We report the observation of nonlinear Hall signal at zero magnetic field in the multilayered organic two-dimensional Dirac fermion system α-(BEDT-TTF)2I3 at a pressure just under the critical pressure for transition into massless Dirac fermion state. The square current dependence (rectification), the current-orientation dependence, and the temperature dependence related to the charge ordering suggest that the observed phenomena originate from the Berry curvature dipole in a gapped Dirac fermion system with tilted cones. Therefore, the presence of the nonlinear anomalous Hall effect indicates that the charge ordered state in the vicinity of the critical pressure is a massive Dirac fermion state.

Nonlinear conduction has attracted renewed interest due to the recently reported nonlinear anomalous Hall (NLAHE) in zero magnetic field condition in 3D Weyl fermion system WTe2 [1, 2]. Since then, it has been reported in other systems, such as bulk 3D Dirac semimetal Cd3As2 [3] and, more recently, in thin film of Weyl semimetal TaIrTe4 [4]. It has also been considered in p-doped trigonal Te crystal [5]. In particular, being a second order phenomenon, NLAHE exhibits rectification effect, which has recently been demonstrated with radiofrequency. NLAHE has also been proposed to probe electron-interaction driven quantum criticality involving inversion symmetry breaking in Dirac fermion (DF) system [6].

NLAHE in zero magnetic field condition was initially predicted by Sodemann and Fu by considering the effect of nonequilibrium distribution of electrons (current-carrying state) on the integral of the Berry curvature; thus, it is a current-induced phenomenon [7]. The system is assumed to be time-reversal invariant having Kramers pair states at general k and −k points in the momentum space, such that their Berry curvatures are related by Ω(k) = −Ω(−k). In such a system, the Berry curvature summed over the states around the chemical potential, also known as the Berry curvature dipole, must vanish in the equilibrium condition. However, in the nonequilibrium, the sum can be finite because the Kramers pair states at k and −k are not required to be equally occupied. In the latter case, electrons gain an anomalous velocity perpendicular to the applied electric field, similar to Hall effect even in the absence of magnetic field. NLAHE requires broken inversion symmetry, and should be more prominent in systems with tilted Dirac or Weyl cones. In bilayer or few-layer WTe2 [1, 2] and Cd3As2 [3], the inversion symmetry is broken by crystallographic consideration, but NLAHE should also occur in the case of phase transition involving removal of symmetry protection of the Dirac point, such as inversion symmetry breaking, which opens a gap at the Dirac point [6].

The system we are considering is organic conductor α-(BEDT-TTF)2I3, which is well recognized as a multilayer two-dimensional massless Dirac fermion system with a pair of tilted Dirac cones at high pressure [8]. At the ambient pressure, upon cooling, it initially shows metallic conduction, followed by a transition into an insulating state due to the formation of a horizontal stripe charge order (CO) at TCO = 135 K, as schematically shown in Fig. 1. In the metallic state the system is described by P1 space group, but in the CO state, the inversion symmetry is lost and the system belongs to P1 space group, creating two domains with different configurations of charge distribution [9, 10]. With increasing hydrostatic pressure, TCO decreases and, finally, above a critical pressure PC ≈ 1.3 GPa the system enters the

![FIG. 1. (Color online) Schematic phase diagram of α-(BEDT-TTF)2I3 constructed from resistivity measurements given in refs. [22] and [25]. Red diamonds indicate CO transition temperatures determined in the present work. Weak CO state is expected at the transition between the CO insulator and the massless DF states below the critical pressure, PC. massless DF state, where the transport shows a nearly temperature-independent, but metallic behavior.

