(Dated: February 2021)

Previously, it has been shown that rapid cooling of yttrium-iron-garnet/platinum (Pt) nanostructures, preheated by an electric current sent through the Pt layer leads to overpopulation of a magnon gas and to subsequent formation of a Bose-Einstein condensate (BEC) of magnons. The spin Hall effect (SHE), which creates a spin-polarized current in the Pt layer, can inject or annihilate magnons depending on the electric current and applied field orientations. Here we demonstrate that the injection or annihilation of magnons via the SHE can prevent or promote the formation of a rapid cooling induced magnon BEC. Depending on the current polarity, a change in the BEC threshold of -8% and +6% was detected. These findings demonstrate a new method to control macroscopic quantum states, paving the way for their application in spintronic devices.

The formation of a Bose-Einstein condensate (BEC) can be achieved by a decrease in the temperature for real-particle systems [1], or in a quasi-particle system by the injection of bosons resulting in an increase in the chemical potential. The latter has been demonstrated experimentally for exciton-polaritons [2, 3], photons [4, 5] or magnons [6–12]. In the case of magnonic systems the injection was realised by the parametric pumping mechanism [9–11, 13], allowing for the injection of a large number of magnons at a given frequency, via the spin-Seebeck effect [14] or by the mechanism of rapid cooling, as it was shown recently [15]. The method of rapid cooling makes use of the application of a DC heating pulse and the subsequent rapid cooling of yttrium iron garnet (YIG)/Pt nano structures. The heating generates a high population of magnons being in thermal equilibrium with the phononic system. A rapid decrease in the phononic temperature results in the break of the equilibrium. Since the lifetime of magnons is larger than the phonon cooling rate in the experiment an overpopulation of magnons over the whole magnon spectrum is generated. This overpopulation results in a redistribution of magnons from higher to lower energies. In this way, if the temperature of the heated YIG film is high enough and the cooling process is fast enough, the magnon chemical potential is increased to the minimal energy of the magnon system and the BEC formation process is triggered.

In the previous experiments, a Pt or Al layer was used to heat the YIG nano structure [15]. For a Pt heater an additional generation of a spin-polarized current transverse to the YIG/Pt interface due to the spin Hall effect (SHE) is expected [16–19]. The resulting spin current is known to act on the magnetization dynamics in the YIG via the spin transfer torque (STT) [20–25]. The SHE-STT contribution, which can be easily checked by the variation of the current polarity with respect to the magnetization orientation in the YIG film [22], was not observed in the original experiments [15]. The reason was the large YIG film thickness of 70 nm (STT is an interface effect) and the high quality of the Pt layer grown by molecular beam epitaxy that results in a small spin Hall angle [26].

Here, we investigate a similar structure but with a smaller YIG film thickness of 34 nm [27] and with the Pt layer deposited by a sputtering technique to achieve a pronounced SHE-STT effect. Using such YIG nano structures, we are now able to investigate the influence of the SHE-STT effect on the formation of the magnon BEC by rapid cooling. We show that the magnons annihilated or injected by the STT effect while the current pulse is applied, strongly influence the threshold of the BEC formation.

