(Dated: June 15, 2021)

This study evaluates data-driven models from a dynamical system perspective, such as unstable fixed points, periodic orbits, chaotic saddle, Lyapunov exponents, manifold structures, and statistical values. We find that these dynamical characteristics can be reconstructed much more precisely by a data-driven model than by computing directly from training data. With this idea, we predict the laminar lasting time distribution of a particular macroscopic variable of chaotic fluid flow, which cannot be calculated from a direct numerical simulation of the Navier–Stokes equation because of its high computational cost.

INTRODUCTION.

Reservoir computing, a brain-inspired machine-learning technique that employs a data-driven dynamical system, is effective in predicting time series and frequency spectra in chaotic behaviors, including fluid flow and global atmospheric dynamics [1–10]. Pathak et al. [3] examined the Lorenz system and the Kuramoto–Sivashinsky system and reported that the data-driven model obtained from reservoir computing could generate an arbitrarily long time series that mimics the dynamics of the original systems.

The extent to which a data-driven model using reservoir computing can capture the dynamical properties of original systems should be determined. Lu et al. [11] reported that a data-driven model has an attractor similar to that of the original system under an appropriate choice of parameters. Nakai and Saiki [12] confirmed that a single data-driven model could infer the time series of chaotic fluid flow from various initial conditions. Zhu et al. [13] identified some unstable periodic orbits of a data-driven model through delayed feedback control. They suggested that a data-driven model could reconstruct the attractor of the original dynamical system.

This paper clarifies that a data-driven model using reservoir computing has richer information than that obtained from a training data, especially from dynamical system point of view, suggesting that dynamical properties of the original unknown dynamical system can be estimated by reservoir computing from a relatively short time series. Besides the invariant sets, such as fixed points and periodic orbits, the dynamical properties, such as Lyapunov exponents and manifold structures between stable and unstable manifolds, can be reconstructed by the data-driven model through reservoir computing, even if the system does not have structural stability.

We mainly deal with the Lorenz system [14]:

\[
\begin{align*}
\frac{dx}{dt} &= 10(y - x), \\
\frac{dy}{dt} &= rx - y - xz, \\
\frac{dz}{dt} &= xy - \frac{8}{3}z,
\end{align*}
\]

(1)

and will be denoted as the actual Lorenz system in this paper. A data-driven model is constructed from a short time training data created from (1), the method of which is explained later. Two different parameter values of \( r \) are considered. One of the parameters \( (r = 28) \) has hyperbolic dynamics, whereas the other \( (r = 60) \) generates dynamics with tangencies between stable and unstable manifolds [15]. The latter property is one of the two primary sources for the breaking structural stability [16], which often appears in the real-world physical phenomena. As an application of the obtained knowledge, this study examines high-dimensional chaotic fluid flow to determine if the laminar lasting time distribution can be predicted using the data-driven model constructed from short training time-series data.

RESERVOIR COMPUTING.

A reservoir is a recurrent neural network whose internal parameters are not adjusted to fit the data in the training process [17, 18]. The reservoir can be trained by feeding it an input time series and fitting a linear function of the reservoir state vector to the desired output time series. We do not use a physical knowledge in constructing a model. The data-driven model using reservoir computing
we study is the following:

\[
\begin{align*}
    \mathbf{u}(t) &= \mathbf{W}_{\text{out}}^* \mathbf{r}(t), \\
    \mathbf{r}(t + \Delta t) &= (1 - \alpha) \mathbf{r}(t) + \alpha \tanh(\mathbf{A} \mathbf{r}(t) + \mathbf{W}_{\text{in}} \mathbf{u}(t)),
\end{align*}
\]

(2)

where \( \mathbf{u}(t) \in \mathbb{R}^M \) is a vector-valued variable, the component of which is denoted as an output variable; \( \mathbf{r}(t) \in \mathbb{R}^N \) \((N \gg M)\) is a reservoir state vector; \( \mathbf{A} \in \mathbb{R}^{N \times N} \), \( \mathbf{W}_{\text{in}} \in \mathbb{R}^{N \times M} \), and \( \mathbf{W}_{\text{out}}^* \in \mathbb{R}^{M \times N} \) are matrices; \( \alpha \) \((0 < \alpha \leq 1)\) is a coefficient; \( \Delta t \) is a time step. We define \( \tanh(\mathbf{q}) = (\tanh(q_1), \tanh(q_2), \ldots, \tanh(q_N))^T \), for a vector \( \mathbf{q} = (q_1, q_2, \ldots, q_N)^T \), where \( T \) represents the transpose of a vector.