The massless DF state at high pressure in \(\alpha-(BEDT-TTF)_{2}\)I\(_{3}\) has been firmly established. Theoretical work \([11-13]\) and experimental results confirm the gapless Dirac cones at high pressure. Interlayer magnetoresistance suggests the effect of zero mode Landau level characteristic to DF \([14-16]\). Specific heat exhibits the characteristic \(C \propto T^2\) associated with linear density of states \([17]\). Furthermore, site-selective NMR supports the tilting of Dirac cones \([18]\). In the massless DF phase just above the critical pressure, it was claimed that the Dirac cone slope decreases owing to electron correlation based on the magnetotransport in doped systems \([19]\). On the other hand, a recent magnetotransport study suggested the existence of massive DF state (weak CO) within the charge ordered state in the vicinity of the critical point \([20]\). Here, the weak CO state refers to a CO state having gapped, tilted Dirac cones with a finite Berry curvature. Optical study by Uykur et al., also demonstrated a frequency-dependent conductivity at intermediate pressure, which can be interpreted as Dirac electron with a pseudogap behavior \([21]\). More recently, it has been shown that the temperature dependence of the interlayer magnetoresistance features a peak structure, whose magnetic field dependence can only be reproduced when the massive DF state is taken into consideration \([22]\). We have previously considered the NLAHE in \(\alpha-(BEDT-TTF)_{2}\)I\(_{3}\) near the CO-massless DF transition, rectification effect, and estimated its magnitude to be in the observable range \([23]\). Hence, the purpose of this experiment is to directly verify the existence of the massive DF state in \(\alpha-(BEDT-TTF)_{2}\)I\(_{3}\) independent from calculation model.

In our experiment, a single crystal with a dimension of approximately \(0.56 \times 0.48 \times 0.04\) mm\(^3\) was used. Eight contacts were attached with carbon paint to perform current-direction dependence measurements (Fig. 2(a)), with contact numbering shown in Fig. 2(b). Since a whole crystal was used, the crystallographic axis can be determined from its shape \([24]\). The line connecting the corners with \(99^\circ\) angle is the direction of the crystallographic b-axis, as shown in Fig. 2(b). The a-axis direction is then almost parallel to a line connecting contacts 4-5. The sample was enclosed in a Be-Cu piston-cylinder type pressure cell with Daphne 7373 as the pressure medium. The pressure at room temperature was determined by measuring the resistance of a manganin wire enclosed with the sample. To reach the weak CO state, the sample was pressurized up to 1.25 GPa. The measurements were performed in the dc limit by using Keithley 2182 nanovoltmeter and Yokogawa 7651 dc current source.

To confirm the applied pressure, we performed temperature dependent resistance measurements at several pressures, as shown in Fig. 2(c). Hereafter, we denote the resistance and voltage as \(R_{ij,kl}\) and \(V_{ij,kl}\), where the indices \(i, j, k, \text{ and } l\) indicate the positive current, negative current, positive voltage, and negative voltage electrodes, respectively. Our in-plane resistivity data at 1.25 GPa are in agreement with known result \([8]\) and show a resistivity upturn at \(T_{\text{Min}} = 37\) K, consistent with the measurement result by Liu et al. \([25]\). In the CO state, \(T_{\text{CO}}\) can be evaluated by finding the peak of \(-d\ln\rho_{zz}/dT\) of the interlayer resistivity. As the weak CO state is approached, the CO transition becomes less abrupt and more second-order like. We evaluated \(T_{\text{CO}}\) by finding the peak of \(d\ln\rho/d(1/T)\) at each pressure (Fig. 1). At 1.25 GPa, the peak is broad and centered at \(T \approx 20\) K. These results justify that the sample is in the desired range of pressure for the weak CO state. Since NLAHE requires carrier imbalance, we checked the carrier density with conventional Hall measurement and determined the majority carrier as holes, with a density of \(n \approx 10^{17}$/cm\(^3\). We note that the carrier density is one order of magnitude higher than that used in the calculation \((n \sim 10^{16}$/cm\(^3\)) \([23]\).

