can be affected by the method we use to perform time evolution. Suppose we have access to a unitary circuit that performs $e^{-i\tau H}$ exactly for some fixed $\tau$. Then in order to run coherent time evolution for time $T$ we only need to use a circuit of depth $O(T)$. Therefore the circuit depth scales linearly with respect to the maximal evolution time. Similarly the total runtime scales linearly with respect to the total evolution time.

However, if we can only perform time evolution through Hamiltonian simulation, then these relations become more complicated. If advanced Hamiltonian simulation methods [7, 31, 32] can be used, the additional cost would be asymptotically negligible, since to ensure an $\epsilon'$ error for time evolution for time $T$ the cost is $O(T \text{polylog}(T\epsilon'^{-1}))$. Hence the cost is only worse than that in the ideal case by a poly-logarithmic factor. However, for early fault-tolerant quantum computers, as discussed in Refs. [11, 27], Trotter formulas [45] are generally favored. Running time evolution for time $T$ with error at most $\epsilon'$ would entail a runtime of $O(T^{1+1/p} \epsilon'^{-1/p})$. The additional cost will therefore prevent us from reaching the Heisenberg limit, though high-order Trotter formulas (i.e.
with a large $p$) can allow us to get arbitrarily close to the Heisenberg limit. If one does not insist on having a Heisenberg-limited scaling, then randomized algorithms [8, 10, 13] may lead to lower gate count when only low precision is required.

In Appendix D we analyze the circuit depth and the total runtime of our algorithm with time evolution performed using Trotter formulas. We also compare with QPE based on Trotter formulas. We found that when using Trotter formulas, our method has some additional advantage over QPE, achieving a polynomially better dependence on $p_0$ (i.e. $\eta$ in Appendix D) in the total runtime. The total runtime scales like $\epsilon^{-1-o(1)}$ using our algorithm with Trotter formulas, and this only approximately reaches the Heisenberg limit $\epsilon^{-1}$ in terms of the total runtime. However, it is worth noting that none of the other methods can strictly reach the Heisenberg limit using Trotter formulas. Otherwise we can instead perform Hamiltonian simulation with the exponentially accurate methods to go below the Heisenberg limit, which is an impossible task.

1.2 Organization

The rest of the paper is organized as follows. In Section 2 we introduce the quantum circuit we are going to use, and introduce the CDF which is going to play an important role in our algorithm, and give an overview of the ground state energy estimation algorithm. In Section 3 we discuss how to approximate the CDF. In Section 4 we show that the ground state energy can be estimated by inverting the CDF, and present the complexity of our algorithm (Corollary 3). In Section 5 we present the details of our algorithm for post-processing the measurement data and analyze the complexity.

2 Overview of the method

We want to keep the quantum circuit we use as simple as possible. In this work we use the following circuit

$$|0\rangle \xrightarrow{H} W H \xrightarrow{e^{-ij\tau H}}$$

where $H$ is the Hadamard gate. We choose $W = I$ or $W = S^\dagger$ where $S$ is the phase gate, depending on the quantity we want to estimate. The quantum circuit is simple and uses only one ancilla qubit as required. The quantum circuit itself has been used in previous methods [26, 45]. However, our algorithm uses a different strategy for querying the circuit and for classical post-processing, and results in lower total evolution time and/or maximal evolution time achieving the goals (1) and (3) listed on Page 2.

This circuit requires controlled time evolution, which can be non-trivial to implement. Alternatively, one can use the circuit for evaluating matrix elements in Ref. [23], which does not require controlled time evolution, but requires a eigenstate of $H$ with known eigenvalue that is easy to prepare. In a second-quantized setting we can simply use the vacuum state. However, $n + 1$ ancilla qubits will be needed in this alternative approach, where $n$ is the number of qubits $H$ acts on.

Using the circuit in (1), in order to estimate $\text{Re} \text{Tr}[\rho e^{-ij\tau H}]$, we set $W = I$. We introduce a random variable $X_j$ and set it to be 1 when the measurement outcome is 0, and $-1$ when the measurement outcome is 1. Then

$$\mathbb{E}[X_j] = \text{Re} \text{Tr}[\rho e^{-ij\tau H}].$$

(2)
Similarly for $\operatorname{Im} \operatorname{Tr}[\rho e^{-ijH}]$, we set $W = S^I$, and introduce a random variable $Y_j$ that depends in the same way on the measurement outcome. We have

$$
\mathbb{E}[Y_j] = \operatorname{Im} \operatorname{Tr}[\rho e^{-ijH}].
$$

The parameter $\tau$ is chosen to normalize the Hamiltonian. Specifically, we choose $\tau$ so that $\tau \|H\| < \pi/3$.

We can define a spectral measure of $\tau H$ associated with $\rho$. The spectral measure is

$$
p(x) = \sum_{k=0}^{K-1} p_k \delta(x - \tau \lambda_k), \quad x \in [-\pi, \pi].
$$

We extend it to a $2\pi$-periodic function by $p(x + 2\pi) = p(x)$ in order to make the discussion below more convenient. Note that because of the assumption $\tau \|H\| < \pi/3$, in the interval $[-\pi, \pi]$ $p(x)$ is supported in $(-\pi/3, \pi/3)$. Next we consider the cumulative distribution function (CDF) associated with this measure.

We define the $2\pi$-periodic Heaviside function by

$$
H(x) = \begin{cases} 
1, & x \in [2k\pi, (2k+1)\pi), \\
0, & x \in [(2k-1)\pi, 2k\pi),
\end{cases} \quad k \in \mathbb{Z}.
$$

The CDF is usually defined by $C(x) = \sum_{k: \lambda_k \leq x} p_k$. This is however not a $2\pi$-periodic function and thus will create technical difficulties in later discussions. Therefore instead of the usual definition, we define

$$
C(x) = (H \ast p)(x),
$$

where $\ast$ denotes convolution. There is ambiguity at the jump discontinuities, and we define the values of $C(x)$ at these points by requiring $C(x)$ to be right-continuous. One can check that this definition agrees with the usual definition when $x \in (-\pi/3, \pi/3)$, which is the interval that contains all the eigenvalues of $\tau H$. $C(x)$ is a right-continuous non-decreasing function in $(-\pi/3, \pi/3)$.

If we could evaluate the CDF then we would be able to locate the ground state energy. We will see that we are able to approximate, in a certain sense as will be made clear later, the CDF using a function we call the approximate CDF (ACDF). To this end we first define an approximate Heaviside function $F(x) = \sum_{|j| \leq d} \tilde{F}_j e^{ijx}$ such that

$$
|F(x) - H(x)| \leq \epsilon, \quad x \in [-\pi + \delta, -\delta] \cup [\delta, \pi - \delta].
$$

The construction of this function is provided in Lemma 6. We omit the $d$ and $\delta$ dependence in the notation for simplicity. With this $F(x)$ we define the ACDF by

$$
\tilde{C}(x) = (F \ast p)(x).
$$

In Section 3 we will discuss how to evaluate this ACDF using the circuit in (1). The ACDF and CDF are related through the following inequalities

$$
C(x - \delta) - \epsilon \leq \tilde{C}(x) \leq C(x + \delta) + \epsilon
$$

for any $|x| \leq \pi/3$, $0 < \delta < \pi/6$ and $\epsilon > 0$. We prove these inequalities in Appendix B.