We explain how to determine \( \mathbf{W}_{\text{out}}^* \) in (2). Time development of the reservoir state vector \( \mathbf{r}(l \Delta t) \) are determined by

\[
\mathbf{r}(t + \Delta t) = (1 - \alpha) \mathbf{r}(t) + \alpha \tanh(\mathbf{A} \mathbf{r}(t) + \mathbf{W}_{\text{in}} \mathbf{u}(t)),
\]

(3)
together with training time-series data \( \{\mathbf{u}(l \Delta t)\} \)\((L_0 \leq l \leq L)\), where \( L_0 \) is the transient time and \( L \) is the time length to determine \( \mathbf{W}_{\text{out}} \). For given random matrices \( \mathbf{A} \) and \( \mathbf{W}_{\text{in}} \), we determine \( \mathbf{W}_{\text{out}} \) so that the following quadratic form takes the minimum:

\[
\sum_{l=0}^{L} \| \mathbf{W}_{\text{out}} \mathbf{r}(l \Delta t) - \mathbf{u}(l + 1 \Delta t) \|^2 + \beta |T(\mathbf{W}_{\text{out}}^T \mathbf{W}_{\text{out}})|,
\]

(4)

where \( \| \mathbf{q} \|^2 = \mathbf{q}^T \mathbf{q} \) for a vector \( \mathbf{q} \). The minimizer is

\[
\mathbf{W}_{\text{out}}^* = \delta \mathbf{U} \delta \mathbf{R}^T (\delta \mathbf{R} \delta \mathbf{R}^T + \beta \mathbf{I})^{-1},
\]

(5)

where \( \mathbf{I} \) is the \( N \times N \) identity matrix, \( \delta \mathbf{R} \) (respectively, \( \delta \mathbf{U} \)) is the matrix whose \( l \)-th column is \( \mathbf{r}(l \Delta t) \) (respectively, \( \mathbf{u}(l \Delta t) \)). (see \[19\] P.140 and \[20\] Chapter 1 for details).

Note that \( \mathbf{A} \) is chosen to have a maximum eigenvalue \( \rho \) \((|\rho| < 1)\) in order for (3) to satisfy so called echo state property. It is known that adding noise to the training time-series data can be useful in the construction of a data-driven model \[2\]. More details about the reservoir computing can be found elsewhere \[3, 4\].

FIG. 1. Poincaré section-like plots \((r = 28\) (left) and 60 (right))\). The sets of points \((x, z)\): along a trajectory of the data-driven model using reservoir computing and along a long trajectory of the actual Lorenz system and along a short trajectory used for the training data are plotted when \( |x - y| < \epsilon_p \), where \( \epsilon_p = 0.05 \). The time lengths of the three trajectories are \( T = 10^6 \), \( 10^6 \), and \( 5000 \), respectively.

LORENZ SYSTEM

In this paper we evaluate a data-driven model \( (2) \) constructed using short training time series data from a dynamical system perspective. The main focus is on the properties in the space of output variables (corresponding to \( x \), \( y \) and \( z \) for the case of the Lorenz system), which compare them with those of the actual system. The sets of parameter values used to construct the data-driven model are shown in Table 1.

