Disorder Enhanced Quantum Process Tomography using Quantum Light

Max Marcus

University of Oxford, Oxford, OX1 3QZ, United Kingdom

Quantum process tomography might be the most important paradigm shift which has yet to be translated fully into theoretical chemistry. Its fundamental strength, long established in quantum information science, offers a wealth of information about quantum dynamic processes which lie at the heart of many (if not all) chemical processes. However, due to its complexity its application to real chemical systems is currently beyond experimental reach. Furthermore, it is susceptible to errors due to experimental and theoretical inaccuracies and disorder has long been thought to be an obstacle in its applicability. Here, I present the first results of a study into the use of quantum light for quantum process tomography. By using a toy model and comparing numerical simulations to theoretical predictions the possible enhancement of using non-conventional light is studied. It is found, however, that disorder is necessary make the use of quantum light suitable for process tomography and that, in contrast to conventional wisdom, disorder can make the results more accurate than in an ordered system.

I. INTRODUCTION

Translating concepts from quantum information science into chemistry will be one of the most important tasks in the coming years. The field has evolved some techniques and ideas which take aim at the heart of most chemical processes. For instance, elucidating the role of quantum coherences in excitonic energy transport has been a central quest within physics and chemistry for some years now[9–14]. The notion, that a quantum effect could aid a process at ambient temperature and that, moreover, nature has adapted to harvest that effect is as fascinating as it is bizarre[8]. The biggest problem is the unambiguous detection of quantum coherences in any kind of system[9–14]. The direct observation is excluded on the basis that it is a quantum effect, so indirect data has to be used. It can be intuitive to think of this as a crime scene: when examination begins the perpetrators have left - leaving us with little else than perhaps a witness. However, in general witnesses are imperfect and consequently we may only obtain part of the information we may be after. But it may be enough.

Much research has gone into making sure that the information we obtain in order to prove the effect of coherences is unambiguous, but has always fallen short: classical models can explain the data just as well as a model invoking quantum coherences. This holds particularly true for the often cited ‘quantum beats’ in optical spectroscopy[13]. While it is a strong piece of evidence, it it by no means the smoking gun that is needed; and sadly the witness we have are of no use. Previously, others and I have reported on a new approach: instead of taking whichever witness we can find and try to get as much information out of them as we can, we construct our ‘ideal’ witness and place them at the crime scene[15,16]. For that, we returned to the definition of coherences and defined a spectroscopic protocol which is able of distinguishing unambiguously between coherent and probabilistic transport. It does so by relying solely on what coherences are. The problem of all of these previous results, however, is in their experimental realisation: the witness relies on instantaneous optical measurement, something that comes at the expense any energetic focus, which is unfortunately required, as well. With classical light, bound by the Heisenberg Uncertainty Principle (HUP), we cannot achieve both. We have to choose between a narrow width in time or energy, making our proposed witness imperfect and - at worst - useless. The crucial step involves quantum process tomography (QPT) which aims to reconstruct the process which has evolved some initial state into the state we observe. This idea is well established within quantum information science but is relatively new in chemistry[9,10]. Improving QPT will improve the results obtained with our constructed witness.

Here I report on the first results of a theoretical investigation into the use of quantum light in QPT. By utilising the fact that we can circumvent the HUP we can focus our pulse in energy and time, avoiding the the pitfalls mentioned above[17–19]. Allowing for high-accuracy QPT in chemical systems, using quantum light, will therefore allow us to probe quantum coherences and may thereby open up the possibility to settle the first of two questions: are quantum coherences present in ambient systems? If they are, further research can be conducted into how important they are. But if they are not present to begin with, then why keep looking for them? One perceived problem is always the disordered nature of chemical systems at ambient temperature. In spectroscopy this usually leads to finite line widths which can, in some cases, make any further investigation impossible. Using quantum light, which targets one energy specifically, may overcome this by not ‘seeing’ the disorder. But, the question then is, how can we make sure that it does interact with the sample in the way that we want, and how can we detect it?
Before presenting the first results of my study, I will briefly recount the idea of our quantum coherence witness and why QPT is the crucial step in it, before introducing the central object of this study, the quantum process operator. By linking it to the spectroscopic observables, which are comparatively simply to obtain, I will then proceed to model such an experimental setup and present the results thereof compared to the purely theoretical derivation.