By approximately evaluating the ACDF $\tilde{C}(x)$ for certain chosen $x$, and through (8), we can perform a binary search to locate the ground state energy in smaller and smaller intervals. The algorithm to do this and the total computational cost required to estimate the ground state energy to precision $\epsilon$ at a confidence level $1 - \vartheta$ are discussed in Sections 4 and 5.
Figure 2: An illustration of the classical and quantum components of our algorithm: (1) generate samples \( \{J_k\} \) from (10); (2) use \( \{J_k\} \) to generate \( \{Z_k\} \) according to (12); (3) compute \( \bar{G}(x) \) through (15). The ground state energy estimate can be obtained through post-processing as discussed in Section 4. Only Step (2) needs to be performed on a quantum computer.

3 Evaluating the ACDF

In this section we discuss how to evaluate the ACDF \( \tilde{C}(x) \). We first expand it in the following way:

\[
\tilde{C}(x) = \sum_{|j| \leq d} \hat{F}_j \int_{-\pi}^{\pi} p(y) e^{ij(x-y)} dy = \sum_{|j| \leq d} \hat{F}_j e^{ijx} \text{Tr}[\rho e^{-ij\tau H}].
\]  

One might want to evaluate each \( \text{Tr}[\rho e^{-ij\tau H}] \) using Monte Carlo sampling since this quantity is equal to \( E[X_j + iY_j] \). If we want to evaluate all \( \text{Tr}[\rho e^{-ij\tau H}] \) to any accuracy at all, we need to sample each \( X_j \) and \( Y_j \) at least once. Then the total evolution time is is at least \( \tau \sum_{|j| \leq d} |j| = \Omega(\tau d^2) \). Later we will see we need to choose \( d = O(\epsilon^{-1}\text{polylog}(\epsilon^{-1}p_0^{-1})) \) to ensure the ground state energy estimate has an additive error smaller than \( \epsilon \). Hence this total evolution time would give rise to a \( \epsilon^{-2} \) dependence in the runtime.

In order to avoid this \( \epsilon^{-2} \) dependence, instead of evaluating all the terms we stochastically evaluate (9) as a whole. The idea we are going to describe is similar to the unbiased version of the multi-level Monte Carlo method [43, 44]. We define a random variable \( J \) that is drawn from \( \{-d, -d+1, \ldots, d\} \), with probability

\[
\Pr[J = j] = \frac{\hat{F}_j}{\mathcal{F}},
\]

where the normalization factor \( \mathcal{F} = \sum_{|j| \leq d} |\hat{F}_j| \). We let \( \theta_j \) be the argument of \( \hat{F}_j \), i.e. \( \hat{F}_j = |\hat{F}_j| e^{i\theta_j} \). Then

\[
E[(X_j + iY_j)e^{i(\theta_j + jx)}] = \sum_{|j| \leq d} \underbrace{E[X_j + iY_j]e^{i(\theta_j + jx)}}_{\text{is real}} \Pr[J = j] = \frac{1}{\mathcal{F}} \sum_{|j| \leq d} \text{Tr}[\rho e^{-ij\tau H}] e^{ijx} \hat{F}_j = \frac{\tilde{C}(x)}{\mathcal{F}},
\]
where we have used (2) and (3). For simplicity we write $X_J$ and $Y_J$ into a complex random variable

$$Z = X_J + iY_J \in \{\pm 1 \pm i\}. \quad (12)$$

Therefore we can use

$$G(x; J, Z) = FZ e^{i(\theta_J + Jx)} \quad (13)$$

as an unbiased estimate of $\tilde{C}(x)$. The variance can be bounded by:

$$\text{var}[G(x)] \leq F^2 \mathbb{E}[|X_J|^2 + |Y_J|^2] \leq 2F^2. \quad (14)$$

Here we have used the fact that $|X_j|, |Y_j| \leq 1$.

From the above analysis, we can generate $N_s$ independent samples of $(J, Z)$, denoted by $(J_k, Z_k)$, $k = 1, 2, \ldots, N_s$, and then take the average

$$\bar{G}(x) = \frac{1}{N_s} \sum_{k=1}^{N_s} G(x; J_k, Z_k), \quad (15)$$

which can be used to estimate $\tilde{C}(x)$ in an unbiased manner. The variance is upper bounded by $2F^2/N_s$. In order to make the variance upper bounded by a given $\sigma^2$, we need $N_s = \mathcal{O}(F^2/\sigma^2)$. The expected total evolution time is

$$N_s \tau \mathbb{E}[|J|] = \frac{F\tau}{\sigma^2} \sum_{|j| \leq d} |\hat{F}_j||j|. \quad (16)$$

Furthermore, by Lemma 6(iii) we have $|\hat{F}_j| \leq C|j|^{-1}$ for some constant $C$. Therefore

$$\mathcal{F} = \mathcal{O}(\log(d)), \quad \sum_{|j| \leq d} |\hat{F}_j||j| = \mathcal{O}(d).$$

The number of samples and the expected total evolution time are therefore

$$N_s = \mathcal{O}\left(\frac{\log^2(d)}{\sigma^2}\right), \quad N_s \tau \mathbb{E}[|J|] = \mathcal{O}\left(\frac{\tau d \log(d)}{\sigma^2}\right),$$

respectively. We can see that in this way we have avoided the $d^2$ dependence, which shows up in a term-by-term evaluation.

In Figure 3 we show the plot of the ACDF obtained through our method for the Fermi-Hubbard model. The details on this numerical experiment can be found in Appendix E. We can estimate the ground state energy from the ACDF in a heuristic manner: we let

$$x^* = \inf\{x : \bar{G}(x) \geq p_0/2\},$$

and $x^*/\tau$ is an estimate for the ground state energy $\lambda_0$. In Section 5 we describe a more elaborate method to achieve the prescribed accuracy and confidence level. However, this heuristic method seems to work reasonably well in practice. In Figure 4 we show the scaling of the ground state energy estimation error, the total evolution time, and the maximal evolution time, with respect to $\delta = \tau \epsilon$ ($\delta$ here is the parameter needed to construct $\{\hat{F}_j\}$ using Lemma 6), where $\epsilon$ is the allowed error. Both the total evolution time and the maximal evolution time are proportional to $\epsilon^{-1}$. The details on this numerical experiment can also be found in Appendix E.
4 Estimating the ground state energy

In this section we discuss how to estimate the ground state energy with guaranteed error bound and confidence level from the samples generated on classical and quantum circuits discussed in Sections 2 and 3. Getting the ground state energy out of the CDF can be seen as inverting the CDF. We consider the following problem:

**Problem 1** (Inverting the CDF). For $0 \leq \delta < \pi/6$, $0 < \eta < 1$, find $x^* \in (-\pi/3, \pi/3)$ such that

$$C(x^* + \delta) > \eta/2, \quad C(x^* - \delta) < \eta.$$  \hfill (17)

Note that (17) is a weaker requirement than $\eta/2 < C(x^*) < \eta$, for which due to the discontinuity of $C(x)$ the required $x^*$ may not exist. However an $x^*$ satisfying (17) must exist. In fact, let $a = \sup\{x \in (-\pi/3, \pi/3) : C(x) \leq \eta/2\}$ and $b = \inf\{x \in (-\pi/3, \pi/3) : C(x) \geq \eta\}$. Then we can prove $a \leq b$, and any $x^* \in [a - \delta, b + \delta]$ satisfies (17).

