Worsening Perception: Real-time Degradation of Autonomous Vehicle Perception Performance for Simulation of Adverse Weather Conditions

Ivan Fursa, Elias Fandi, Valentina Mușat, Jacob Culley, Enric Gil, Louise Bilous, Isaac Vander Sluis, Alexander Rast and Andrew Bradley*

Abstract
Autonomous vehicles rely heavily upon their perception subsystems to ‘see’ the environment in which they operate. Unfortunately, the effect of varying weather conditions presents a significant challenge to object detection algorithms, and thus it is imperative to test the vehicle extensively in all conditions which it may experience. However, unpredictable weather can make real-world testing in adverse conditions an expensive and time consuming task requiring access to specialist facilities, and weatherproofing of sensitive electronics. Simulation provides an alternative to real world testing, with some studies developing increasingly visually realistic representations of the real world on powerful compute hardware. Given that subsequent subsystems in the autonomous vehicle pipeline are unaware of the visual realism of the simulation, when developing modules downstream of perception the appearance is of little consequence - rather it is how the perception system performs in the prevailing weather condition that is important. This study explores the potential of using a simple, lightweight image augmentation system in an autonomous racing vehicle - focusing not on visual accuracy, but rather the effect upon perception system performance. With minimal adjustment, the prototype system developed in this study can replicate the effects of both water droplets on the camera lens, and fading light conditions. The system introduces a latency of less than 8 ms using compute hardware that is well suited to being carried in the vehicle - rendering it ideally suited to real-time implementation that can be run during experiments in simulation, and augmented reality testing in the real world.

1 Introduction

Autonomous driving presents a number of major outstanding challenges for the vehicle to be able to be truly independent. In particular, a crucial part of the overall system is perception - the method by which the Autonomous Vehicle (AV) ‘sees’ and interprets its environment. The majority of both race and road AVs operate via a pipeline of subsystems responsible for perception, localisation and mapping, decision making, and control (Van Brummelen et al., 2018).

The perception subsystem commonly employs an AI object detector to identify other road users and particular landmarks of interest (e.g. road signs, traffic lights etc). The location and range of these landmarks from the vehicle’s perspective are then passed to the localisation and mapping subsystem - which generates an updated map based on the detected position of landmarks, and identifies the location and orientation of the AV within this map (Jo et al., 2018). The perception pipeline also includes detection of transient objects, (e.g. pedestrians and other vehicles), typically using some sort of machine learning-based object identification (Pendleton et al., 2017). The information contained within the map is then used by the decision subsystem to select how to proceed, and plan a trajectory through the environment - which is passed to the control subsystem to generate commands to physically drive the vehicle. This creates a complex, deep pipeline of dependent interacting systems, and these systems need to be tested rigorously to ensure that they work under a wide range of operating conditions.

Here, performance loss may be critical. Indeed, various weather conditions can significantly degrade perception, and if not accounted for, subsequent subsystems in the control system pipeline may be susceptible to incomplete or erroneous information. Weather conditions have historically proven to be one of the more challenging aspects to mitigate against in perception systems. A vehicle that works well in initial testing may perform poorly in the real world, thus “it is of utmost importance to test automated driving function under adverse weather conditions” (Hasirlioglu & Riener, 2018). AV technology needs to be developed to be suitable for, and undergo rigorous testing in the complete variety of environments and weather conditions which may occur.

Two complementary approaches have been used to test AVs: real-world testing, which is typically considered the ‘gold standard’, and simulation - a valuable additional resource given the time and expense of real-world data collection. Developing and testing software using real vehicles is expensive, inherently risky (thus typically requires access to a specialised testing facility), and demands many hours or indeed months of data collection and iterative improvements. Data gathering requires hours of driving, under different sets of conditions, which of course themselves cannot be scheduled: the data collection process is at the mercy of what the weather decides to do.