To obtain NLAHE signal, we performed \(V-I\) measurement for eight electrode configurations. Due to contact offset, the raw data contain longitudinal resistance component, which is antisymmetric upon current reversal. NLAHE, on the other hand, must be symmetric due to

FIG. 2. (Color online) Contact configuration and resistivity of \(\alpha-(BEDT-TTF)_{2}\)I\(_{3}\). (a) Picture of the sample showing the contact configuration. (b) Schematic showing contact numbering. (c) Temperature dependent resistivity data of \(\alpha-(BEDT-TTF)_{2}\)I\(_{3}\) at various pressures below \(P_{C}\).
its second order nature. Therefore, we biased the current from $-1$ mA to $1$ mA, then the resulting $V - I$ curve was symmetrized as

$$V_{\text{NLAHE}} = \frac{V(I \geq 0) + V(I \leq 0)}{2} \quad (1)$$

First, we show the NLAHE data at $P = 1.25$ GPa and $T = 4.2$ K as a function of $I^2$ for various current directions in Fig 3(a). NLAHE characteristics can be seen in the symmetrized voltage part, namely the second order $V \propto I^2$ behavior and its current direction dependence. In our measurement, the configuration $V_{45,27}$ and its reverse $V_{54,72}$, where the current is directed almost parallel to the $a$-axis give the largest magnitude of nonlinear voltage. The signal decreases as the current direction is rotated towards the $V_{63,81}$ or $V_{36,18}$ configuration. It can be seen in the symmetrized voltage that the side of the sample with contacts 2, 3, and 4 tend to be more positively charged than the opposite side. Therefore, our data show current rectification effect in the symmetrized voltage part.

The current direction dependence of NLAHE voltage at $T = 4.2$ K with an applied current of $1$ mA is shown in Fig 3(b). Here, the current direction angle $\theta$ is measured relative to the direction parallel to the line connecting contacts 4-5 (almost parallel to the $a$-axis) in a counterclockwise manner. NLAHE signal is the strongest when the current is biased parallel to the Dirac cone tilting direction. For a 2D system, the optimal current bias direction can only be constrained when mirror symmetry is present. In such a case, the largest NLAHE signal is produced when the current is biased perpendicular to the mirror axis [7]. In $\alpha$-(BEDT-TTF)$_2$I$_3$ in the CO state, mirror axis is absent, so the Dirac cone tilting direction cannot be determined simply from the crystallographic axis. Because the contacts are sparsely distributed on the sample, it is not easy to pinpoint exactly the direction of the tilting axis.

The nonlinear current due to the NLAHE in the weak CO state in $\alpha$-(BEDT-TTF)$_2$I$_3$ is represented as $j = (\chi_{xy}E_xE_y)n_x + (\chi_{yx}E_x^2)n_y$. Here, the $xy$-plane is parallel to the conducting layer, and the tilting direction of Dirac cones is chosen as the $x$-axis. $E = (E_x, E_y)$ is the in-plane electric field, and $n_x$ and $n_y$ are unit vectors in the $x$- and $y$-directions, respectively. The elements $\chi_{yx}$ and $\chi_{xy}$ are finite nonlinear Hall conductivity elements, which are represented by the Berry curvature dipole of the system. In the current carrying state, the normal linear transport $j = \sigma_{xx}E$ coexists with the NLAHE, where $\sigma_{xx}$ is the scalar longitudinal conductivity. The total current is given by $j = j^{(1)} + j^{(2)}$. Assuming $|\chi_{yx}E_x^2/\sigma_{xx}^3| \ll 1$, we can obtain the following asymptotic formula for the anomalous Hall field as a function of electric current directed at angle $\alpha$ away from the $x$-axis in the presence of normal linear transport

$$E_\perp = -\frac{\chi_{yx} \cos \alpha}{\sigma_{xx}^3} j^2 \quad (2)$$

Therefore, in the case of an isotropic sample, symmetrized voltage with a current dependence of the form $V \propto \cos(\alpha)$ is expected. Previously, at $4.2$ K and in the weak CO state, the $x$-axis was found to be rotated by approximately $\theta \approx -30^\circ$ away from the $a$-axis towards the $b$-axis [20]. Although a more detailed understanding of the current direction dependence requires the conductivity tensor, in addition to the effect of sample geometry,
we fitted the data to a cosine function by assuming an isotropic sample and ignoring the sample geometry. This gives tilting direction of \( \theta = -21^\circ \pm 11^\circ \).

