Device-independent quantum key distribution is a secure quantum cryptographic paradigm that allows two honest users to establish a secret key, while putting minimal trust in their devices. Most of the existing protocols have the following structure: first, a bipartite nonlocal quantum state is distributed between the honest users, who perform local projective measurements to establish nonlocal correlations. Then, they announce the implemented measurements and extract a secure key by post-processing their measurement outcomes. We show that no protocol of this form allows for establishing a secret key when implemented on certain entangled nonlocal states, namely on a range of entangled two-qubit Werner states. To prove this result, we introduce a technique for upper-bounding the asymptotic key rate of device-independent quantum key distribution protocols, based on a simple eavesdropping attack. Our results imply that either different tools—such as different reconciliation techniques or non-projective measurements—are needed for device-independent quantum key distribution in the large-noise regime, or Bell nonlocality is not sufficient for this task.

Introduction.— Device-independent quantum key distribution (DIQKD) is the strongest form of quantum cryptographic protocols [1,2]. DIQKD security proofs are based on the assumption that quantum theory is correct, and on physically observable quantities. Most importantly, the honest users do not need to make any assumptions about the inner workings of their devices and, hence, they do not need to trust the preparation by the manufacturer. These facts make DIQKD a promising paradigm for providing complete security, in that DIQKD protocols are not vulnerable to implementation flaws that may be exploited in hacking attacks [3–5].

In DIQKD protocols, two distant honest parties aim at sharing a cryptographic key, while assuring it to be unknown to any eavesdropper limited by quantum theory. To achieve this, a quantum state is distributed between them in each round of the protocol, and in each of these rounds they measure the part of the state that is available to them. The resulting set of measurement outcomes is the raw data from which they extract the secure key. This data is characterised by the set of measurement outcome probabilities, called the correlation. If the observed correlation violates a Bell inequality, the information of any quantum eavesdropper about the outcomes is limited, which opens up the possibility of extracting a secure key.

The first quantitative security proofs were achieved based on the violation of the Clauser–Horne–Shimony–Holt (CHSH) Bell inequality [6], using one-way public communication for key extraction [1,2]. The original proofs, valid under collective attacks, were later extended to the most powerful coherent attacks [7–9]. Furthermore, moderate improvements on key rates were recently achieved using the more general biased CHSH inequalities [10], and applying noisy pre-processing [11,13]. Similarly, advantage distillation—a protocol for key distillation using two-way public communication—has been shown to be useful under the assumption of collective attacks [14].

While nonlocality of the observed correlations is necessary for DIQKD, it remains an open question whether it is also sufficient. Recently, methods have been proposed for upper-bounding secure key rates in DIQKD, even if two-way communication is allowed [19,17]. However, all the bounds constructed thus far remain strictly positive for nonlocal correlations, suggesting that nonlocality may be sufficient for DIQKD.

In this work, we show this not to be the case for DIQKD protocols consisting of the following two steps: (i) nonlocal correlations are established by applying projective measurements on an entangled quantum state; (ii) the implemented measurements are announced and the key is constructed by classically post-processing the outcomes. Most of the existing DIQKD protocols have this form and, hence, in what follows we refer to such protocols as standard protocols. To prove the result, we provide a generic tool for upper-bounding key rates in DIQKD. We then apply our tool to standard protocols implemented on a two-qubit Werner state [18] using an arbitrary number of measurements. We show that for a range of visibilities for which the Werner state is known to be nonlocal, the upper bound on the key rate is zero, and therefore no standard DIQKD protocol can be secure. We also show how the provable region of insecurity can be enlarged when fixing the number of measurements in the protocol. In particular, we compute visibilities for which the commonly used protocols based on the (biased) CHSH inequality [1,2,9,11,13] all become insecure de-
spite the correlations still being nonlocal.

Methods.— Formally, in a DIQKD protocol two parties, Alice and Bob, have access to a bipartite quantum state, $\rho_{AB}$, represented by a positive semidefinite operator with unit trace on the tensor product Hilbert space, $\mathcal{H}_A \otimes \mathcal{H}_B$. The protocol consists of several rounds, in each of which Alice and Bob choose a particular quantum measurement to measure their part of a fresh copy of $\rho_{AB}$. In particular, Alice chooses a measurement labelled by $x \in \{0, 1, \ldots, n_A - 1\} \equiv [n_A]$, and Bob chooses a measurement labelled by $y \in [n_B]$. Without loss of generality, we assume that each of Alice’s (Bob’s) measurements has $k_A$ ($k_B$) possible outcomes. According to quantum theory, $k_A$-($k_B$-)outcome measurements correspond to a set of $k_A$ ($k_B$) positive semidefinite operators on $\mathcal{H}_A$ ($\mathcal{H}_B$), adding up to the identity operator $\mathbb{1}_A$ ($\mathbb{1}_B$).