II. QUANTUM PROCESS TOMOGRAPHY

A. Interrupting the Process

From its outset the proposed witness is deceptively simple and schematically shown in Fig. 1. It relies on a very basic idea: if we interrupt a process after some initial evolution and change something (instantaneously), does any evolution afterwards reproduce the same results as a continuous evolution? If the answer is ‘yes’, then whatever we have changed in the interruption does not in any way contribute to the final result. If the answer is ‘no’, and the two results differ, then there is clearly some functional connection between the result and whatever we have changed. It then follows very straightforwardly that, if we are interested in the role quantum coherences play in population transfer, that the result we are interested in is the distribution of populations of states, while during the interruption we need to somehow alter the coherences. This basic idea is in no way new and fairly well established within quantum information science, where it is known as the No-Signalling-In-Time (NSIT) protocol [20, 21].

Thankfully, as outlined previously, we do not actually need a coherence-only scrambling pulse. The proposed witness decomposes into three pump-probe experiments at different times, eliminating the need for this hypothetical dephasing pulse. Instead, performing QPT with pump-probe spectroscopy allows us to formulate the witness in the language of state populations, linking it directly to observables. However, in order to eliminate any other process, we require the pulses to be near-instantaneous, which can unfortunately lead to large uncertainties within QPT, rendering the witness useless.

Quantum light is the obvious candidate to overcome these obstacles and I will now introduce the central object of this study, the quantum process operator, and how it can be linked to spectroscopy.

B. Process Tensor

As so often, the derivation starts with the partitioning of the object we want to observe into system and bath - in our context we will take this to be a separation of the electronic degrees of freedom (S) from all others which may be present (B). In general, the corresponding Hamiltonian can then be decomposed as,

$$\tilde{H} = \tilde{H}_S + \tilde{H}_B + \tilde{H}_{SB}.$$  

(1)

Now, consider our system and bath initialised in some uncorrelated (thermal) state at time $t = 0$,

$$\hat{\rho}(0) = \hat{\rho}_S \otimes \hat{\rho}_B.$$  

(2)

Any unitary evolution of the system to some subsequent time is then given as,

$$\hat{\rho}(t) = \hat{U}(t)\hat{\rho}(0)\hat{U}^\dagger(t).$$  

(3)

However, if we are only interested in the dynamics of the system then we can take the trace across the bath degrees of freedom and define the quantum process superoperator, $\tilde{\chi}(t)$, as

$$\hat{\rho}_S(t) = \text{tr}_B \left[ \hat{U}(t)\hat{\rho}(0)\hat{U}^\dagger(t) \right] \equiv \tilde{\chi}(t)\hat{\rho}_S(0),$$  

(4)

which is then defined as,

$$\tilde{\chi}(t) = \sum_i \tilde{K}_i(t)\tilde{K}_i^\dagger(t),$$  

(5)

with $\tilde{K}_i$ being a Kraus-decomposition of the unitary evolution. Eq. 4 shows that $\tilde{\chi}$ describes the evolution of the system alone. This process superoperator contains all information about the evolution of the system from 0 to $t$ and can be thought of as a black box: taking any input state of the system it will transform it into the final state at time $t$. $\tilde{\chi}$ has some interesting and useful properties: it is a completely positive and trace preserving map (CPTP map) and, in general, $\tilde{\chi}(t_1 + t_2) \neq \tilde{\chi}(t_2)\tilde{\chi}(t_1)$. This latter inequality implies that for a system which has a memory the process superoperator cannot be decomposed into smaller timesteps, which can be shown easily from Eq. 4. However, if the Markovian approximation is made, in particular that the bath correlation times are very short, then we can decompose the process superoperator, and I shall make use of this for the remainder of this paper.