Figure 1 shows the structure under investigation and a sketch of the experimental setup. The structure consists of a 2-μm-wide YIG/Pt stripe (34 nm/7 nm) on a (111) gadolinium gallium garnet (GGG) substrate. The YIG structure was fabricated using electron-beam lithography with subsequent argon-ion milling [28]. Afterwards a 3-μm-long Pt layer was deposited on the waveguide using a RF-sputtering technique. To establish electrical contacts to the platinum pads, Ti/Au-leads (10 nm/150 nm) with a distance of 2 μm between the inner edges were fabricated by electron beam evaporation. In the presented experiments DC pulses of a duration of τp = 100 ns are applied to the Pt pad. Standard ferromagnetic resonance (FMR) measurements were performed on two reference pads on the same sample, one bare and one covered with platinum. These yielded Gilbert-damping-constants of αYIG = 1.8 × 10−4 for the bare YIG pad and αYIG|Pt = 1.7 × 10−3 for the YIG/Pt pad, corresponding to a spin mixing conductance of g∥ = 5.1 × 1018 m−2 [29]. The magnetization dynamics is measured by means
of Brillouin light scattering spectroscopy (BLS). A laser beam with 457 nm wavelength and 5.0 ± 0.5 mW power is focused onto the YIG waveguide through the backside of the transparent GGG substrate, allowing to measure below the platinum-covered YIG region [28]. The inelastically scattered light, carrying the information about the magnon intensity and frequency, is analyzed by a multi-pass tandem Fabry-Pérot interferometer with a time resolution of about 2 ns [15, 30]. The laser focus was scanned along the platinum layer between the two contact pads on a line in the middle of the stripe (see scan line indicated in Fig. 1). The resulting BLS signal was integrated along this scan line to reduce any influence of an inhomogeneous heating of the platinum region on the experimental results.

Figures 2(a-c) show the measured color-coded BLS intensities (log-scale) as a function of time and the BLS frequency. The amplitude of the applied DC heating pulse is \(|U| = 1.5\, V\), corresponding to a current density of \(|j_C| = 1.6 \times 10^{12}\, A\, m^{-2}\).

Figure 2(a) shows the reference experiment with an external field \(\mu_0 H\) aligned parallel to the long axis of the waveguide, parallel to the direction of the current \(j_C\) (\(\mu_0 H_{\text{ext}} \parallel j_C\)). In this geometry, no contribution of the SHE-STT effect is expected and the application of the current pulse only results in a Joule heating-induced increase of the YIG/Pt temperature. While the DC pulse is applied (black box in the figure), the BLS intensity decreases, as originally investigated in Ref. [31]. Further, the spectrum of thermal magnons shifts to lower frequencies due to the decrease in the saturation magnetization [15, 32]. After the DC pulse is switched off at \(t = 100\, ns\), the heat-dissipation-induced rapid cooling triggers the formation of the BEC at the bottom of the spectrum [15]. The BEC manifests itself as a pronounced peak in the magnon intensity. The accompanying frequency increase is due to the cooling.

The contribution of the SHE can be switched on by rotating the magnetic field by 90°, hence pointing along the short axis of the stripe [see insets in Figs. 2(b,c)], i.e. perpendicular to the direction of the DC current [22].

In this geometry the SHE-STT contribution can be damping- or anti-damping like [16, 33]. The change in the effective damping can also be described by the annihilation or injection of magnons [22], or by the change in the magnon chemical potential \(\mu\) [17, 21]. In the case without a STT-contribution [Fig. 2(a), pulse duration of \(\tau_P = 100\, ns\) and a voltage of \(U = 1.5\, V\)], the magnon and the phonon system are in thermal equilibrium at the end of the DC heating pulse, and both are highly populated. The SHE-STT contribution increases or decreases the number of magnons at the end of the pulse with respect to the reference case. Thus, the SHE-STT is expected to change the BEC formation via a change of the number and distribution of excess magnons prior to the rapid cooling process [15].

Figures 2(b) and (c) depict the cases for a magnon annihilation and a magnon injection via the SHE-STT effect, respectively. The injection or annihilation of magnons via the SHE-STT mechanism can be seen by an increased or decreased BLS intensity during the DC pulse.

The magnon annihilation process [Fig. 2(b)], in contrast to experiments on thicker YIG micro structures used previously [15], is now large enough to compensate for the rapid cooling-induced increase of the chemical potential \(\mu\), thus suppressing BEC formation.

In the case of the SHE-STT-induced magnon injection process [Fig. 2(c)], \(j_{C,x} < 0, \mu \mu_0 H_{\text{ext}} \parallel j_C\) the SHE-STT effect enhances the magnon redistribution, which is manifested by the even higher BLS intensity measured after the DC pulse, compared to Fig. 2(a).