Poincaré section-like plots. The Poincaré section of the data-driven model of the Lorenz system has been studied \[3\]. We compare the shape and size of the attractor of a data-driven model \( (2) \) with those of the attractor of the actual Lorenz system \( (1) \), and also with those of the set of points along the training time series data. Figure 1 presents their Poincaré section-like plots for \( r = 28 \) and 60. For each of the two parameter cases, a set of trajectory points generated from the data-driven model...
The density distribution of the $x$ variable along a trajectory of the data-driven model (top) and the corresponding unstable fixed points of the actual Lorenz system (bottom) are plotted together with trajectory points with the time length $T = 10^6$. The three fixed points of the data-driven model are close to those of the actual Lorenz system, despite the fixed points being outside the training data, which is part of the actual trajectory. See the coordinates and the eigenvalues of the Jacobian matrix at each fixed point in Table II.

FIG. 2. Density distributions of a variable ($r = 28$ (top) and $r = 60$ (bottom)). The density distribution of the $x$ variable calculated from a length $T = 10^6$ trajectory of the data-driven model by reservoir computing ($\Phi_{\text{res}}$) is plotted together with that computed from the length $T = 10^6$ long trajectory of the actual Lorenz system ($\Phi_{\text{act}}$) and with that computed from the length $T = 5000$ short trajectory ($\Phi_{\text{tra}}$) used as training data for constructing the data-driven model. Here the length $T = 10^6$ long trajectory is used to obtain a distribution which approximates the limiting distribution. The difference in the distributions are shown on the right. The average $\Sigma$ and the standard deviation $\sigma$ of the density distribution are as follows; $(\Sigma, \sigma) = (-0.004, 7.924)$ for the data-driven model, and $(0.009, 7.925)$ for the Lorenz system with $r = 28$; $(\Sigma, \sigma) = (-0.018, 12.092)$ for the data-driven model, and $(-0.018, 12.091)$ for the Lorenz system with $r = 60$. $\int |\Phi_{\text{res}} - \Phi_{\text{act}}| dx / \int |\Phi_{\text{tra}} - \Phi_{\text{act}}| dx \approx 1/8$ for $r = 28$, and $\approx 1/6$ for $r = 60$.

FIG. 3. Fixed points. The three fixed points $(x^*, y^*, z^*)$ of the data-driven model (left) and the corresponding unstable fixed points of the actual Lorenz system (right) are plotted together with trajectory points with the time length $T = 10^6$. The three fixed points of the data-driven model are close to those of the actual Lorenz system, despite the fixed points being outside the training data, which is part of the actual trajectory. See the coordinates and the eigenvalues of the Jacobian matrix at each fixed point in Table II.

seem to coincide with the chaotic attractor of the actual Lorenz system. Furthermore, the data-driven model has an attractor which is significantly larger than the set of training data used to construct the model.

Density distribution. The density distribution of $x$ variable along a trajectory of the data-driven model is presented in Fig. 2. We compare the distribution with that obtained from the trajectory of the actual Lorenz system and that calculated directly from the training data. The distribution of the actual Lorenz system can be captured by employing the data-driven model. Remarkably, the distribution with a singular structure in $r = 60$ can be recovered using the data-driven model.

Fixed points and their stabilities. Fixed points, which are fundamental structures of dynamical systems, are examined. We identify fixed points in the space of the output variables directly, even though they were identified through the fixed points in the space of the reservoir state vector using the directional fibers method [22]. We also study the stability of each unstable fixed point in the space of output variables. For the data-driven model we consider a point $x^* = (x^*, y^*, z^*)$ as a fixed point, when the following condition is satisfied: $\delta = \max_{\epsilon \in [0, n_0]} ||x^* - \psi_{x^*}(n\Delta t)||/\epsilon < \epsilon_0$ for some $\epsilon_0$ sufficiently small and for some $n_0$ sufficiently large, where $\psi_{x^*}(n\Delta t)$ is the point iterated $n$ times from $x^*$ by the data-driven model with the time step $\Delta t$. For the computation of a trajectory from a given point $x^*$ of the data-driven model, reservoir state vector $r(0)$ is determined to correspond to $x^*$ by the pre-iterates. The echo state property in which our choice of parameters in the data-driven model (2) is satisfied guarantees that for each $x^*$, the corresponding reservoir state vector is determined uniquely. Table II lists the obtained coordinates of the three fixed points, $L_{\text{res}}$, $R_{\text{res}}$ and $O_{\text{res}}$, together with those of the actual Lorenz system. We fix $(\epsilon_0, n_0) = (0.01, 10000)$ for $L_{\text{res}}$ and $R_{\text{res}}$, and $(\epsilon_0, n_0) = (1, 30)$ for $O_{\text{res}}$. Figure 3 shows the fixed points together with the trajectory points. Table II also lists the eigenvalues of the Jacobian matrix at each fixed point. The values are obtained from the estimated formula of the Jacobian matrix described later for calculating the Lyapunov exponents and vectors.