![Diagram](image-url)
\[ \hat{\chi} \] can be expressed (choosing a suitable basis) as a rank-4 tensor, \( \chi \), and, if our system has \( d \) accessible states, will have \( d^4 \) entries with four indices each. \( \chi_{abcd} \) then is the process tensor element which links the state \(| c \rangle \langle d | \) with the state \(| a \rangle \langle b | \). We can therefore think of the elements as the weight an initial state has on the final state. Knowing all elements of \( \chi \) system, regardless of the initial state. It is clear then, that knowledge of \( \chi \) is of central interest to many applications, particularly excited state dynamics in molecules and molecular aggregates.

QPT is exactly the process of obtaining the process tensor and pump-probe spectroscopy is the conceptually easiest way to perform such a measurement if we are interested in the tensor describing the excited state dynamics of a system.

### C. Spectroscopic signals

The spectroscopic response of the electronic system to a series of light pulses can most easily be understood in terms of double-sided Feynman diagrams, Fig. 2. To first order in perturbation theory, a system interacting with a train of two pulses will undergo either of three basic processes: Excited State Absorption (ESA), in which an already excited electron is promoted into a higher level, Stimulated Emission (SE), in which the second pulse acts in a deexciting manner, leading the system to a lower excited state (or the ground state), and Ground State Bleaching, in which the first pulse did not interact measurably with the electronic system. Denoting the first (pump) pulse as \( P \) and the second (probe) pulse as \( P' \) we can write the obtained signals in the following way:

\[ S_{\text{ESA}}(\tau) = \sum_{pq'q} \Omega^P_{pq'q} \chi^P_{pq'q} \Omega^P_{pq'q}, \]  

\[ S_{\text{SE}}(\tau) = \sum_{pq'q} \Omega^P_{pq'q} \chi^P_{pq'q} \Omega^P_{pq'q}, \]  

\[ S_{\text{GSB}}(\tau) = \sum_{pq'q} \Omega^P_{pq'q} \chi^P_{pq'q} \Omega^P_{pq'q}. \]

where \( \Omega^P_{pq} \) denotes the probability amplitude of a transition from ket \(| b \rangle \) to ket \(| a \rangle \) under pulse \( p \), \( \Omega^P_{pq} \) denotes the same transition arising in the bra \( p \) to the complex conjugated field, \( \bar{p} \), of \( p \). As is clearly visible and easily justified, the GSB process does not depend on any process operator, while the other two responses do. The signals therefore contain information about the elements of \( \chi \). As these signals cannot be recorded separately, however, it is clear that \( d^4 \) separate measurements are needed to reconstruct \( \chi \) fully, as each index can take any value for \( d \) states accessible to our system. This is clearly a formidable task and one that is insurmountable for most realistic systems. While we have recently reported a method of determining the number of excited states available to a system, performing \( d^4 \) experiments is difficult, to say the least[25]. Moreover, these need to be linearly independent, that is contain new information, as outlined below.

It is for this reason that we have introduced the witness mentioned above. By only considering pulses that interact with populations (that is states of the form \(| a \rangle \langle a | \)) we can reduce the number of experiments needed to \( d^2 \) - at the expense of loosing all numerical information about possible coherences bar an indication of their existence. This is the conceptual strength of the witness: by sacrificing information we make a yes/no answer possible.

By assuming that the pulses only interact with populations of states the equations above simplify greatly and, by introducing the transition probability \( \Pi^P_{ab} = \Omega^P_{ab} \Omega^P_{ab} \) we can write for the overall signal,

\[ S_{\text{PP'}}(\tau) = \sum_{pq} \left( \Pi^P_{pq} \Pi^P_{pq} - \Pi^P_{pq} \Pi^P_{pq} \right) \chi_{pqpq} - \sum_{pq} \Pi^P_{pq} \Pi^P_{pq}. \]

Assuming the pulses do not interact with coherences is an approximation and the choice of \( S \) vs. \( \mathbf{S} \) is meant to underline the approximate nature of this expression compared to the previous expressions.