If we can solve Problem 1 for any $\eta$ and $\delta$, then we can estimate the ground state energy to within additive error $\delta/\tau$. Suppose we know, for some $\eta > 0$, $p_0 \geq \eta$. Then if we solve Problem 1 we will find an $x^*$ such that $C(x^* + \delta) > \eta/2 > 0$ and $C(x^* - \delta) < \eta \leq p_0$. $C(x^* + \delta) > 0$ indicates that
Remark 4. For each output $x$, the evolution time is $\eta \leq \delta$. Hence we know $|x^* - \tau \lambda_0| \leq \delta$. If we choose $\delta = \tau \epsilon$, then
\[
|\lambda_0 - \lambda_0| \leq \epsilon.
\]
And $\lambda_0$ is the estimate we want.

Using the samples $\{J_k\}$ and $\{Z_k\}$ generated on classical and quantum circuits respectively, we are able to solve Problem 1.

**Theorem 2** (Inverting the CDF). With samples $\{J_k\}_{k=1}^M$ satisfying $|J_k| \leq d$ and $\{Z_k\}_{k=1}^M$, generated according to [10] and [12], respectively, we can solve Problem 1 on a classical computer with probability at least $1 - \theta$, for $d = O(\delta^{-1} \log(\delta^{-1} \eta^{-1}))$ and $M = O(\eta^{-2} \log^2(d)(\log \log(\delta^{-1}) + \log(\theta^{-1})))$.

The classical post-processing cost is
\[
O(\eta^{-2} \log(\delta^{-1})(\log \log(\delta^{-1}) + \log(\theta^{-1}))\log(\delta^{-1}) + \log \log(\delta^{-1} \eta^{-1}))^2)
\]
To generate the samples $\{Z_k\}_{k=1}^M$ on a quantum circuit, the expected total evolution time and the maximal evolution time are
\[
\tau M \mathbb{E}[|J|] = O(\tau \delta^{-1} \eta^{-2} \log(\delta^{-1} \eta^{-1})(\log \log(\delta^{-1}) + \log(\theta^{-1}))
\times (\log \log(\delta^{-1}) + \log \log(\delta^{-1} \eta^{-1}))^2).
\]
\[
\tau d = O(\tau \delta^{-1} \log(\delta^{-1} \eta^{-1})).
\]
respectively.

We will prove this theorem by constructing the algorithm for classical post-processing in Section 5. Since solving Problem 1 enables us to estimate the ground state energy as discussed above, from Theorem 2 we have the following corollary:

**Corollary 3** (Ground state energy). With samples $\{J_k\}_{k=1}^M$ satisfying $|J_k| \leq d$ and $\{Z_k\}_{k=1}^M$, generated according to [10] and [12] respectively, we can estimate the ground state energy $\lambda_0$ to within additive error $\epsilon$ on a classical computer with probability at least $1 - \theta$, if $p_0 \geq \eta/2$ for some known $\eta$, $d = O(\epsilon^{-1} \tau^{-1} \log(\epsilon^{-1} \tau^{-1} \eta^{-1}))$, and $M = O(\eta^{-2} \log^2(d)(\log \log(\epsilon^{-1} \tau^{-1}) + \log(\theta^{-1})))$. The classical post-processing cost is $O(\eta^{-2} \text{polylog}(\epsilon^{-1} \tau^{-1} \eta^{-1}))$. The expected total evolution time and the maximal evolution time are $O(\eta^{-1} \text{polylog}(\epsilon^{-1} \tau^{-1} \eta^{-1}))$ and $O(\epsilon^{-1} \text{polylog}(\epsilon^{-1} \tau^{-1} \eta^{-1}))$ respectively.

**Remark 4.** If we do not know a lower bound for $p_0$, we can simply choose $\eta = 2^{-\ell}$ for $\ell = 1, 2, 3, \ldots$. For each $\eta$ we solve Problem 1 with $\delta = \tau \epsilon$, then if no error occurs, we will end up getting a sequence of outputs $x^*_i$ each of which is greater than $\tau(\lambda_0 - \epsilon)$. Eventually for large enough $\ell = O(\log(p_0^{-1}))$ we will have $|x^*_i/\tau - \lambda_0| \leq \epsilon$. Although we cannot know it for sure by looking at $x^*_i$, in practice we will see many $x^*_i$ concentrated in the interval $[\tau(\lambda_0 - \epsilon), \tau(\lambda_0 + \epsilon)]$, and we can pick an estimate among them. This can be further complemented by some prior knowledge about the ground state energy.

## 5 Inverting the CDF

In this section we prove Theorem 2 by constructing the classical post-processing algorithm to solve Problem 1 given independent samples of $(J, Z)$ defined in [10] and [12]. We denote these samples by $\{(J_k, Z_k)\}_{k=1}^M$. We divide them into $N_0$ batches of size $N_s$, where $N_s N_b = M$. The maximal evolution time needed to generate these samples is proportional to $\max_k |J_k| \leq d$. The expected total evolution time we will need is proportional to $\mathbb{E}[|J|]$. 

We first reduce Problem 1 into a decision problem. For any \( x \in (-\pi/3, \pi/3) \), one of the following must be true:

\[
C(x + \delta) > \eta/2, \quad \text{or} \quad C(x - \delta) < \eta. \tag{21}
\]

If there is a subroutine that tells us which one of the two is correct, or randomly picks one when both are correct, then we can use it to find \( x^* \). We assume such a subroutine, which uses \( \{(J_k, Z_k)\}_{k=1}^M \), exists and denote it by the name \( \text{CERTIFY}(x, \delta, \eta, \{(J_k, Z_k)\}) \). The subroutine returns either 0 or 1: 0 for \( C(x + \delta) > \eta/2 \) being true, and 1 for \( C(x - \delta) < \eta \) being true.

In Algorithm 1 with \( \text{CERTIFY}(x, \delta, \eta, \{(J_k, Z_k)\}) \), we describe the algorithm to solve Problem 1. This algorithm we denote by \( \text{INVERT.CDF}(\delta, \eta, \{(J_k, Z_k)\}) \). It runs as follows: we start with \( x_{0,0} = -\pi/3 \) and \( x_{1,0} = \pi/3 \). They are chosen so that \( C(x_{1,0}) > \eta/2 \) and \( C(x_{0,0}) < \eta \). Let \( \ell \) be the number of iterations we have performed, and \( \ell = 0 \) at the beginning. At each iteration, we let \( x_{\ell} = (x_{0,\ell} + x_{1,\ell})/2 \), and run \( \text{CERTIFY}(x_{\ell}, (2/3)\delta, \eta, \{(J_k, Z_k)\}) \). This tells us either \( C(x_{\ell} + (2/3)\delta) > \eta/2 \) or \( C(x_{\ell} - (2/3)\delta) < \eta \). If the former then we let \( x_{0,\ell+1} = x_{0,\ell}, x_{1,\ell+1} = x_{\ell} + (2/3)\delta \), and if the latter we let \( x_{0,\ell+1} = x_{\ell} + (2/3)\delta, x_{1,\ell+1} = x_{1,\ell} \). This is done so that for each \( \ell \) we have

\[
C(x_{0,\ell}) < \eta, \quad C(x_{1,\ell}) > \eta/2. \tag{22}
\]