We denote these measurement operators by $A_x^a$ and $B_y^b$, where $x \in [n_A]$, $a \in [k_A]$, $y \in [n_B]$ and $b \in [k_B]$. Then, the correlation shared by Alice and Bob reads

$$p_{AB}(a, b|x, y) = \text{tr}[\rho_{AB}(A_x^a \otimes B_y^b)],$$

specifying the probabilities of observing the outcomes $a$ and $b$, given that the measurements $x$ and $y$ were selected.

The raw data in the protocol corresponds to the pair of strings held by Alice and Bob containing the measurement outcomes and the implemented measurements, collected over all protocol rounds. Since individually Alice and Bob only have access to their marginal statistics, they publicly reveal the measurement settings and outcomes for a fraction of this data to estimate the joint statistics and detect its nonlocality. This part of the dataset is discarded. The secret key is distilled by classically post-processing the remaining dataset with the help of public communication, so that they finally hold identical strings that must appear perfectly random to any third party.

As stated earlier, in this work we consider what we call standard protocols, in which the measurements implemented by Alice and Bob are (i) projective and (ii) announced in the key distillation part. Apart from these two constraints, the rest of the protocol is arbitrary. This family is quite broad and covers most DIQKD protocols introduced so far [1, 2, 9, 11–14], with only a few exceptions proposed to date (see e.g. Ref. [19]).

In order to upper-bound the key rate for a given DIQKD protocol, it suffices to consider a particular model of the eavesdropper, Eve. Here, we restrict the analysis to individual attacks that do not require any quantum memory [20]. In device-independent protocols, Alice and Bob have no knowledge of the form of the state $\rho_{AB}$ and the measurements $\{A_x^a\}$, $\{B_y^b\}$, and it is precisely this lack of knowledge that Eve makes use of in her attack. In particular, we assume that she knows the precise form of the measurement operators and that she is the one distributing the quantum state (therefore effectively distributing quantum correlations) to Alice and Bob in each round.

In our convex combination (CC) attack—originally considered for eavesdroppers limited only by the no-signalling principle [19, 21]—Eve distributes local deterministic correlations with certain probabilities that give rise to a local correlation $p^{NL}_{AB}(a, b|x, y)$ with overall probability $q_L$, and she distributes a nonlocal quantum correlation $p^{NL}_{AB}(a, b|x, y)$ with probability $1 - q_L$. While presented in this form for the sake of simplicity, Eve can equally implement the attack by fixing the measurements of Alice and Bob and preparing a unique quantum state $\rho_{ABE}$. Eventually, the observed correlation of Alice and Bob takes the form

$$p_{AB}(a, b|x, y) = q_L \cdot p_{AB}^{C}(a, b|x, y) + (1 - q_L) \cdot p_{AB}^{NL}(a, b|x, y),$$

and we call $q_L \in [0, 1]$ the local weight. Since nonlocality is necessary for secure DIQKD, in the CC attack Eve maximises $q_L$ for the given observed correlation $p_{AB}(a, b|x, y)$ and a judiciously chosen nonlocal quantum correlation $p_{AB}^{NL}(a, b|x, y)$. After the attack, Eve holds classical random variables correlated with the data of Alice and Bob.

We apply the CC attack to the standard DIQKD protocols introduced above. Since Alice and Bob announce their inputs for every round, Eve knows their outcomes in all rounds in which she distributes a local correlation. On the other hand, we assume in what follows that Eve is not correlated to the nonlocal part of the correlation of Alice and Bob. Therefore, for any combination of inputs $x$ and $y$, Alice, Bob and Eve share correlated random variables distributed as

$$p_{ABE}(a, b, e|x, y) = q_L \cdot p_{AB}^{C}(a, b|x, y)\delta_{e,a,b}
+ (1 - q_L) \cdot p_{AB}^{NL}(a, b|x, y)\delta_{e,?}.$$  (3)