Periodic trajectory. Periodic orbits are also the fundamental structures of dynamical systems. We confirm that the data-driven model of discrete time has a periodic orbit-like trajectory that travels near the corresponding periodic orbit of the actual Lorenz system of continuous time. We call $\{\psi_{x(0)}(n\Delta t)\}_{n \in [0, n_0]}$ a periodic orbit-like trajectory, if the following value is sufficiently small for a periodic trajectory $\{x(t)\}$ of period $T_p$.

TABLE II. Coordinates and eigenvalues of the Jacobian matrix at each of the three unstable fixed points. $L_{\text{res}}$, $R_{\text{res}}$, and $O_{\text{res}}$ are fixed points of the data-driven model, whereas $L_{\text{actual}}$, $R_{\text{actual}}$, and $O_{\text{actual}}$ are fixed points of the actual Lorenz system with $r = 28$. The coordinates ($x^*$, $y^*$, $z^*$) and the eigenvalues ($\Lambda_1, \Lambda_2, \Lambda_3$) of the Jacobian matrix at each fixed point of the data-driven model are close to those of the corresponding fixed point of the actual Lorenz system.

![Figure 4. A periodic orbit-like trajectory.](image)

A periodic orbit-like trajectory obtained from the data-driven model is plotted together with the corresponding unstable periodic orbit (period $T_p = 5.9973192969$) of the actual Lorenz system with $r = 28$ (left), and their time developments of the $x$ variable (right).

Lyapunov exponents and Lyapunov vectors. The Lyapunov exponents are used to evaluate the degree of instability and estimate the Lyapunov dimension of a dynamical system. In some studies, the Lyapunov exponents of a data-driven model by reservoir computing were calculated in the space of output variables corresponding to $x, y$ and $z$ for the Lorenz system. Here we describe how to compute Lyapunov exponents and vectors in the original variables numerically from a trajectory of the data-driven model. We first estimate the Jacobian matrix at each point $(x, y, z)$ along the trajectory of the data-driven model as follows: (i) Apply the Taylor series expansion of order six to estimate $\dot{x} = dx/dt$, $\dot{y} = dy/dt$ and $\dot{z} = dz/dt$ at each sample point along the discrete trajectory; (ii) Apply linear regression to the estimated values of $\dot{x}$, $\dot{y}$ and $\dot{z}$ by $x^t y^m z^n$ ($0 \leq l + m + n \leq 3, l, m, n \geq 0$) as explanatory variables; (iii) Obtain the Jacobian matrix $J(x)$ at each point $x$ by differentiating polynomials with the regression coefficients estimated in (ii).

We compute Lyapunov exponents and vectors by integrating the linear ordinary differential equation having coefficients determined by the Jacobian matrices ($\dot{x}(t) = J(x(t))x(t)$), while the orbit is given by the trajectory of the data-driven model. Note that in this computation the discrete time trajectory points of a data-driven model are considered samples of the continuous time trajectory. For the high-accuracy computation with a rather large time step $\Delta t = 0.05$ of the reservoir computing, we employ four-stage and fourth-order Runge-Kutta method with time step $2\Delta t$ from the points along an orbit trajectory.

The results are compared with those of the actual Lorenz system [1] for two sets of parameters. Table III shows the agreement of the Lyapunov exponents and the Lyapunov dimensions. We also compute (co-variant) Lyapunov vectors, which measure the degree of hyperbolicity by calculating the angle between the stable and unstable manifolds at some trajectory point [20].