With this, it becomes clear that if we perform \( d^2 \) experiments we obtain an overall expression for the population elements of the process tensor which we can write as,

\[ \mathbf{S} = \mathbf{M} \hat{\chi} + \mathbf{G}, \]

where \( \mathbf{M} \) is a matrix containing the coefficients in the bracket of Eq. 9 and \( \mathbf{G} \) is the constant offset, the contribution of the ground state bleach. Here, I have vectorised \( \hat{\chi} \) (expressed by \( \hat{\chi} \) by arranging the elements under consideration in a vector) to ease notation. To recover the process tensor elements from this we then invert to obtain,

\[ \hat{\chi} = \mathbf{M}^{-1} (\mathbf{S} - \mathbf{G}). \]
This procedure clearly relies on the invertability of the coefficient matrix $M$ and we therefore require the experiments we perform to be linearly independent. Moreover, the better conditioned this matrix, the more accurate the estimation of the population elements, and thereby the more accurate the information obtained from our quantum coherence witness. The conditioning clearly relies on the accuracy of the transition probabilities which are given as the Fourier transform of the pulse envelops. For a Gaussian pulse at time $t_p$ with a width of $\sigma_p$ we can write this probability as,

$$\Pi_{ij}^p = |\mu_{ij} \cdot e_p|^{2} \exp \left( -\frac{(\omega_{ij} - \omega_p)^2}{2\sigma_p^2} \right),$$

where $\omega_{ij}$ and $\mu_{ij}$ are the energy and transition dipole moment of the transition between state $|i\rangle$ $\langle i|$ and $|j\rangle$ $\langle j|$, while $e_p$ is the polarisation of the pulse $p$ with spectral width $\delta_p$ centred at $\omega_p$. The magnitude of these elements directly influence the success of the inversion described above, which thereby directly links to the quality of our results to the nature of the light pulses employed for a given system. In other words: the estimation of coherences rises and falls with the choice of light pulses used.

The different aspects of this require some careful analysis and in particular the question can be asked what advantage - if any - the use of quantum light will bring.

D. Quantum Light and Conditioning

When performing the experiments laid out above one problem arises: the light pulses used need to be short compared to the natural evolution. As the process tensor does not distinguish between natural evolution and any perturbation induced by the light pulse, ideally the light would be instantaneous. This naturally comes with a lower bound on the spectral width for the pulse, using conventional light. Namely, the pulses need to comply with the uncertainty condition,

$$\sigma_p \delta_p \geq \frac{\hbar}{2}.$$ 

However, spectrally broad pulses will induce a myriad of different processes in the sample. With the loss of spectral targeting the obtained signal will be composed of many more contributions than laid out above and the method will fail.

The use of quantum light therefore seems to be the solution: having spectrally and temporally targeted pulses should overcome the problems and provide near-instantaneous pulses with a small spectral width. The ‘quantumness’ of the light can be parameterised by a parameter, $\varphi$, given as the (dimensionless) product of the uncertainties, namely,

$$\sigma_p \delta_p = \frac{\varphi \hbar}{2}.$$ 

We therefore obtain two simple measures for the quantum limit: by reducing $\sigma_p$ and $\varphi$ we will approach the limit of instantaneous and targeted pulses.

III. NUMERICAL RESULTS

I have used a tight-binding model laid out in our previous work to analyse the quality of the process tensor recovery. Namely, a two-site model with no bath interactions, described by,

$$\hat{H} = \sum_{i=a,b} \varepsilon_i \langle i| - J (|a\rangle \langle b| + |b\rangle \langle a|),$$

has been used (for simplicity) and subjected to two perturbations induced by the pulse train to simulate the pump-probe experiment. The required parameters can be found in our previous work. The delay between the pulses as been varied from 1 fs to 2 fs to obtain a time signature of the recovered process tensor elements. The temporal width of the pulses has been scanned from 0.001 fs to 0.01 fs, while the uncertainty product has been taken between 0 and 2, with 1.0 corresponding to minimum uncertainty light in the conventional sense. The polarisations of the pulses was taken to be rotated by $90^\circ$ relative to each other, and the dipole moments of the two sites were orientated at random with respect to the polarisations with an angle of $60^\circ$ between them. These orientations were chosen as they stabilise the numerics.