That is, when the correlation is local, Eve registers the outcomes $a$ and $b$, and when and when the correlation is nonlocal, she registers “?”. Well-established results in classical cryptography prove that the asymptotic key rate $r$ extractable from a dataset of strings distributed according to $p_{ABE}(a, b, e)$ is upper-bounded by the intrinsic information [22, 23],

$$I(A, B \downarrow E) = \min_{E \rightarrow \bar{E}} I(A : B|\bar{E}),$$

where $I(A : B|\bar{E}) = \sum_{\bar{e}} p_{E}(\bar{e}) \cdot I(A : B|\bar{E} = \bar{e})$ is the conditional mutual information of $p_{ABE}(a, b, e)$, and the minimisation is taken over all stochastic maps $E \rightarrow \bar{E}$ such that the alphabet size of $\bar{E}$ is at most that of $E$ [23]. While the minimisation in [4] may be hard, any candidate stochastic map provides a valid upper bound.

When applying this bound to the CC attack, the key rate is upper-bounded by

$$r \leq \sum_{x,y} p_{xy} \cdot I_{xy}(A : B \downarrow E),$$  (5)
where the sum runs over all those settings \((x, y)\) from which the key is distilled, \(p_{xy}^v\) is the probability of Alice and Bob choosing the settings \(x\) and \(y\), respectively, and \(I_{xy}(A : B \downarrow E)\) is the intrinsic information of the distribution in Eq. (2).

Nonlocality is not sufficient for DIQKD.— We apply the CC attack to DIQKD protocols that use the two-qubit Werner state [15] with visibility \(v \in [0, 1],\

\[\rho_{AB}^v = v |\psi_-\rangle\langle \psi_-| + (1 - v) \frac{I}{4},\]  

where \(|\psi_-\rangle = (|01\rangle - |10\rangle)/\sqrt{2}\). It is known that for arbitrary (even infinitely many) projective measurements \(\{A_x^e\}\) and \(\{B_y^q\}\), the correlation \(p_{xy}^v(a, b | x, y) := \text{tr}[\rho_{xy}^v (A_x^e \otimes B_y^q)]\) is local whenever the visibility is at most \(v \leq v_{\text{NC}}^w := 999 \cdot 689 \cdot 10^{-6} \cdot \cos^4(\pi/50) \approx 0.6829\), see [24]. On the other hand, it is also known that there exist projective measurements that give rise to nonlocal correlations for \(v \geq v_{\text{NC}}^w \approx 0.7012\), see [26].

Let us consider all DIQKD protocols that use the Werner state and arbitrarily many projective measurements \(A_x^e = \frac{1}{2}[1 + (-1)^a \alpha_x \cdot \vec{\alpha}]\) and \(B_y^q = \frac{1}{2}[1 + (-1)^b \beta_y \cdot \vec{\beta}]\), where \(a, b \in \{0, 1\}\), \(\alpha_x\) and \(\beta_y\) are unit vectors in \(\mathbb{R}^3\), and \(\vec{\alpha} = (X, Y, Z)\) is a vector containing the Pauli matrices.

\[p_{AB|\vec{E}}(a, b | ?; x, y) = \frac{1}{2(1 - q_{xy}^w \cdot s_{xy}^w)} \left(\frac{(1 - q_{xy}^w) s_{xy}^1}{(1 - q_{xy}^w)(1 - s_{xy}^1) + q_{xy}^w (1 - s_{xy}^w)} + \frac{(1 - q_{xy}^w)(1 - s_{xy}^1) + q_{xy}^w (1 - s_{xy}^w)}{(1 - q_{xy}^w) s_{xy}^1}\right),\]  

Note that while \(I_{xy}(A : B | \vec{E} = ?)\) is in general positive for \(v < v_{xy}\), a slight modification of the CC attack leads to \(I_{xy}(A : B | \vec{E} = ?) = 0\) for all \(v \leq v_{xy}\). To see this, note that for \(v \leq v_{xy}\), the correlation \(p_{xy}^v(a, b | x, y)\) is a convex combination of \(p_{xy}^v(a, b | x, y) = 1/4\). Then, the observed correlation can be obtained by Eve distributing either \(p_{xy}^v\) or \(p_{xy}^v\), both of which having zero intrinsic information. Therefore, Eve can clearly keep \(I_{xy}(A : B | \vec{E} = ?) = 0\) for all \(v \leq v_{xy}\). It is easy to verify that

\[\begin{bmatrix} p_{xy}^v(0, 0 | x, y) & p_{xy}^v(0, 1 | x, y) \\ p_{xy}^v(1, 0 | x, y) & p_{xy}^v(1, 1 | x, y) \end{bmatrix} = \frac{1}{2} \begin{bmatrix} s_{xy}^v & 1 - s_{xy}^v \\ 1 - s_{xy}^v & s_{xy}^v \end{bmatrix},\]  

where \(s_{xy}^v = (1 - v\alpha_x \cdot \beta_y) \in [0, 1]\).