Given the difficulties and inherent risks in testing and validating the reliability and accuracy of algorithms for perception, mapping, decision making, and control for an autonomous vehicle, the ability to perform testing in simulation offers a number of appealing advantages (Li et al., 2019). Many different hypothetical scenarios can be tested, possibly in parallel, given access to appropriate compute resources, and the time required to optimise the system can be dramatically reduced. Multisensor systems that form part of complex processing pipelines can be automatically unit tested in isolation, reducing integration time.

Regardless of whether simulation or real-world testing is used, effective methods for recreating the effects of weather are needed. For real-world testing, facilities (Bijelic et al., 2018) exist that can physically emulate various weather conditions, but these are expensive, need to be carefully scheduled,
and are not typically accessible to any group who might wish to use them. Some simulators (Dosovitskiy et al., 2017; Shah et al., 2018; Best et al., 2018) have made efforts to incorporate the physical and visual effects of weather (Rosique, et al. 2019), e.g. modelling the effect of wet roads on tyre behaviour, and modelling visual effects representing various weather conditions, e.g. snow. For example, Halder et al., (2019) propose a realistic physics-based rain rendering pipeline and validate its appearance via photometric, qualitative and user study validation. However, the focus of such simulators with respect to perception is typically to model the impact of accurate weather effects on the sensor 'front-end' rather than the perception 'back-end'.

The combination of real-world testing and simulation development introduces the intriguing possibility of a third method: Augmented-reality testing - where weather augmentations are added directly into the perception pipeline of an AV being physically tested in the real world. Some work has been done on real-time ‘de-weathering’ (Hassan et al., 2020), however there are very few studies which deliberately attempt to worsen the perception in an autonomous vehicle in the real world - let alone an autonomous racing vehicle.

Ultimately, developing robust control systems relies precisely upon testing in non-ideal conditions, which cannot themselves be relied upon, and thus artificial worsening either in real world testing or simulation may be an attractive option - although such techniques will need to be simple and meet the strict real-time requirements of autonomous driving.

This paper explores the potential of applying 'drop-in' real-time augmentations to worsen perception system performance as part of a pipeline for both simulation and real-world testing in an autonomous racing vehicle.
2 Related work

2.1 Visually realistic weathering

There have been several approaches to artificially recreating weather effects. A popular method is to employ graphics-editing tools from existing open-source frameworks such as OpenGL (Praveen et al., 2017) to apply effects that simulate weather conditions. Models have been developed to simulate the rain by modeling the traversing of light through raindrops (Bernard et al., 2013), while Creus & Patow (2013) developed a photorealistic rendering of rain by modelling the dynamics of the raindrops. However, these engine-based approaches use sophisticated physics models - and thus are computationally expensive, and require significant knowledge of parameters specific to the conditions. Typically, these parameters are empirically determined by subjective assessment of the realism of the generated images. It is therefore an open question how accurately these model actual sensor degradation under adverse weather.

Recent advances in machine learning approaches to image processing have led to the development of methods that enable both weather appearance transfer and generation - with many approaches aimed at weather removal (Yang et al., 2020). Generative Adversarial Networks (and their variants) have been successfully used for de-weathering (i.e. de-raining, de-hazing) are Zhang et al. (2020), Porav et al. (2019), Porav et al. (2020), Anvari et al. (2020) and Uřičář et al. (2019), whereas weathering (i.e. adding fog) and light manipulation is done by Lin et al. (2019), Porav et al. (2018) and Dai et al. (2020). Whilst these AI approaches offer visually pleasing weather effects, they generally require hardware acceleration (GPUs), and extensive training datasets in each target weather condition. As a result, most of the work has been applied in offline urban or more general scenes, as opposed to the high-speed conditions of autonomous racing.

Though visually realistic, simulating the physics directly is computationally expensive and comes with no strong guarantee that it is better at modelling the downstream effect, and the machine learning approaches require extensive training data. Thus there is a need for a simpler, computationally cheaper methodology for simulating adverse weather, attuned to the downstream processing requirements. Such approaches include noise addition, rotations, translations, random cropping and flipping (Shorten et al., 2019). In this context, Rusak et al. (2020) explore Gaussian and a learned Adversarial noise to make neural networks more robust, while Moreno-Barea et al. (2018) explore both Uniform and Gaussian noise. Other effects, such as rain and fog, have been applied previously, with an emphasis on photorealism. For example, Volk et al. (2019) used classic augmentations including Gaussian noise or Salt-and-Pepper noise as a benchmark with which to compare their more complex physics-based rendering.