We then let \( \ell \leftarrow \ell + 1 \) and go to the next iteration. The algorithm stops once \( x_{1,\ell} - x_{0,\ell} \leq 2\delta \). We denote the total number of iterations by \( L \). The output is \( x_L = (x_{0,L} + x_{1,L})/2 \). Because (22) holds for each iteration we have

\[
C(x_L - \delta) \leq C(x_{0,L}) < \eta, \quad C(x_L + \delta) \geq C(x_{1,L}) > \eta/2.
\]

Thus we can see \( x_L \) satisfies the requirements for \( x^* \) in Problem 1. The next question is, how many iterations does it take to satisfy the stopping criterion? Regardless of the outcome of the \( \text{CERTIFY} \) subroutine, we always have

\[
x_{1,\ell+1} - x_{0,\ell+1} = \frac{1}{2}(x_{1,\ell} - x_{0,\ell}) + \frac{2}{3}\delta.
\]

From this we can see

\[
x_{1,\ell} - x_{0,\ell} = \frac{2\pi/3 - (4/3)\delta}{2^\ell} + \frac{4}{3}\delta.
\]

Therefore it takes \( L = \mathcal{O}(\log(\delta^{-1})) \) iterations for the algorithm to stop.

**Algorithm 1 INVERT.CDF**

**Input:** \( \delta, \eta, \{(J_k, Z_k)\} \)

\[
x_0 \leftarrow -\pi/3, \ x_1 \leftarrow \pi/3;
\]

**while** \( x_1 - x_0 > 2\delta \) **do**

\[
x \leftarrow (x_0 + x_1)/2;
\]

\[
u \leftarrow \text{CERTIFY}(x, (2/3)\delta, \eta, \{(J_k, Z_k)\});
\]

**if** \( u = 0 \) **then**

\[
x_1 \leftarrow x + (2/3)\delta;
\]

**else**

\[
x_0 \leftarrow x - (2/3)\delta;
\]

**end if**

**end while**

**Output:** \( (x_0 + x_1)/2 \)

Next we discuss how to construct the subroutine \( \text{CERTIFY}(x, \delta, \eta, \{(J_k, Z_k)\}) \). While we cannot directly evaluate the CDF \( C(x) \) for any \( x \), we can estimate the ACDF \( C(x) \) using the data \( \{J_k\} \) and \( \{Z_k\} \). We can let \( \epsilon = \eta/8 \) in (6) and choose \( d = \mathcal{O}(\delta^{-1} \log(\delta^{-1} \eta^{-1})) \) according to Lemma 3. Then...
by (8), we have $C(x - \delta) \leq \tilde{C}(x) + \eta/8$ and $C(x + \delta) \geq \tilde{C}(x) - \eta/8$. One of the following must be true:

$$\tilde{C}(x) > (5/8)\eta, \text{ or } \tilde{C}(x) < (7/8)\eta,$$

then the former implies $C(x + \delta) > \eta/2$ and the latter $C(x - \delta) < \eta$. Therefore the CERTIFY subroutine only needs to decide which one of the two is correct or to output a random choice when both are correct.

As discussed in Section 3, $\bar{G}(x)$ is an unbiased estimate of $\tilde{C}(x)$. We use $\{J_k\}$ and $\{Z_k\}$ to get $N_b$ samples for $\bar{G}(x)$, denoted by $\bar{G}_r(x)$, via

$$\bar{G}_r(x) = \frac{1}{N_s} \sum_{k=1}^{N_s} G(x; J_{(r-1)N_s+k}, Z_{(r-1)N_s+k})$$

for $r = 1, 2, \ldots, N_b$. Here $G(x; J, Z)$ is defined in (13). For each $r$, we compare $\bar{G}_r(x)$ with $(3/4)\eta$. If $\bar{G}_r(x) > (3/4)\eta$ for a majority of batches, then we tend to believe $\tilde{C}(x) > (5/8)\eta$ and output 0 for $C(x + \delta) > \eta/2$. Otherwise, we tend to believe $\tilde{C}(x) < (7/8)\eta$ and output 1 for $C(x - \delta) < \eta$. For the pseudocode for the subroutine see Algorithm 2.

### Algorithm 2 CERTIFY

**Input:** $x, \delta, \eta, \{J_k, Z_k\}$

$b \leftarrow 0$, $c \leftarrow 0$;

for $r = 1, 2, \ldots, N_b$ do

$\bar{G}_r(x) \leftarrow (1/N_s) \sum_{k=1}^{N_s} G(x; J_{(r-1)N_s+k}, Z_{(r-1)N_s+k}); \{G(x; J, Z)\} \text{ defined in (13)}$

if $\bar{G}_r(x) > (3/4)\eta$ then

$c \leftarrow c + 1$;

end if

end for

if $c \leq B/2$ then

$b \leftarrow 1$;

end if

**Output:** $b$

In the CERTIFY subroutine, an error occurs when $\bar{C}(x) > (5/8)\eta$ yet a majority of estimates $\bar{G}_r(x)$ are smaller than $(3/4)\eta$, or when $\bar{C}(x) < (7/8)\eta$ yet a majority of estimates $\bar{G}_r(x)$ are larger than $(3/4)\eta$. We need to make the probability of this kind of error occurring upper bounded by $\nu$.

First we assume $\bar{C}(x) > (5/8)\eta$. Then for each $r$, by Markov’s inequality, we have

$$\Pr[\bar{G}_r(x) < (3/4)\eta] \leq \frac{64 \text{var}[\bar{G}_r(x)]}{\eta^2}.$$

We want to make this probability at most $1/4$. Therefore we need $\text{var}[\bar{G}_r(x)] \leq \eta^2/256$. To ensure this, by (16) in which we let $\sigma^2 = \eta^2/256$, we can choose

$$N_s = \mathcal{O}\left(\frac{\log^2(d)}{\eta^2}\right).$$

Then by the Chernoff bound the probability of the majority of estimates $\bar{G}_r(x)$ being smaller than $(3/4)\eta$ is at most $e^{-C'N_b}$ for some constant $C'$. In order to make this probability bounded by $\nu$ we only need to let $N_b = \mathcal{O}(\log(\nu^{-1}))$.

In the algorithm INVERT_CDF, the subroutine CERTIFY is used $L = \mathcal{O}(\log(\delta^{-1}))$ times. If an error occurs in a single run of CERTIFY with probability at most $\nu$ then in the total $L$ times we use
this subroutine the probability of an error occurring is at most \( L\nu \). Therefore in order to ensure that an error occurs with probability at most \( \vartheta \) in \textsc{InvertCDF}, we need to set \( \nu = \vartheta / L \). Therefore \( N_b = \mathcal{O}(\log((L\vartheta)^{-1})) = \mathcal{O}(\log(\delta^{-1}) + \log(\vartheta^{-1})) \).