The CC attack we consider is rather intuitive: it uses the nonlocal correlation \(p_{AB}^{\text{NC}}(a, b | x, y)\), and local deterministic correlations that sum up to the correlation for the provable local Werner state, \(p_{AB}^w (a, b | x, y)\). It is easy to verify that in this case we have that \(q_{xy}^w = q_{xy}^w := (1 - v)/(1 - v^w)\). Numerical simulations suggest that the optimal stochastic map by Eve minimising the intrinsic information is such that \((a, b)\) is mapped to "w" whenever \(a \neq b\), while the other values are unchanged. The resulting distribution reads

\[p_{AB|\vec{E}}(a, b | ?; x, y) = q_{xy}^w \cdot p_{AB}^{\text{NC}}(a, b | x, y) \times \left[\delta_{a,b} \cdot \delta_{E,a} + (1 - \delta_{a,b}) \cdot \delta_{E,b}\right] + (1 - q_{xy}^w) \cdot p_{AB}^w (a, b | x, y) \cdot \delta_{E,a}.\]  

This equation implies that \(I_{xy}(A : B | \vec{E} = a) = 0\) for all \(a\), so the final bound on the key rate is given by

\[r \leq \sum_{x,y} p_{xy} \cdot p_{\vec{E}_x}(?) \cdot I_{xy}(A : B | \vec{E} = ?),\]  

where \(I_{xy}(A : B | \vec{E} = ?)\) is the mutual information of the distribution \(p_{AB|\vec{E}}(a, b; x, y) = p_{AB|\vec{E}}(a, b; ?, x, y) = p_{\vec{E}_x}(?) \cdot p_{\vec{E}_y}(?) / p_{\vec{E}_x}(?)\).

To compute the upper bound, we need to calculate the terms \(I_{xy}(A : B | \vec{E} = ?)\) in Eq. (9), that is, the mutual information of the distribution

\[\begin{aligned}
&I_{xy}(A : B | \vec{E} = ?) = \sum_{x,y} p_{xy} \cdot p_{\vec{E}_x}(?) \cdot I_{xy}(A : B | \vec{E} = ?), \\
& \text{where } I_{xy}(A : B | \vec{E} = ?) = \text{the mutual} \\
& \text{information of the distribution } p_{AB|\vec{E}}(a, b; x, y).
\end{aligned}\]  

Also note that \(v_{xy}\) is monotonically decreasing in \(s_{xy}^1\), and hence, it reaches its lowest possible value at \(s_{xy}^1 = 1\). This gives rise to the critical visibility of the Werner state,

\[v_{\text{crit}}^w = \frac{v_{\text{crit}}^w + 1}{3 - v_{\text{crit}}^w} \approx 0.7263 > v_{\text{NC}}^w \approx 0.7012.\]  

From the above arguments, it follows that whenever the visibility is \(v_{\text{NC}}^w \leq v \leq v_{\text{crit}}^w\), Alice and Bob cannot extract a secure key from the Werner state with any (even infinite) number of projective measurements, even though the state is nonlocal (i.e., there exist projective measurements that, measured on the state, give rise to nonlocal correlations) and distillable [27]. This means that Bell nonlocality (or entanglement distillability) is in general not sufficient for DIQKD whenever Alice and Bob
announce their measurement settings and the measurements are projective.

**CHSH-based protocols.**—The most commonly used DIQKD protocols\(^1\)\(^2\)\(^3\)\(^4\)\(^5\)\(^6\)\(^7\)\(^8\)\(^9\)\(^10\)\(^11\)\(^12\)\(^13\)\(^14\)\(^15\)\(^16\)\(^17\)\(^18\)\(^19\) are based on the maximal violation of the biased CHSH inequality\(^19\). In these protocols the shared state is \(\rho_{AB} = |\psi_\rightarrow\rangle|\psi_\rightarrow\rangle\), and Alice’s measurements are described by \(\alpha_0 = (0, 0, -1)\) and \(\alpha_1 = (-1, 0, 0)\), while Bob’s measurements are described by \(\beta_0 = (\sin \theta, 0, \cos \theta)\), \(\beta_1 = (- \cos \theta, 0, \sin \theta)\) and \(\beta_2 = (0, 0, 1)\), where \(0 < \theta < \frac{\pi}{2}\). The protocol based on the standard CHSH inequality is reproduced by setting \(\theta = \frac{\pi}{4}\)\(^11\)\(^12\). The noisy versions of these protocols with visibility \(v\) can be described by sharing a Werner state, and our results from the previous section readily apply. In particular, \(v_{\text{crit}}^0\) in Eq. (12) is a lower bound on the critical visibility for CHSH-based protocols.