Manifold structure and Tangency. Using the computed Lyapunov vectors we investigate the manifold structures of the data-driven model, particularly the degree of hyperbolicity and the tangencies between the stable and unstable manifolds. We consider the Lorenz system of $r = 28$ without tangencies and of $r = 60$ with tangencies for the comparison [13]. Figure 4 shows the probability density function of an angle between a tan-
TABLE III. Lyapunov exponents and Lyapunov dimensions. Lyapunov exponents of the data-driven model using reservoir computing \((\lambda^{(1)}_{\text{res}},\lambda^{(2)}_{\text{res}},\lambda^{(3)}_{\text{res}})\) and those of the actual Lorenz system \((\lambda^{(1)}_{\text{actual}},\lambda^{(2)}_{\text{actual}},\lambda^{(3)}_{\text{actual}})\) are listed. The values are computed using the four-stage and fourth-order Runge–Kutta method with time step \(2\Delta t\) from the points along an orbit trajectory and the estimated Jacobian matrices. The Lyapunov dimensions \(D^\text{KY}_\text{res}\) for the data-driven model and \(D^\text{KY}_\text{actual}\) for the actual Lorenz system are estimated from the Kaplan–Yorke formula [23].

FIG. 5. Distribution of the angle between stable and unstable manifolds along a trajectory \((r = 28\) (left) and \(r = 60\) (right)). The density distribution of the manifold angles (degree) at points along a trajectory is shown for a data-driven model using reservoir computing together with that of the actual Lorenz system.

gent vector of a stable manifold and that of an unstable manifold along an orbit trajectory for each of the actual system and the data-driven model. For each case of the parameters, \(r = 28\) and \(r = 60\), the angle distributions are quite similar in shape, indicating that the data-driven model can reconstruct the manifold structures. Moreover, Fig. 5 (right) suggests that the data-driven model can represent a non-hyperbolic structure with tangencies between stable and unstable manifolds.

CHAOTIC FLUID FLOW.

Laminar lasting time distribution of chaotic fluid flow. For the Lorenz system we have clarified that hyperbolic fixed points and their eigenvalues are estimated in high accuracy by constructing a data-driven model using reservoir computing, even if the training time-series data are far away from the fixed points. We study a chaotic flow in macroscopic variables whose behavior has a random switching between laminar and bursting states. Here we consider the set of laminar state as a certain chaotic saddle and compute the lasting time distribution staying in the neighborhood of it. We are interested in the lasting time distribution where an or-
putation. The Navier–Stokes equation is calculated by 13718 dimensional ODEs with the 4-stage Runge–Kutta method (time step 0.05), whereas the model is calculated by 5000 dimensional map whose iterate corresponds to the time step 2.

**CONCLUDING REMARKS.**

We have clarified by employing the time-series of the Lorenz system that a data-driven model using reservoir computing has quite similar dynamical system properties to those of the original Lorenz system, such as fixed points and their eigenvalues, periodic orbits, Lyapunov exponents and Lyapunov vectors. It should be remarked that the fixed points exist far away from the training time-series data, but the corresponding points are found to exist nearby the original ones in the data-driven model. We have also shown that the negative Lyapunov exponent computed not in the space of the reservoir state vector but in the space of output variables, and the degree of hyperbolicity measured by the angle between stable and unstable manifolds are shown to be quite similar to those of the original system.

We confirmed that qualitatively the same results are obtained for the Rössler system [27]. The fixed point far outside the set of training time-series data is identified from the data-driven model using reservoir computing, and periodic orbit-like trajectories corresponding to the periodic orbits of the original Rössler system exist in the data-driven model. The Lyapunov exponents including the negative one are confirmed to have a good agreement with those of the original system.

For a chaotic fluid flow we computed the lasting time distribution staying in the neighborhood of a certain chaotic saddle showing laminar behavior by using the data-driven model. The model is constructed from a relatively short time-series data created from the direct numerical simulation of the Navier–Stokes equation. The obtained distribution cannot be computed from the direct computation of the Navier–Stokes equation because of its high computational cost. This result implies that a chaotic saddle can be reconstructed by the data-driven model.