For a better comparison of the three cases described above, Figs. 2(d,e) depict the extracted BLS spectra at the time frames marked in Figs. 2(a-c). The BLS intensity during the pulse duration for the STT injecting magnons [dashed red line in Fig. 2(d)] is more than one magnitude larger compared to the case without a SHE-STT contribution [black curve in Fig. 2(d)]. The increase in intensity is observed although the BLS sensitivity is significantly decreased at higher temperatures [31]. In addition, in the case of a SHE-STT induced magnon an-

FIG. 1. Colored scanning-electron microscopy-image of the structure under investigation and sketch of the experimental setup. The structure consists of a 2-\(\mu m\)-wide and 34-nm-thick YIG stripe. A 3-\(\mu m\)-long and 7-nm-thick platinum-heater is placed on top and contacted by Ti/Au-leads separated by a distance of 2 \(\mu m\).
nihilation [solid red line in Fig. 2(d)], the BLS intensity seems to be decreased compared to the case without SHE-STT contribution [black line in Fig. 2(d)]. In addition, a large shift of the magnon frequency is observed for an SHE-STT-injection with respect to the non-heated, thermal spectra [filled curves in Fig. 2(d), for two different directions of $\mu_0 H_{ext}$, which is in the range of $\Delta f = 1$ GHz. The shift is caused by the decrease in saturation magnetization due to the large number of magnons injected via the SHE-STT mechanism.

Note that a purely thermal excitation of magnons takes place over the whole spectral range [Fig. 2(a), black solid line in Fig. 2(d)]. The subsequent decrease of the saturation magnetization leads to a decrease in the BLS intensity [31]. In contrast, for a STT-injection of magnons the BLS intensity increases [Fig. 2(c), red dashed line in Fig. 2(d)], in spite of the heating-induced decrease of the BLS sensitivity (which does not depend on the field orientation). The reduction of the BLS sensitivity is given by the decrease in the saturation magnetization that can be treated as a thermally-induced increase of the number of magnons over the whole magnon spectrum [34]. Thus, the fact that the BLS intensity in Fig. 2(c) increases rather than decreases during the heating process suggests that the SHE-STT mechanism injects magnons primarily into the low energy part of the spectrum accessible with micro focused BLS.

Figure 2(e) depicts the spectra after pulse termination during the rapid cooling process. It can be seen, that the STT-annihilation of magnons suppresses the BEC formation, the rapid cooling process causes only a minor increase of the BLS intensity (compare the solid red line with the thermal spectrum for the same geometry, grey filled curve). The SHE-STT driven injection of magnons (red dashed line) causes a larger BLS intensity compared to the case without a SHE-STT contribution (black dashed line).

The presented results in Fig. 2 show that the SHE-STT effect can control the BEC formation process via the injection or annihilation of magnons. To investigate the threshold of the BEC formation process in the presence of the SHE-STT effect, we first characterize the state of the magnon system right before the cooling takes place.

Figure 3(a) shows the inverse BLS intensity as a func-
the case when the STT effect annihilates magnons (a decreased spin mixing conductance due to the heating of the BLS intensity decreases again, which is attributed to the STT-injection. This BLS intensity at the end of the pulse is switched off (\(\tau_p < t < \tau_p + 95\) ns) as a function of the absolute value of the voltage. The blue curves correspond to the situation in (b), the black curves show the reference curve for \(\mu_0 H_{\text{ext}} \parallel j_c\), without a SHE-STT contribution. (d) Integrated intensity as in (c), the residual signal caused by the decaying STT-injected magnons is subtracted. Due to the injection or annihilation of magnons via the STT the thresholds are shifted with respect to the case without a SHE-STT contribution (pink line).