However, for a fixed protocol, the bound on the critical visibility can be improved. This is because in the setting of the CHSH-based protocols, the polytope of local correlations is completely characterised\(^19\). One can verify that the critical visibility for the Werner state with visibility \(v\), then this correlation is local if and only if \(v \leq v_{\text{crit}}^0 := 1/(\cos \theta + \sin \theta)\)\(^29\). Therefore, an improved bound on the critical visibility for the CHSH-based protocols is given by

\[
v_{\text{crit}}^\theta = \frac{v_{\text{crit}}^0 + 1}{3 - v_{\text{crit}}^0} > v_{\text{crit}}^0 \quad \forall \theta \in (0, \pi/2).
\]

That is, for a range of visibilities for which the observed correlation is nonlocal, Alice and Bob cannot extract a secure key. Note that the same critical visibility holds for the recently introduced modulation of the standard CHSH-based protocol in Ref.\(^19\), where the authors add a fourth setting for Bob. Indeed, since the local polytope is completely characterised in this case as well\(^28\), one can verify that the correlation becomes local at the same visibility \(v_{\text{crit}}^0\)\(^29\).

Last, we note that in the CHSH-based protocols, Alice and Bob usually extract their key from the setting pair \(x = 0\) and \(y = 2\), by setting \(p_{02}\) in Eq. (9) arbitrarily close to 1. In this case, it is possible to compute the upper bound in Eq. (9) for any visibility \(v \geq v_{\text{crit}}^\theta\), and we get

\[
r^\theta(v) \leq 2(1 - s^\theta q_{\text{crit}}^0) + (1 - q_{\text{crit}}^0) \log_2 \left[ \frac{1 - q_{\text{crit}}^0}{2(1 - s^\theta q_{\text{crit}}^0)} \right] + q_{\text{crit}}^0 (1 - s^\theta) \log_2 \left[ \frac{q_{\text{crit}}^0 (1 - s^\theta)}{2(1 - s^\theta q_{\text{crit}}^0)} \right]
\]

where \(s^\theta = \frac{1}{2}(1 + v_{\text{crit}}^0)\) and \(q_{\text{crit}}^0 = (1 - v)/ (1 - v_{\text{crit}}^0)\). In Fig. 1\(^4\) we plot the bound for the standard CHSH protocol (\(\theta = \frac{\pi}{4}\)), and show that it outperforms the recently derived upper bounds\(^15\)\(^17\) near the critical visibility. Within the inset of Fig. 1\(^4\) we also depict a two-dimensional region in the set of quantum correlations that is nonlocal but cannot be used to extract a key with the biased CHSH protocol (see\(^29\) for details).

**Discussion.**—We introduced a generic tool for upper-bounding DIQKD key rates using a simple eavesdropping attack. Using our tool, we showed that Bell nonlocality is not sufficient for secure DIQKD when the honest parties announce their measurement settings and the measurements are projective. Our results also imply that all the commonly used DIQKD protocols become insecure in the noisy case already in the nonlocal regime, even when assisted by arbitrary two-way communication. Our analysis does not prove that the considered nonlocal correlations are useless for secure key distribution, but it shows that the standard reconciliation—where the settings are announced by both parties—does not work for all nonlocal correlations.

Given the above, one possibility to lower the stringent requirements on noise parameters is to employ protocols such as that of Ref.\(^19\), in which only one party announces their settings. Indeed, for this protocol we were not able to find an upper bound that vanishes in the nonlocal regime. Whether a secure key can be distilled from all nonlocal correlations using these protocols is an open question that deserves further investigation. Another possibility for improving key rates is to employ measurements that are not projective. However, we note that no state is known thus far that is local for all arrangements of projective measurements, while exhibiting
nonlocality for some arrangement of non-projective measurements. Hence, the critical visibilities derived in this work also hold for all the hitherto studied arrangements of non-projective measurements.