2.2 Modelling weather effect upon sensor & perception performance

In contrast to the studies above which largely focus on weather photo-realism, this study considers the impact of weather from the point of view of an integrated perception, mapping, and control pipeline. In such a pipeline, where components are connected through interfaces that abstract the functionality of other components, downstream systems are unaware of the source of their data. How the data is generated or how realistic the imagery is, is largely irrelevant: it only matters that the data produce similar behaviour in the systems concerned. In other words, it is not essential that the weather in the simulated images looks realistic; it is much more important that the effects of the modelled weather result in a realistic change in the performance of the perception system.
To this end, Hasirlioglu & Riener (2018) develop noise filters for camera, LIDAR and Radar sensors and compare them with rain streaks simulated in a test facility where the rain parameters (i.e. rain intensity, drop size distribution) can be controlled. Although initially the validation of the effects is done at sensor level, in a follow up paper (Hasirlioglu & Riener (2020)) they test object detection (using YOLOv3) as a function of the distance between the sensor and the object to be detected. Although the study highlights the opportunity to explore the use of similar modelling on simulated datasets, they present limited results in terms of applying the rain effects upon synthetic imagery.

A framework to simulate and analyse noise factors was proposed by Chan et al. (2020) to predict sensor performance degradation in autonomous vehicles, concluding that analysis of noise factors individually is insufficient, and as a result perception is drastically affected when multiple noises sources are combined. However, this study focuses upon LiDAR data rather than visual imagery. In a similar vein, Byeon & Yoon (2020) simulate the effects of rain on synthetic sensory data, again focusing on LIDAR sensors.

For the high performance requirements of an autonomous racing car, Zadok et al. (2019) perform weather augmentation including light intensity and cloudiness, distortions and lens flare reflection by modelling these effects directly into the simulation environment using Airsim. They achieve impressive visual representations which enabled them to train a vehicle to drive in the real world using end-to-end learning in a simulator. However, in the end-to-end approach, there is no introspection into the pipeline used for controlling the vehicle - and thus no way to measure, validate or quantitatively worsen the performance of a perception subsystem in response to weather conditions. Furthermore, this implementation of weathering effect is built into the simulation, and thus cannot be mapped into real-world testing.
3 Methodology

3.1 Method overview

The downstream processing algorithms for localisation, mapping, path planning and control are ignorant of the aesthetic appearance of the images produced by the camera - they simply receive identified objects, with range and centreline offset information. If the perception system is unable to identify an object accurately, downstream algorithms will receive incomplete or erroneous information and may cause location and map to diverge from reality.

Thus, the methodology developed in this study aims to create a pipeline of weather augmentations that can be run in real time. Rather than focussing upon accurately modelling the visual quality of weather effects, this study focuses on developing a model which accurately replicates the inference found in real-world weather conditions. The model is designed to be lightweight, introduce minimal latency to the system, and run using hardware suitable for carrying on-board in a racing vehicle to facilitate application to both simulation and real-world testing. The system can be run in online mode as part of the perception pipeline, or offline to post-process existing data into a range of identical scenes in different weather conditions.

The following sections describe the simulation environment used for this study, the perception system in operation on the vehicle, and the method of implementing the weather augmentations.

Both pathways (real and simulated) feed the perception pipeline, which forms the input for the localisation and mapping systems (not shown). The perception pipeline can receive either unmodified data from a simulated or real system, or data with weather augmentation superimposed. A separate comparison system acts as a test harness and records the difference between real and simulated inputs.