We estimated the nonlinear Hall coefficient \( \chi_{yxz} \) using equation (2). We consider \( V_{z1,36} \) data because they show a large response, and both current density and longitudinal conductivity can be evaluated with a regular geometry. Further, we limit our analysis for data taken at 4.2 K with an applied current range of 0.5 - 1 mA, where the uncertainty is small. The conductivity taken at 4.2 K with an applied current range of 0.5 - 1 mA, where the uncertainty is small. The conductivity as a factor \( 1/\sigma \) falls with temperature more rapidly than \( 1/\sigma \) with normalized \( 1/\sigma \) and vanishes above \( T_{CO} \). The temperature dependent conductivity as a factor \( 1/\sigma^3 \) shown in equation (2), in addition, causes a rapid decrease due to its activated form. It can be seen in Fig. 4(b) that the NLAHE signal falls with temperature more rapidly than \( 1/\sigma_{xx} \), which explains the appearance of the signal at \( T < 20 \) K.

The present result indicates that NLAHE exists at \( P = 1.25 \) GPa, close to the critical point between the CO-massless DF transition. In \( \alpha-(BEDT-TTF)_2I_3 \), strong electron correlation plays a large role and responsible for the resistivity upturn in both the CO state and the massless DF state [25]. This is supported by infrared spectroscopy measurement that shows appearance of CO gap and a pseudogap feature at low temperature and high pressure [21]. Both the transport and the optical studies suggest charge gap closure with increasing pressure. Near the transition into the massless DF state, several models show, as a general feature, that a massive DF state can emerge in \( \alpha-(BEDT-TTF)_2I_3 \) under uniaxial pressure [26–29]. The existence of the massive DF state has been suggested to explain the interlayer transport behavior by obtaining the mass gap as a fitting parameter [22]. NLAHE, on the other hand, appears for general gapped Dirac systems with tilted cones, producing finite Berry curvature. Our observation of NLAHE, therefore, suggests the existence of the massive DF state (weak CO state) before the complete closure of the gap, independent from any specific model for \( \alpha-(BEDT-TTF)_2I_3 \).

Finally, we address the discrepancy between the \( \chi_{yxz} \) obtained in this experiment and the theory. We note that all of the NLAHE data were obtained under zero-field cooling, whereas the theory predicted the necessity of the current-field cooling technique [23]. The transition from the metallic state into the CO state breaks the inversion symmetry, resulting in two domains. The two domains are randomly aligned and opposite in sign for NLAHE; thus, under zero field cooling the signal should vanish. The proposed current-field cooling method is expected to align the domains by exploiting de current induced magnetization (orbital Edelstein effect) as the sample is being cooled in a constant magnetic field. As described above, the experimentally determined \( \chi_{yxz} \) is about six times smaller than the predicted value. The
discrepancy can be understood since the prediction assumes a single-domain system, so it gives only the upper limit of $\chi_{xx}$. The existence of the two types of domains has been investigated by Yamamoto et al. using infrared second-harmonic spectroscopy [30]. The domains were found to be mobile, and macroscopic in size. Difference in proportion of the domains has also been reported by Kakiuchi et al. [9], so it is likely that one type of domain already dominates across the sample. Therefore, we assert that the nonzero signal observed in this study resulted from the asymmetry in the domain formation.

In conclusion, we observed the nonlinear anomalous Hall effect in $\alpha$-(BEDT-TTF)$_2$I$_3$ in the CO region close to the critical pressure of 1.3 GPa. Since nonlinear anomalous Hall effect requires finite Berry curvature dipole, the present observation suggests the existence of the massive Dirac fermion state with tilted Dirac cones, whose gap opens due to charge ordering.