We further note that our eavesdropping attack can be applied to a broad class of DIQKD protocols, and gives rise to bounds on the critical visibility in experimentally relevant scenarios. We elaborate on these findings in [31].

[31] In preparation.
Local visibility for CHSH-based protocols

Consider the correlation \( p_{AB}^{\theta,\psi}(a, b|x, y) = \text{tr}\{\rho_{AB}^{\psi}[A^x_a \otimes B^y_b(\theta)]\} \), obtained by measuring the Werner state

\[ \rho_{AB}^{\psi} = v|\psi-\rangle\langle\psi-| + (1-v)\frac{I}{4} \]

with the projective measurements \( A^x_a = \frac{1}{2}[I + (-1)^a\vec{\alpha}_x \cdot \vec{d}] \) and \( B^y_b(\theta) = \frac{1}{2}[I + (-1)^b\vec{\beta}_y \cdot \vec{d}] \) with \( a, b \in \{0, 1\} \), given by

\[ \vec{\alpha}_0 = (0, 0, -1), \quad \vec{\alpha}_1 = (-1, 0, 0) \]
\[ \vec{\beta}_0 = (\sin \theta, 0, \cos \theta), \quad \vec{\beta}_1 = (-\cos \theta, 0, \sin \theta), \quad \vec{\beta}_2 = (0, 0, 1). \]

Note that with the above notation, we have that \( p_{AB}^{\theta,\psi}(a, b|x, y) = \frac{1}{4}[1 - v(-1)^{a+b}\vec{\alpha}_x \cdot \vec{\beta}_y] \).

In this section, we show that \( p_{AB}^{\theta,\psi}(a, b|x, y) \) is local if and only if

\[ v \leq v^0_L = \frac{1}{\cos \theta + \sin \theta}. \]

In order to prove this, we note that for the case of two binary measurements on Alice’s side and three binary measurements on Bob’s side, the polytope of local correlations is completely characterised [28]. In particular, all the facets that correspond to non-trivial constraints (i.e., do not correspond to the positivity and normalisation of the probabilities) are of the CHSH-type:

\[ -2 \leq \langle A_{x_0}B_{y_0}\rangle + \langle A_{x_1}B_{y_1}\rangle - \langle A_{x_2}B_{y_2}\rangle \leq 2 \]
\[ x_0, x_1 \in \{0, 1\}, \quad y_0, y_1 \in \{0, 1, 2\}, \quad x_0 \neq x_1, y_0 \neq y_1, \]
\[ x_2 \neq x_0, x_1, y_2 \neq y_0, y_1. \]

where

\[ \langle A_{x_2}B_{y_2}\rangle = p_{AB}(0, 0|x, y) + p_{AB}(1, 1|x, y) - p_{AB}(0, 1|x, y) - p_{AB}(1, 0|x, y) \]

are the correlators. In other words, a correlation \( p_{AB}(a, b|x, y) \) in this setting is local if and only if it satisfies all the inequalities in Eq. (18).

Let us denote the correlators of \( p_{AB}^{\theta,\psi}(a, b|x, y) \) by \( \langle A_{x_2}B_{y_2}\rangle^{\theta,\psi} \). Note that \( \langle A_{x_2}B_{y_2}\rangle^{\theta,\psi} = -v\vec{\alpha}_x \cdot \vec{\beta}_y \), and hence \( \langle A_{x_2}B_{y_2}\rangle^{\theta,\psi} = v \cdot \langle A_{x_2}B_{y_2}\rangle^{0.1} \). Therefore, the statement that \( p_{AB}^{\theta,\psi}(a, b|x, y) \) is local is equivalent to

\[ -2 \leq v \cdot S_{x_0, x_1, y_0, y_1}^{\theta} \leq 2 \]
\[ \forall x_0, x_1 \in \{0, 1\}, \quad y_0, y_1 \in \{0, 1, 2\}, \quad x_0 \neq x_1, y_0 \neq y_1, \]

where we have defined

\[ S_{x_0, x_1, y_0, y_1}^{\theta} = \langle A_{x_0}B_{y_0}\rangle^{\theta,1} + \langle A_{x_1}B_{y_1}\rangle^{\theta,1} + \langle A_{x_1}B_{y_0}\rangle^{\theta,1} - \langle A_{x_2}B_{y_1}\rangle^{\theta,1}. \]