The above analysis shows that in order to solve Problem 1 the total evolution time is \( M\mathbb{E}[J] = N_b N_s \mathbb{E}[J] \). We evaluate \( N_s \mathbb{E}[J] \) by (16) in which we let \( \sigma^2 = \eta^2 / 256 \) as discussed before when we estimate how large \( N_s \) needs to be in (24). Multiplying this by \( N_b \) we have (19). Note here we do not need to multiply by \( L \) because in each \textsc{Certify} subroutine we can reuse the same \( \{J_k\}, \{Z_k\} \).

The maximal evolution time required is \( \tau d \) and this leads to (20). The main cost in classical post-processing comes from evaluating \( \bar{G}_r(x) \). This needs to be done \( LN_b \) times. Each evaluation involves \( \mathcal{O}(N_s) = \mathcal{O}(\eta^{-2} \log^2(d)) \) arithmetic operations. The total runtime for classical post-processing is therefore \( LN_b N_s = LM \), which leads to (18). Thus we have obtained all the cost estimates in Theorem 2 and proved the theorem.

6 Discussions

In this paper we presented an algorithm to estimate the ground state energy with Heisenberg-limited precision scaling. The quantum circuit we used requires only one ancilla qubit, and the maximal evolution time needed has a poly-logarithmic dependence on the overlap \( p_0 \). Such dependence on \( p_0 \) is exponentially better than that required by QPE using a similarly structured circuit. Both rigorous analysis and numerical experiments are done to validate the correctness and efficiency of our algorithm.

Although our algorithm has a near-optimal dependence on the precision, the dependence on \( p_0 \) (more precisely, on its lower bound \( \eta \)), which scales as \( p_0^{-2} \) in Corollary 3 is far from optimal compared to the \( p_0^{-1/2} \) scaling in Refs. [29, 29]. Whether one can achieve this \( p_0^{-1/2} \) scaling without using a quantum circuit with substantially larger maximal evolution time, and without using such techniques as LCU or block-encoding, remains an open question.

The probabilistic choice of the simulation time according to Eq. (10) plays an important role in reducing the total evolution time. However, we may partially derandomize the algorithm following the spirit of the multilevel Monte Carlo (MLMC) method in the classical setting. The method we developed for computing the approximate CDF in Section 3 is in fact a quite general approach for evaluating expectation values from matrix functions. This method can act as a substitute of the LCU method in many cases, especially in a near-term setting. Using this method to compute other properties of the spectrum, such as the spectral density, is a direction for future work.

A Constructing the approximate Heaviside function

In this appendix we construct the approximate Heaviside function satisfying the requirement in (26). We need to first construct a smeared Dirac function, which we will use as a mollifier in constructing the approximate Heaviside function.

**Lemma 5.** We define $M_{d,\delta}(x)$ by

$$M_{d,\delta}(x) = \frac{1}{N_{d,\delta}} T_d \left( \frac{1 + 2 \cos(x) - \cos(\delta)}{1 + \cos(\delta)} \right),$$

where $T_d(x)$ is the $d$-th Chebyshev polynomial of the first kind, and

$$N_{d,\delta} = \int_{-\pi}^{\pi} T_d \left( \frac{1 + 2 \cos(x) - \cos(\delta)}{1 + \cos(\delta)} \right) dx.$$

Then

(i) $|M_{d,\delta}(x)| \leq \frac{1}{N_{d,\delta}}$ for all $x \in [-\pi, -\delta] \cup [\delta, \pi]$, and $M_{d,\delta}(x) \geq - \frac{1}{N_{d,\delta}}$ for all $x \in \mathbb{R}$.

(ii) $\int_{-\pi}^{\pi} M_{d,\delta}(x) dx = 1, 1 \leq \int_{-\pi}^{\pi} |M_{d,\delta}(x)| dx \leq 1 + \frac{4\pi}{N_{d,\delta}}$.

(iii) When $\tan(\delta/2) \leq 1 - 1/\sqrt{2}$, we have

$$N_{d,\delta} \geq C_1 e^{d/\sqrt{2}} \sqrt{\frac{d}{\delta}} \text{erf}(C_2 \sqrt{d/\delta})$$

for some constants $C_1$ and $C_2$ that do not depend on $d$ or $\delta$.

**Proof.** We first note that, by the property of Chebyshev polynomials, when $x \in [-\pi, -\delta] \cup [\delta, \pi]$, i.e.

$$\cos(x) \leq \cos(\delta),$$

we have $|T_d \left( \frac{1 + 2 \cos(x) - \cos(\delta)}{1 + \cos(\delta)} \right)| \leq 1$. This proves the first inequality in (i). Note that when $x \in [-\delta, \delta], T_d \left( \frac{1 + 2 \cos(x) - \cos(\delta)}{1 + \cos(\delta)} \right) \geq -1$. Combine this and the first inequality with the fact that $M_{d,\delta}(x)$ is $2\pi$-periodic we prove the second inequality in (i).

The first part of (ii) is obvious because of the definition of $N_{d,\delta}$. For the second part, we have

$$\int_{-\pi}^{\pi} |M_{d,\delta}(x)| dx \geq \int_{-\pi}^{\pi} M_{d,\delta}(x) dx = 1.$$

Also

$$\int_{-\pi}^{\pi} |M_{d,\delta}(x)| dx = \left( \int_{-\pi}^{-\delta} + \int_{\delta}^{\pi} \right) |M_{d,\delta}(x)| dx + \int_{-\delta}^{\delta} M_{d,\delta}(x) dx$$

$$\leq \frac{4\pi}{N_{d,\delta}} + \left( \int_{-\pi}^{-\delta} + \int_{\delta}^{\pi} \right) M_{d,\delta}(x) dx + \int_{-\delta}^{\delta} M_{d,\delta}(x) dx$$

$$= 1 + \frac{4\pi}{N_{d,\delta}}.$$

We now prove (iii). This requires lower bounding $T_d \left( \frac{1 + 2 \cos(x) - \cos(\delta)}{1 + \cos(\delta)} \right)$ when $x \in [-\delta, \delta]$. For $\delta$ small enough so that

$$\max_x 2 \frac{\cos(x) - \cos(\delta)}{1 + \cos(\delta)} = 2 \tan^2(\delta/2) \leq 3 - \sqrt{2},$$

which is equivalent to $\tan(\delta/2) \leq 1 - 1/\sqrt{2}$, we can use [20, Lemma 13] to provide a lower bound for the $x \in [-\delta, \delta]$ case:

$$T_d \left( \frac{1 + 2 \cos(x) - \cos(\delta)}{1 + \cos(\delta)} \right) \geq \frac{1}{2} \exp \left( \sqrt{2d} \frac{\cos(x) - \cos(\delta)}{1 + \cos(\delta)} \right).$$