*Figure 1: Weather augmentations can be applied to both real and simulated camera feeds*
3.2. The software pipeline
This section describes the software setup and perception pipeline as illustrated in Fig.1. The majority of the software is a development of the work of Culley et al. (2020), and is developed in Python 3.8 (Python Software Foundation, 2019) utilising the ROS2-Foxy (Open Robotics, 2020) middleware layer to connect modules.

3.2.1 Replicating the real world
For testing, a number of real-world datasets were generated under various conditions. Simple circuits were laid out using cones (Fig. 2) and frames generated by lapping the track. The frames were then manually annotated to provide a basis for comparison.

Simulated replicas of real world testing scenarios were developed in the Gazebo simulator (Open Robotics, 2020) based upon manual measurements of tracks laid out using cones. Care was taken to replicate accurately the positions of the objects to be identified by the perception system (in this case cones) demarcating the boundaries of the test track, such that the structure is kept consistent and it does not play a role in the variation of performance. The methods of Ahamed et al. (2018), which simply modelled the circuit, were extended to provide a representation of the actual environment encountered by the vehicle and perception system, including salient surrounding objects and features.

![Figure 2: Test track layout (left) and surrounding environment modelled in simulation (right)](image)

3.2.2 Simulating the vehicle and sensors
The vehicle model and sensor behaviour simulation developed by Culley et al. (2020) was used as the basis for this study. This simulation was selected as it incorporates accurate models of the vehicle dynamic behaviour, and all sensors from the autonomous vehicle - including GPS, IMU, stereoscopic cameras, and LiDAR sensors. The simulator was run on an Intel 16-core Xeon processor and an Nvidia GTX 980 graphics card.

Since the focus of this study is on modelling the effects of weather upon vision-based sensors, the camera models in Gazebo were developed further to accurately replicate the real-world camera feed, including parameters defining the mounting position and angle of the camera upon the vehicle, horizontal / vertical field of view, CCD sensor size, focal length and frame rate. Culley et al. (2020)’s simple camera noise model was removed from the simulation, so that weather effects could be inserted as a post-process using the augmentations presented in the following sections.
3.2.3 Perception system

The perception system uses YOLOv3-tiny (Redmon and Fahradi 2018) to identify the objects of interest - in this case cones - from the camera input. Processing was undertaken at a resolution of 608×352, providing a balance between frame rate and object detection accuracy. The depth map from the camera is then used to provide visual range indication, and the system builds a map of cone locations in the body reference frame of the vehicle. This (local) map provides the input to the downstream localisation and (global) mapping subsystem.

3.3 Noise models

On the track, light conditions can deteriorate rapidly late in the day, and adherent droplets can occur if racing is taking place on wet surfaces - whether it is currently raining or not. Therefore, this study prioritises augmentations for low light conditions and water droplets on camera lenses.

The weather effects were replicated by employing image augmentation and deterioration using the Albumentations library (Buslaev et al., 2020) developed in PyTorch (Paszke et al., 2019), and Pillow - a basic image processing library (Pillow, 2021). This was selected as it contains a plethora of additional weather effects (such as rain, fog, shadow, snow, noise, histogram matching), allows for composable augmentations, and has been optimised for fast performance - making it ideally suited to real-time application in an autonomous racing vehicle.

It should be noted that the simulation of adherent droplets was achieved by using the library’s ‘fog’ effect, as it was empirically found to visually replicate them well in terms of randomness, transparency and size. The table below shows a description of the effects used and the latency incurred.

<table>
<thead>
<tr>
<th>Weather effect</th>
<th>Description</th>
<th>Control Parameter</th>
<th>Latency (ms)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adherent droplets</td>
<td>Randomly applies droplet effects (circles) onto image, with adjustable transparency</td>
<td>$k_{drolpet}$</td>
<td>8</td>
</tr>
<tr>
<td>Light dimming</td>
<td>Reduces the overall brightness of the image</td>
<td>$k_{dim}$</td>
<td>3</td>
</tr>
</tbody>
</table>

*Table 1: Augmented weather effects and latency incurred*

Although this study targets an overall worsening of perception performance, it is important to note that each augmentation operates in a very different manner - light dimming is applied uniformly across the entire image, while the droplets exhibit more random behaviour components, such as random positions for circles and randomly varying degrees of transparency. Thus each augmentation has a distinct effect upon the resulting degradation in perception system performance.