A straightforward computation yields

\[ S_{0,0,0,1}^{\theta} = 2(\cos \theta + \sin \theta) \]
\[ S_{0,0,0,2}^{\theta} = 1 + \cos \theta + \sin \theta \]
\[ S_{0,0,1,0}^{\theta} = -\cos \theta - \sin \theta \]
\[ S_{0,0,1,2}^{\theta} = 1 - \cos \theta + \sin \theta \]
\[ S_{0,1,0,2}^{\theta} = 1 + \cos \theta - \sin \theta \]
\[ S_{0,1,2,0}^{\theta} = 1 + \cos \theta - \sin \theta \]
\[ S_{0,1,2,1}^{\theta} = 1 + \cos \theta + \sin \theta \]
\[ S_{1,0,0,1}^{\theta} = 0 \]
\[ S_{1,0,0,2}^{\theta} = -1 + \cos \theta + \sin \theta \]
\[ S_{1,0,1,0}^{\theta} = 2(-\cos \theta + \sin \theta) \]
\[ S_{1,0,1,2}^{\theta} = -1 - \cos \theta + \sin \theta \]
\[ S_{1,0,2,0}^{\theta} = 1 - \cos \theta + \sin \theta \]
\[ S_{1,0,2,1}^{\theta} = 1 - \cos \theta - \sin \theta. \]
By comparing Eqs. (20) and (22), it is straightforward to verify that \( p_{AB}^{\theta}(a, b|x, y) \) is local if and only if \( v_\theta^L = 1/(\cos \theta + \sin \theta) \).

This argument naturally extends to the CHSH-based protocol recently introduced in Ref. [30]. This protocol is based on the state in Eq. (15) and the measurements in Eq. (16) (with \( \theta = \frac{\pi}{4} \), but our argument works for arbitrary \( \theta \)), with an added setting for Bob, described by \( \beta_0^\theta = (1, 0, 0) \). These new correlations trivially satisfy Eq. (22), and additionally, it is easy to verify that

\[
S_{\theta, x_0, x_1, 1, 2}^0 = S_{x_0, y_0, 2}^0 \quad \text{and} \quad S_{\theta, x_0, x_1, 3, y}^0 = S_{x_0, y_1, 3, 2}^0.
\] (23)

The local polytope is completely characterised in this scenario as well [28], and all the non-trivial facets are of the CHSH-type:

\[
-2 \leq \langle A_{x_0} B_{y_0} \rangle + \langle A_{x_0} B_{y_1} \rangle + \langle A_{x_1} B_{y_0} \rangle - \langle A_{x_1} B_{y_1} \rangle \leq 2 \quad x_0, x_1 \in \{0, 1\}, \ y_0, y_1 \in \{0, 1, 2, 3\}, x_0 \neq x_1, y_0 \neq y_1.
\] (24)

Hence, it is clear that these new correlations are also local in the noisy case if and only if \( v \leq v_\theta^L \).

The two-dimensional slice of the quantum set

In this section, we describe the region depicted in the inset of Fig. 1 of the main text. The points in the inset are based on correlations with two inputs and two outputs, \( p_{AB}(a, b|x, y) = \text{tr}[\rho_{AB}(A^a \otimes B^b)] \), such that \( a, b, x, y \in \{0, 1\} \). The full set of these correlations can be embedded in an 8-dimensional real vector space [28]. To see this, let us define the observables

\[
A_x = A^{x}_0 - A^{x}_1 \quad \text{and} \quad B_y = B^{y}_0 - B^{y}_1.
\] (25)

The original measurement operators can be recovered from the observables via

\[
A^a_x = \frac{1}{2} [I + (-1)^a A_x] \quad \text{and} \quad B^b_y = \frac{1}{2} [I + (-1)^b B_y].
\] (26)

In terms of these observables, we define the marginals

\[
\langle A_x \rangle = \text{tr}[\rho_{AB}(A_x \otimes I)] \quad \text{and} \quad \langle B_y \rangle = \text{tr}[\rho_{AB}(I \otimes B_y)]
\] (27)

and the correlators

\[
\langle A_x B_y \rangle = \text{tr}[\rho_{AB}(A_x \otimes B_y)]
\] (28)