(26)
By the elementary inequality $|\sin(x)| \leq |x|$, we have
\[
\sqrt{\frac{\cos(x) - \cos(\delta)}{1 + \cos(\delta)}} = \sqrt{\frac{\tan^2\left(\frac{\delta}{2}\right) - \sin^2(x/2)}{\cos^2(\delta/2)}} = \tan\left(\frac{\delta}{2}\right) \sqrt{\frac{1 - \sin^2(x/2)}{\sin^2(\delta/2)}}
\geq \tan\left(\frac{\delta}{2}\right) \left(1 - \frac{\sin^2(x/2)}{\sin^2(\delta/2)}\right) \geq \tan\left(\frac{\delta}{2}\right) \left(1 - \frac{x^2}{4 \sin^2(\delta/2)}\right).
\]
Substituting this into (26) we have
\[
T_d \left(1 + 2 \frac{\cos(x) - \cos(\delta)}{1 + \cos(\delta)}\right) \geq \frac{1}{2} e^{\sqrt{2} \tan(\delta/2)} \exp\left(-\frac{d x^2}{\sqrt{2} \sin(\delta)}\right).
\]
Then
\[
N_{d,\delta} \geq \int_{-\delta}^{\delta} T_d \left(1 + 2 \frac{\cos(x) - \cos(\delta)}{1 + \cos(\delta)}\right) dx - 2\pi
\geq \frac{1}{2} e^{\sqrt{2} \tan(\delta/2)} \sqrt{\frac{2\pi \sin(\delta)}{d}} \operatorname{erf}\left(\sqrt{\frac{d}{2 \sin(\delta)}}\right) - 2\pi
\geq C_1 e^{d\sqrt{\delta}/\sqrt{2}} \sqrt{\frac{\delta}{2}} \operatorname{erf}(C_2 \sqrt{d\delta}),
\]
for $\delta \in (0, \pi/2)$ and some constants $C_1, C_2 > 0$. This proves (iii).

A plot of $M_{d,\delta}$ is shown in Figure 5. As we can see it roughly takes the shape of a Dirac function. We then use it as a mollifier to approximate the Heaviside function using the convolution of $M_{d,\delta}$ and the Heaviside function.

**Lemma 6.** Let $H(x)$ be the periodic Heaviside function defined in (4). For any $\delta \in (0, \pi/2)$ such that $\tan(\delta/2) \leq 1 - 1/\sqrt{2}$ and $\epsilon > 0$, there exists $d = O(\delta^{-1} \log(\delta^{-1} \epsilon^{-1}))$, and a $2\pi$-periodic function $F_{d,\delta}(x)$ of the form
\[
F_{d,\delta}(x) = \frac{1}{\sqrt{2\pi}} \sum_{k=-d}^{d} \hat{F}_{d,\delta,k} e^{ikx},
\]
satisfying
(i) \(-\epsilon/2 \leq F_{d,\delta}(x) \leq 1 + \epsilon\) for all \(x \in \mathbb{R}\);

(ii) \(|F_{d,\delta}(x) - H(x)| \leq \epsilon\) for all \(x \in [-\pi + \delta, -\delta] \cup [\delta, \pi - \delta]\);

(iii) \(|\hat{F}_{d,\delta,k}| \leq 2(1 + \epsilon)/(\sqrt{2\pi}|k|)\) for \(k \neq 0\).

**Proof.** We first construct the function \(F_{d,\delta}(x)\). Let \(M_{d,\delta}(x)\) be the mollifier in Lemma 5. Because of Lemma 5 (i) and (ii) \(M_{d,\delta}(x)\) can be used as to mollify non-smooth functions. Also because \(T_d(x)\) is a polynomial of degree \(d\), the Fourier coefficients

\[
\hat{M}_{d,\delta,k} = \frac{1}{\sqrt{2\pi}} \int_{-\pi}^{\pi} M_{d,\delta}(x)e^{-ikx} \, dx
\]

are non-zero only for \(-d \leq k \leq d\). Also

\[
|\hat{M}_{d,\delta,k}| \leq \frac{1}{\sqrt{2\pi}} \int_{-\pi}^{\pi} |M_{d,\delta}(x)| \, dx = \frac{1 + \epsilon}{\sqrt{2\pi}}.
\]

We construct \(F_{d,\delta}\) by mollifying the Heaviside function with \(M_{d,\delta}(x)\):

\[
F_{d,\delta}(x) = (M_{d,\delta} \ast H)(x) = \int_{-\pi}^{\pi} M_{d,\delta}(x')H(x - x') \, dx'.
\]

We then show we can choose \(d = \mathcal{O}(\delta^{-1} \log(\delta^{-1}\epsilon^{-1}))\) to satisfy (ii). We have

\[
|F_{d,\delta}(x) - H(x)| = \left| \int_{-\pi}^{\pi} M_{d,\delta}(x')(H(x - x') - H(x)) \, dx' \right|
\leq \int_{-\pi}^{\pi} M_{d,\delta}(x')|H(x - x') - H(x)| \, dx'.
\]

For any \(x\) such that \(|x| \in [\delta, \pi - \delta]\), first we consider the case where \(|x'| < \delta\). In this case \(H(x - x') = H(x)\) and therefore the integrand \(M_{d,\delta}(x')|H(x - x') - H(x)| = 0\). Then we consider the case where \(|x'| \geq \delta\). By Lemma 5 (i) we have \(M_{d,\delta}(x') \leq 2/N_{d,\delta}\), and as \(|H(x - x') - H(x)| \leq 1\), \(M_{d,\delta}(x')|H(x - x') - H(x)| \leq 2/N_{d,\delta}\). Thus for any \(x\) such that \(|x| \in [\delta, \pi - \delta]\),

\[
|F_{d,\delta}(x) - H(x)| \leq \frac{4\pi}{N_{d,\delta}}.
\]

If we want to keep the approximation error for \(x \in [-\pi + \delta, -\delta] \cup [\delta, \pi - \delta]\) to be below \(\epsilon\), we will need, by Lemma 5 (i) and (29),

\[
C_1 \epsilon^{d\delta/\sqrt{\pi}} \sqrt{\frac{\delta}{d}} \text{erf}(C_2 \sqrt{d\delta}) \geq \frac{4\pi}{\epsilon}.
\]

It can be checked that we can choose \(d = \mathcal{O}(\delta^{-1} \log(\epsilon^{-1}\delta^{-1}))\) to achieve this.

We then show this choice of \(d\) ensures (i) as well. From Eq. (25)

\[
F_{d,\delta}(x) \leq \int_{-\pi}^{\pi} |M_{d,\delta}(y)| \, dy \leq 1 + \frac{4\pi}{N_{d,\delta}} \leq 1 + \epsilon
\]

and by the second inequality in Lemma 5 (i)

\[
F_{d,\delta}(x) \geq -\frac{1}{N_{d,\delta}} \int_{-\pi}^{\pi} H(y) \, dy = -\frac{2\pi}{N_{d,\delta}} \geq -\frac{\epsilon}{2}.
\]
Finally we prove our construction satisfies (iii). Because $F_{d,\delta}(x)$ is defined through a convolution, its Fourier coefficients can be obtained through

$$\hat{F}_{d,\delta,k} = \sqrt{2\pi} \hat{M}_{d,\delta,k} \hat{H}_k,$$

where $\hat{H}_k$’s are the Fourier coefficients of the rectangle function $H(x)$. Therefore $\hat{F}_{d,\delta,k} \neq 0$ only for $-d \leq k \leq d$. Because of (27), we have

$$|\hat{F}_{d,\delta,k}| \leq (1 + \epsilon)|\hat{H}_k|.$$

Since when $k \neq 0$

$$\hat{H}_k = \frac{1}{\sqrt{2\pi}} \int_{-\pi}^{\pi} H(x)e^{-ikx}dx$$

$$= \begin{cases} \frac{2}{i\sqrt{2\pi}} & \text{if } k \mid d \\ 0 & \text{otherwise} \end{cases}$$

we have (iii).

\[\square\]