Figure 3(c) shows the BLS intensity after the pulse is switched off, integrated in the time interval \(\tau_p < t < \tau_p + 95\) ns. As a reference, the black curves show the integrated BLS intensities without a SHE-STT contribution \((\mu_0 H_{\text{ext}} \parallel j_c)\). These two curves (positive and negative current polarity) show a sudden increase at a voltage of \(U = 1.42\) V, which is the threshold of the BEC formation without a SHE-STT contribution. For the case of a STT-annihilation (bright blue graph) a pronounced threshold at a higher voltage of \(U = 1.51\) V is observed.

In the case of STT-injection, the BLS intensity after termination of the pulse (dark blue curve) is the interplay of the rapid cooling induced magnon redistribution and the (decaying) STT-injected magnons during the pulse. To investigate if these two contributions are a linear superposition or if the SHE-STT effect driven injection influences the redistribution process, we need to subtract the intensity originating from an exponential decay of the STT-injected magnons. This intensity can be derived as \(I_{\text{STT}}(t) = I_{\text{STT}} \exp[-2(t - \tau_p)/\tau_m]\), where \(I_{\text{STT}}\) is the intensity at the end of the pulse \(\int_{t=\tau_p}^{t+95}\) as a function of the applied voltage yields threshold information.

In the case of STT-injection, the BLS intensity after termination of the pulse (dark blue curve) is the interplay of the rapid cooling induced magnon redistribution and the (decaying) STT-injected magnons during the pulse. To investigate if these two contributions are a linear superposition or if the SHE-STT effect driven injection influences the redistribution process, we need to subtract the intensity originating from an exponential decay of the STT-injected magnons. This intensity can be derived as \(I_{\text{STT}}(t) = I_{\text{STT}} \exp[-2(t - \tau_p)/\tau_m]\), where \(I_{\text{STT}}\) is the intensity at the end of the pulse \(\int_{t=\tau_p}^{t+95}\) as a function of the applied voltage yields threshold information.
Thus, by using the starting intensity of the SHE-STT effect injected magnons we can calculate the expected magnon intensity after the pulse if no rapid cooling process would take place. The experimental BLS intensity after the pulse with the calculated STT-contribution subtracted is shown in Fig. 3(d). For $U > 1.30\, \text{V}$ we find that the intensity after the end of the pulse is larger than the intensity given by the finite lifetime of the STT-injected magnons. This lowest voltage that leads to an increase of the number of magnons above the STT-injected level is identified as the threshold of the BEC formation. In summary, the shift of the BEC formation threshold is from $U = 1.42\, \text{V}$ down to $1.30\, \text{V}$ or up to $U = 1.51\, \text{V}$, corresponding to a relative change of -8% or +6% respectively.

The decreasing intensity at higher voltages [$U > 1.65\, \text{V}$ in Fig. 3(c)] requires further investigations but might be attributed to the increased temperature of the YIG. At the time, at which the magnon BEC occurs, the YIG is not yet cooled down to room temperature. Thus, at higher voltages the temperature at that time is increased, resulting in a decrease of the BLS sensitivity. The difference in the BLS intensity after the pulse between the case of $j_{C,x} > 0$ and $j_{C,x} < 0$ decreases with higher voltages and vanishes for the highest voltages applied. The vanishing contribution of the SHE-STT at higher voltages $U > 1.8\, \text{V}$ is attributed to a decreasing spin mixing conductance with higher temperatures [35].

In conclusion, we found that the SHE-STT effect injects or annihilates magnons and, thus, shifts the threshold values for the rapid cooling-induced magnon BEC up to 8%. Utilizing the SHE-STT effect opens up opportunities for the control (triggering or suppression) of the magnon BEC formation when the applied voltage is close to the threshold value. The comparison between the magnon populations during the application of a DC pulse for the cases with and without a SHE-STT contribution has shown that the injection of magnons primarily takes place into the low energy part of the spectrum, and, thus, strongly promotes the formation of a rapid cooling induced magnon BEC. These findings suggest a new way to control the formation of a magnon BEC by the polarity of the applied current, paving the way for the utilization of macroscopic quantum states in spintronic devices.