[notice that these correlators are the same as those in Eq. (19)]. Indeed, any correlation can be written in terms of the marginals and the correlators as

\[
p_{AB}(a, b|x, y) = \text{tr}[\rho_{AB}(A^a_x \otimes B^b_y)] = \frac{1}{4} [1 + (-1)^a \langle A_x \rangle + (-1)^b \langle B_y \rangle + (-1)^{a+b} \langle A_x B_y \rangle].
\] (29)

In order to describe a 2-dimensional slice of the set of correlations in this scenario, we need to describe all correlators and marginals in terms of affine functions of two real variables, which we will denote by \( s \) and \( t \). The slice we are interested in is given by

\[
\begin{align*}
\langle A_x \rangle &= \langle B_y \rangle = 0 \quad \forall x, y \\
\langle A_0 B_0 \rangle &= s \\
\langle A_0 B_1 \rangle &= t \\
\langle A_1 B_0 \rangle &= t \\
\langle A_1 B_1 \rangle &= -s.
\end{align*}
\] (30)

The set of quantum correlations in this case is bounded by the relation \( s^2 + t^2 \leq 1 \), which corresponds to the maximal possible quantum violation of the biased CHSH inequalities [10]. The local set is bounded by four constraints, \( \pm s \pm t \leq 1 \), which are various relabellings of the CHSH inequality, and the inequality \( s + t \leq 1 \) corresponds to the standard CHSH inequality

\[
\langle A_0 B_0 \rangle + \langle A_0 B_1 \rangle + \langle A_1 B_0 \rangle - \langle A_1 B_1 \rangle \leq 2.
\] (31)
Using this parametrisation, the local points on the CHSH facet correspond to \( s + t = 1 \), with the two endpoints being \((s, t) = (1, 0)\) and \((s, t) = (0, 1)\). The boundary of the quantum set (with all points being extremal) corresponds to the curve \( s^2 + t^2 = 1 \). We will be interested in the region \( s + t > 1 \), i.e., correlations violating the standard CHSH inequality, while still being quantum, i.e., \( s^2 + t^2 \leq 1 \). It is convenient to parametrise this region with the polar coordinates \((s, t) = (v \cos \theta, v \sin \theta)\):

\[
\begin{align*}
\langle A_x \rangle &= \langle B_y \rangle = 0 \quad \forall x, y \\
\langle A_0 B_0 \rangle &= v \cos \theta \\
\langle A_0 B_1 \rangle &= v \sin \theta \\
\langle A_1 B_0 \rangle &= v \sin \theta \\
\langle A_1 B_1 \rangle &= -v \cos \theta,
\end{align*}
\]

where \( 0 < \theta < \frac{\pi}{2} \) and \( v^\theta_L < v \leq 1 \) [let us recall that \( v^\theta_L = 1 / (\cos \theta + \sin \theta) \), see the previous section].

The region depicted in the inset of Fig. 1 of the main text corresponds to DIQKD protocols with two binary measurements on Alice’s side and three binary measurements on Bob’s side. The correlation observed in the protocol is given by Eq. (32) with an added binary measurement, \( y = 2 \), on Bob’s side, that gives rise to the final correlation

\[
\begin{align*}
\langle A_x \rangle &= \langle B_y \rangle = 0 \quad \forall x, y \\
\langle A_0 B_0 \rangle &= v \cos \theta \\
\langle A_0 B_1 \rangle &= v \sin \theta \\
\langle A_0 B_2 \rangle &= v \\
\langle A_1 B_0 \rangle &= v \sin \theta \\
\langle A_1 B_1 \rangle &= -v \cos \theta, \\
\langle A_1 B_2 \rangle &= 0.
\end{align*}
\]  

(33)

It is clear that this correlation can be obtained by measuring the state in Eq. [15] with the projective measurements described in Eq. [16].

The region depicted in the inset of Fig. 1 of the main text corresponds to the set of correlations of the form (33) with \( 0 < \theta < \frac{\pi}{2} \) and \( v^\theta_L < v \leq 1 \) [this region is depicted using the polar coordinates \((v, \theta)\), rotated counterclockwise by \( \frac{\pi}{4} \)]. The flat boundary on the bottom corresponds to \( v = v^\theta_L \), and the curved boundary on the top corresponds to \( v = 1 \). The vertical green line is given by \( \theta = \frac{\pi}{4} \). The red region corresponds to \( v \leq v^\theta_{\text{crit}} = (v^\theta_L + 1) / (3 - v^\theta_L) \). As explained in the main text, Alice and Bob cannot extract a secure key if they observe a correlation in the red region, and publicly announce their settings for each round.