### B The relation between the CDF and the approximate CDF

In this appendix we prove (8). Let $0 < \delta < \pi/6$. First we have a $2\pi$-periodic function $F(x)$ from Lemma 6 that satisfies

$$|F(x) - H(x)| \leq \epsilon, \quad x \in [-\pi + \delta, -\delta] \cup [\delta, \pi - \delta],$$

and $F(x) \in [0, 1]$ for all $x \in \mathbb{R}$. We further define $F_L(x) = F(x - \delta)$ and $F_R(x) = F(x + \delta)$. They satisfy

$$|F_L(x) - H(x)| \leq \epsilon, \quad x \in [-\pi + 2\delta, 0] \cup [2\delta, \pi],$$

$$|F_R(x) - H(x)| \leq \epsilon, \quad x \in [-\pi, -2\delta] \cup [0, \pi - 2\delta].$$

(30)

We define the some functions related to the ACDF as follows:

$$\tilde{C}_L(x) = (F_L * p)(x), \quad \tilde{C}_R(x) = (F_R * p)(x).$$

(31)

Then we have

$$\tilde{C}_L(x) = \tilde{C}(x - \delta), \quad \tilde{C}_R(x) = \tilde{C}(x + \delta).$$

(32)

The functions $\tilde{C}_L(x)$ and $\tilde{C}_R(x)$ can be used to bound $C(x)$. Because of (30), the fact that $p(x)$ is supported in $(-\pi/3, \pi/3)$ in $[-\pi, \pi]$, $\delta < \pi/6$, and that $H(y)$ and $F_L(y)$ both take value in $[0, 1]$, for $x \in (-\pi/3, \pi/3)$ we have

$$|\tilde{C}_L(x) - C(x)| \leq \int_{-\pi}^{\pi} p(x - y)|H(y) - F_L(y)|dy$$

$$\leq \epsilon + \int_{0}^{2\delta} p(x - y)dy$$

$$= \epsilon + C(x) - C(x - 2\delta).$$

Therefore

$$\tilde{C}_L(x) \geq C(x) - [\epsilon + C(x) - C(x - 2\delta)] = C(x - 2\delta) - \epsilon.$$

Similarly we have

$$\tilde{C}_R(x) \leq C(x) + [\epsilon + C(x + 2\delta) - C(x)] = C(x + 2\delta) + \epsilon.$$

Combining these two inequalities with (32), we have

$$C(x - 2\delta) \leq \tilde{C}(x - \delta) + \epsilon, \quad C(x + 2\delta) \geq \tilde{C}(x + \delta) - \epsilon.$$

This proves (8).
C  Obtaining the ground state energy by solving the QEEP

Here we discuss how to obtain the ground state energy using algorithm in Ref. [45] to solve the QEEP. The cost of solving the QEEP as analyzed in Ref. [45] scales as $\epsilon^{-6}$. However, the cost can be much reduced for the problem of ground state energy estimation. For simplicity we assume $\|H\| < \pi/3$ and $\tau$ is chosen to be 1.

In order to find the interval of size $2\epsilon$ containing the ground state energy, we first divide the interval $[-\pi/3, \pi/3]$ into $M$ bins of equal size smaller than $2\epsilon$. We then define the indicator function associated with an interval $[a, b]$ to be

$$1_{[a,b]}(x) = \begin{cases} 1, & x \in [a, b], \\ 0, & x \notin [a, b]. \end{cases}$$

In QEEP the goal is to estimate $\text{Tr}[\rho 1_{[a,b]}(H)]$, where $[a, b]$ is one of the $M$ bins, to within precision $O(\epsilon)$. However, in our setting, if we know $p_0 \geq \eta$, one can estimate $\text{Tr}[\rho 1_{[a,b]}(H)]$ to within error $O(\eta)$. If we get $\text{Tr}[\rho 1_{[a,b]}(H)] < \eta$ with high confidence then we know the ground state energy $\lambda_0$ is not in this interval. If $\text{Tr}[\rho 1_{[a,b]}(H)] > \eta/2$ with high confidence then there is an eigenvalue in $[a, b]$. If the above task can be done, then we choose the leftmost bin in which $\text{Tr}[\rho 1_{[a,b]}(H)] > \eta/2$. This will enable us to solve the ground state energy estimation problem.

To estimate $\text{Tr}[\rho 1_{[a,b]}(H)]$, Ref. [45] first approximated the indicator function $1_{[a,b]}(x)$ using a truncated Fourier series [45, Appendix A], similar to what we did in Appendix A. The number of terms $N_{\text{term}}$ and the maximal evolution time $T$ both scale like $\epsilon^{-1}$. In Ref. [45] the author proposed estimating each Fourier mode $\text{Tr}[\rho e^{-iH}]$ to within error $O(\epsilon/N_{\text{term}})$. Because here the estimation precision is $O(\eta)$ rather than $O(\epsilon)$, we should instead estimate $\text{Tr}[\rho e^{-iH}]$ to within error $O(\eta N_{\text{term}}) = O(\eta \epsilon)$. Because we are using Monte Carlo sampling this requires $O(\eta^{-2} \epsilon^{-2})$ samples. We need the same number of samples for each $\text{Tr}[\rho e^{-iH}]$, and therefore the total time we need to run time evolution is $O(N_{\text{term}} T \eta^{-2} \epsilon^{-2}) = O(\eta^{-2} \epsilon^{-4})$. We omitted polylogarithmic factors in the complexity.

However if the analysis is done more carefully the dependence on $\epsilon$ could be improved. First one should notice that the error for each $\text{Tr}[\rho e^{-iH}]$ is independent, and the estimate is unbiased (if we do not consider the Fourier approximation error), as is the case in our algorithm (Section 3). Therefore the total error for estimating $\text{Tr}[\rho 1_{[a,b]}(H)]$ accumulates sublinearly. One can in fact choose to estimate $\text{Tr}[\rho e^{-iH}]$ to within error $O(\eta/\sqrt{N_{\text{term}}}) = O(\eta \epsilon^{-1/2})$. This saves a $\epsilon^{-1}$ factor in the total runtime. Furthermore, one can choose to evaluate the approximate indicator function in a stochastic way, like we did in Section 3. By taking into account the decay of Fourier coefficients, similar to Lemma 6 (iii), it is possible to further reduce the complexity.