3.4 Dataset capture and generation

In order to establish the effects of the augmented weather conditions upon both real and simulated datasets, experimental data was gathered from both real world testing, and from the simulator. A series of keyframes were extracted from each video, and the landmarks (cones) within each keyframe manually labelled to provide a ‘ground truth’, against which the perception system’s object detection performance can be compared in a variety of different (real and augmented) weather conditions.

---

1 Calculated on an Intel(R) Core(TM) i7-10510U CPU @ 1.80GHz with 16 GB RAM; image resolution 672x376
3.4.1 Real-world experimental data
Experimental data was gathered by collecting successive camera data representing laps of two different circuits, in a variety of different real-world weather conditions including:

- ‘Ideal’ weather (i.e. bright but overcast, such that the objects are clearly visible, without excessive shadows or lens flare effects)
- Corresponding ‘ideal’ conditions with water droplets on the camera lens (manually added with a water spray)
- Low light conditions (taken in the early evening)

3.4.2 Simulator data
Datasets are composed of keyframes gathered from the simulator on simulated replicas of both circuits, developed using precise measurements from the real-world circuits, as described in Section 3.2.1. All simulations were performed without additional weather, under uniform lighting resembling bright, overcast weather, and a brightness and contrast adjustment was applied to the simulation output to obtain the highest possible performance from the perception system. Each of the weather effects can then be layered upon each successive frame of the simulator output to produce a composited ‘weathered’ image.

3.5 Experimental method

3.5.1 Semi-automated model parameter tuning
To facilitate rapid bulk testing, it is desirable to develop a simple parameter selection method for each weather augmentation such that parameters can be easily adjusted to replicate any given ‘real world’ environmental conditions. The following parameter tuning method describes this process.

1) Real world data is gathered (under real weather conditions, both ‘ideal’ and adverse), a set of keyframes extracted, manually annotated, and run through the perception pipeline to obtain a quantitative measure of perception performance in both ideal and weathered conditions.

2) The augmentation corresponding to the weather condition encountered is selected and its crucial parameter(s) swept to create a new series of datasets containing augmented degradation of real world images. The perception pipeline is run with these datasets to obtain a series of perception performance values for each parameter.

3) The simulator is set up with a track layout as close as possible to the real-world data. The same parameter sweep is performed for the same augmentation in simulation, and the results tabulated similarly to the real-world dataset.

4) The final parameters are chosen according to the value which matches across real-word, real-weather, real-world-augmented-weather, and simulated-world-augmented-weather.

It was found possible to make the degradation in perception system performance similar in both the real world and in simulation. The same parameter value was found to result in broadly similar degradation when applied to either real world data or simulated world, thus the parameters found from the real world can be carried over into simulation to approximate the performance in the real world, and vice-versa.
3.5.2 Experimental result generation
For the baseline, the pre-trained YOLOv3-tiny model and test it under ‘ideal’ illumination condition on both real and simulated data. These conditions yield uniform isotropic lighting with few shadows and high contrast, resulting in accurate detections of objects in the image - measured as a mean average precision (mAP). The first experiment involves testing the pre-trained object detector on simulated imagery with low light, generated using light dimming and then calculating the mAP. The second experiment involves testing the pre-trained cone detector on simulated imagery with simulated adherent raindrops, again calculating the mAP.

4 Results
Results were generated for both real camera and simulation output datasets. Augmentations were applied emulating the effect of adherent droplets on the camera lens, and poor lighting conditions using light dimming.

4.1 Adherent droplets
The adherent droplet augmentation provides an effect which generates simple circular occlusions in areas of the image, with varying degrees of transparency. The positions of the occlusions are random, which means that individual object detections within the image are confused randomly: some will be obscured while others may be unaffected. In addition to the occlusion, a slight blurring effect further impedes object detection across the entire image. The resulting degradation in perception system performance as the control parameter is varied is shown in Figure 3.