In order to estimate the quality of the process tensor recovery, the calculated process tensor elements were compared to the theoretical prediction and the quality parameter,

$$Q = \frac{\int_{t_1}^{t_2} |\vec{\chi}_{\text{calc}}(t) - \chi_{\text{theo}}(t)|^2 dt}{\int_{t_1}^{t_2} |\chi_{\text{theo}}(t)|^2 dt},$$

which is 0 for perfect recovery, is defined. $t_{1,2}$ here are the start and end point of the delay time over which the process tensor was calculated.

A. Ideal Ordering

Fig. 3 shows the results for $Q$ for a single dimer. This scenario is akin to a perfectly ordered sample in which all dimers are orientated in the same way and do not experience any environmental effects. This is clearly a highly idealised model and as such is generally expected to yield much better results than any kind of disordered arrangement.

What can be seen immediately, is that around $\varphi = 1$ the best agreement between the numerical recovery and the theoretical estimation of the process tensor can be found. Moving to either side of this value shows a steep increase in the quality parameter, $Q$, which is 0 for perfect recovery. In particular, the quantum limit (bottom
left corner) shows some of the worst values for $Q$, implying that quantum light is not advantageous for QPT, but, in fact, a hindrance. This is a surprising find given the discussion above. However, it can be understood in terms of the linear independence we require our signals to have: having a perfectly frequency targeted pulse introduces linear dependence, and thereby making the inversion procedure wildly inaccurate. There is a possibility that a region for very short pulses (less than 1 fs as in width) exists for which the quantum limit becomes favourable, as the pulse will become very broadband in energy otherwise. However, this is subject to further investigation and also of limited use experimentally, currently.

B. Disordered Orientation

Fig. 4 shows the same results, but now averaged over two randomly orientated dimers instead of one. The contrast is remarkable. Not only is the recovery much more accurate over the entire scanned range, it also makes the values of $\varphi$, for which the inversion yields acceptable results ($Q < 1$) much broader. The quantum limit still seems to be the most unfavourable point on the map, but quantum light as a whole performs much better for an even only slightly disordered system.

This stems, once again, from the required linear independence of the signals. Orientating the dimers at random and averaging will produce a much higher threshold for the inversion of the matrix to fail. It is therefore reasonable to assume, that larger ensembles will make QPT more accurate. This is in stark contrast to the perceived notion that quantum effects and quantum measurements are much more accurate on ideal systems. Disorder, in this example, thereby enhances the QPT protocol and also the proposed quantum witness.

FIG. 3. Quality factor, $Q$, for various combinations of $\sigma_p$ and $\varphi$ averaged over two randomly orientated systems. Evident is the failure of the process tensor recovery in the quantum limit (bottom left). Note the log-scale in the color scale.

FIG. 4. Quality factor, $Q$, for various combinations of $\sigma_p$ and $\varphi$ averaged over two randomly orientated systems. Evident is the failure of the process tensor recovery in the quantum limit (bottom left). Note the log-scale in the color scale.

IV. SUMMARY AND OUTLOOK

The results presented above mark a first step of using quantum light to recover process tensors. Highly ordered systems show a problem arising in the quantum regime as the inversion of the spectroscopic signals fails due to the introduction of linear dependence. Introducing disorder, even small amounts, alleviates this and makes the quantum regime usable. While the results presented are only a small step, it is thereby expected that even higher degrees of disorder may shift this even further, perhaps making the quantum regime more suitable for QPT.

Future work will therefore focus on the role of disorder, which is an important consideration for chemical systems. Introducing energetic disorder is expected to make the quantum limit more suitable, as the spectral width of the light is replaced by a spectral width of the system. This could allow the signals’ linear dependence to weaken for energetically targeted pulses, leading to a better recovery. Furthermore, other pulse sequences, for instance a quantum light pump pulse followed by a broadband conventional pulse, would help circumventing this restriction. By selectively targeting a state to excite and measuring the entire response of the system could lead to a much better QPT result.

DATA AVAILABILITY

The data that support the findings of this study are available from the corresponding author upon reasonable request.