D Complexity analysis for using Trotter formulas

In this appendix, instead of using the maximal evolution time and the total evolution time to quantify the complexity, we directly analyze the circuit depth and the total runtime when the time evolution is simulated using Trotter formulas. We suppose the Hamiltonian $H$ can be decomposed as $H = \sum_{\gamma} H_\gamma$, where each of $H_\gamma$ can be efficiently exponentiated. A $p$-th order Trotter formula applied to $e^{-itH}$ with $r$ Trotter steps gives us a unitary operator $U_{HS}$ with error

$$\|U_{HS} - e^{-itH}\| \leq C_{\text{Trotter}} r^{p+1} r^{-p},$$

where $C_{\text{Trotter}}$ is a prefactor, for which the simplest bound is $C_{\text{Trotter}} = O((\sum_\gamma \|H_\gamma\|)^{p+1})$. Tighter bounds in the form of a sum of commutators are proved in Refs. [15] [47].
D.1 The algorithm in this work

Our algorithm requires approximating Eq. (9) to precision $\eta$ (as in Theorem 3; $\eta$ is a lower bound of $p_0/2$) using Trotter formulas. Suppose we are using a $p$-th order Trotter formula, then we want

$$\left\| \sum_j \hat{F}_j e^{ij\tau H} \rho e^{-ij\tau H} - \sum_j \hat{F}_j e^{ij\tau H} \rho U_{\text{HS}}^j \right\| = O(\eta).$$

Since the left-hand side can be upper bounded by

$$\sum_j ||\hat{F}_j|| ||e^{-i\tau H} - U_{\text{HS}}|| = O(d ||e^{-i\tau H} - U_{\text{HS}}||)$$

by Lemma 6 (iii), we only need to choose $r$ so that

$$C_{\text{Trotter}} \tau^{p+1} r - p = O(\eta d - 1).$$

Therefore we can choose

$$r = \max\{1, \tilde{O}(d^{1/p} \eta^{-1/p} C_{\text{Trotter}}^{1/p})\}$$

The maximal evolution time in Corollary 3 tells us how many times we need to use the operator $U_{\text{HS}}$ (multiplied by a factor $\tau$). Multiply this by $r$ we have the maximal circuit depth we need, which is

$$dr = \tilde{O}(\max\{\tau^{-1} \epsilon, \epsilon^{-1} \eta^{-1} C_{\text{Trotter}}^{1/p}/\eta\}).$$

Similarly we have the total runtime

$$\tilde{O}(\max\{\tau^{-1} \epsilon \eta^{-2}, \epsilon^{-1} \eta^{-2} C_{\text{Trotter}}^{1/p}/\eta\}).$$

If we fix $H$ and let $\epsilon, \eta \to 0$, then we can see this gives us an extra $\epsilon^{-1} \eta^{-1/p}$ factor in the circuit depth and total runtime, compared to the maximal evolution time and the total evolution time respectively.

D.2 Quantum phase estimation

We then analyze the circuit depth and total runtime requirement for estimating the ground state energy with QPE, where the time evolution is performed using Trotter formulas. We analyze the multi-ancilla qubit version of QPE and the result is equally valid for the single-ancilla qubit version using semi-classical Fourier transform.

In QPE, when we replace all exact time evolution with $U_{\text{HS}}$, we would like to ensure that the probability of obtaining an energy measurement close to the ground state energy remains bounded away from 0 by $\Omega(\eta)$. Therefore the probability distribution of the final measurement outcome should be at most $O(\eta)$ away from the original distribution in terms of the total variation distance.

Because the only part of QPE that depends on the time evolution operator is the multiply-controlled unitary

$$\sum_{j=0}^{J-1} |j\rangle \langle j| \otimes e^{-ij\tau H},$$

which is replaced by

$$\sum_{j=0}^{J-1} |j\rangle \langle j| \otimes U_{\text{HS}}^j$$

when we use Trotter formulas, we only need to ensure the difference between the two operators to be upper bounded by $O(\eta)$ in terms of operator norm. Therefore we need

$$J ||e^{-i\tau H} - U_{\text{HS}}|| = O(\eta).$$

23
As discussed in Section 1.1, we need to choose 

$$J = \mathcal{O}(\tau^{-1}\epsilon^{-1}\eta^{-1})$$

(we need the \(\tau^{-1}\) factor to account for rescaling \(H\), and \(p_0\) in Section 1.1 is replaced by \(\eta\)). Following the same analysis as in the previous section, we need to choose the number of Trotter steps for approximating \(e^{-\tau H}\) to be

$$r = \max\{1, \mathcal{O}(J^{1/p}\eta^{-1/p}C_{\text{Trotter}}^{1/p}\tau^{1+1/p})\}$$

Therefore the circuit depth needed is

$$J_r = \mathcal{O}(\max\{\tau^{-1}\epsilon^{-1}\eta^{-1}, \epsilon^{-1-1/p}\eta^{-1-2/p}C_{\text{Trotter}}^{1/p}\})$$

(35)

and the total runtime is

$$\mathcal{O}(\max\{\tau^{-1}\epsilon^{-1}\eta^{-2}, \epsilon^{-1-1/p}\eta^{-2-2/p}C_{\text{Trotter}}^{1/p}\})$$

(36)

Again, if we fix \(H\) and let \(\epsilon, \eta \to 0\), then we can see this gives us an extra \(\epsilon^{-1/p}\eta^{-2/p}\) factor in the circuit depth and total runtime, compared to the maximal evolution time and the total evolution time respectively. This is worse by a factor of \(\eta^{-1/p}\) than the cost using our algorithm.

**E Details on the numerical experiments**

In Figure 3 we apply the procedure described in Section 3 to approximate the CDF of the Fermi-Hubbard model, described by the Hamiltonian

$$H = -t \sum_{\langle j,j' \rangle, \sigma} c_{j,\sigma}^\dagger c_{j',\sigma} + U \sum_j \left(n_{j,\uparrow} - \frac{1}{2}\right) \left(n_{j,\downarrow} - \frac{1}{2}\right),$$

(37)

where \(c_{j,\sigma}\) (\(c_{j,\sigma}^\dagger\)) denotes the fermionic annihilation (creation) operator on the site \(j\) with spin \(\sigma \in \{\uparrow, \downarrow\}\). \(\langle \cdot, \cdot \rangle\) denotes sites that are adjacent to each other. \(n_{j,\sigma} = c_{j,\sigma}^\dagger c_{j,\sigma}\) is the number operator. The sites are arranged into a one-dimensional chain, with open boundary condition.

We first evaluate \(\bar{G}(x)\) defined in (15), and the result is shown in Figure 3. We use a classical computer to simulate the sampling from the quantum circuit. The initial state \(\rho\) is chosen to be the Hartree-Fock solution, which has an overlap of around 0.43 with the exact ground state, even when \(U/t = 10\) is in the strong correlation regime. We can see that \(\bar{G}(x)\) closely follows the CDF, and even though there is significant noise from Monte Carlo sampling, the jump corresponding to the ground state energy is clearly resolved.

Then we consider estimating the ground state energy from \(\bar{G}(x)\). In this numerical experiment we use a heuristic approach, and the rigorous approach that comes with provable error bound and confidence level is discussed in Sections 4 and 5. We obtain the estimate by

$$x^* = \inf\{x : \bar{G}(x) \geq p_0/2\},$$

and \(x^*/\tau\) is an estimate for the ground state energy \(\lambda_0\). We expect \(x^* \in [\tau\lambda_0 - \delta, \tau\lambda_0 + \delta]\). In the above equation we used \(p_0/2\) but in practice we can replace this by any number between 0 and \(p_0\), as long as it is sufficiently far away from 0 and \(p_0\) to account for the approximation and sampling errors.

The error of the estimated ground state energy, the total evolution time, and the maximal evolution time are shown in Figure 4, in which we have chosen \(U/t = 4\) for the Hubbard model. In the right panel of Figure 4 we can see the line for total evolution time runs parallel to the line for the maximal evolution time. Because the maximal evolution time scales linearly with respect to \(\delta^{-1}\), and this plot uses logarithmic scales for both axes, we can see the total evolution time has a \(\delta^{-1}\) scaling, and is therefore inversely proportional to the allowed error of ground state energy estimation.