Increasing the strength of the effect produces a result analogous to greater moisture in the atmosphere - more droplets accumulate, resulting in a greater degradation in perception performance. Sweeps were run 5 times for each parameter value and averaged to produce the results shown.

![Figure 3: Effect of adherent droplet augmentation upon perception performance on real-world camera (left) and simulator output (right) - Solid line shows the mean of all sweeps](image)

The graphs above enable the identification of the parameter value which can be applied for use in the augmentation, resulting in either an augmented reality, or a simulation which delivers similar object detection performance to that of the real world.
The dimming parameter found using the data from the augmentations upon the real-world camera was applied to both the real-world image and that from the simulator, as in Figure 4, with the resulting bounding boxes detected by the perception algorithm.

Using a single approximated value of $k_{\text{droplet}}$ for augmentation of both real world and simulation provides similar mean average precision results from the perception system in both cases, differing by approximately 4%. Thus the parameter could be tuned using either of the two datasets and applied directly to the other to provide similar perception performance in conditions with adherent droplets.
4.2 Light dimming
In contrast to the random nature of the droplet augmentation, the light dimming effect provides a global worsening of the perception system performance, similar to that experienced in the real world as the light fades in the evening. As stronger effects are applied, the object detector performance drops significantly in both cases (Figure 5). When augmentations are performed upon simulated data, the object detection is relatively robust against the reduction in lighting, while those applied to real-word images result in a steeper roll-off of performance.

![Figure 5: Effect of light dimming augmentation upon perception performance on real-world camera (left) and simulator output (right)](image)

When applying the value of $k_{dim}$ identified using augmentations to replicate the reduction in perception performance in the real camera imagery, the augmented simulation returns a mAP approximately 7% higher than that from augmented reality.

Due to directional effects of the lighting and blurring in the real world, the edges of objects from the simulator remain more clearly defined than those from the real camera at low lighting levels. We believe that the detection of features representing edges / rough shapes within YOLO’s convolutional layers may be impaired more easily than with the crisp edges and uniform lighting in the simulator.

This augmentation can be individually tuned to deliver similar reductions in perception performance to the real weather conditions. However, the results suggest that for ultimate accuracy care should be taken when carrying across the $k_{dim}$ value between real and simulated conditions, and it may be necessary to consider additional work may be required in modelling effects such as camera blur or the camera automatically adjusting ISO sensitivity for changes in lighting. It should also be noted that the simulator used in this study provides relatively rudimentary graphics, and the use of more advanced simulator visuals may mitigate this effect.
Figure 6: Real and simulated camera imagery with corresponding low light augmentations

a) Real world, low light  
dataset mAP = 0.24
b) Real world, ideal conditions  
dataset mAP = 0.75
c) Augmented reality, \( \kappa_{成都市} = 0.77 \)  
dataset mAP = 0.26
d) Simulation, ideal conditions  
dataset mAP = 0.72
e) Augmented simulation, \( \kappa_{成都市} = 0.77 \)  
dataset mAP = 0.33
5 Discussion
The results obtained, although preliminary, indicate the potential to use simple and easily tunable image degradation methods to simulate the real-world effects of weather upon perception system performance. These effects can be applied as a post-process, thus existing datasets can be enhanced as easily as simulations performed de novo, and the simulator itself does not need to be loaded with additional (expensive) computational steps. The latencies introduced were minimal (~5 ms - Table 1) and can be applied in real time without noticeable impact on performance. Critical to the method is the observation that the qualitatively perceived 'realism' of the degradation is irrelevant - the goal is not specifically a believable visual representation, but instead a model that accurately replicates what will be received downstream by the perception system. Such effects are low-cost and could be easily applied to autonomous racing and other AV development applications without requiring investment either in complex proprietary weathering pipelines or expensive simulation hardware. Since the effects applied are not specific to a particular simulator or data interface, such a tool could be developed as a plugin for various simulation platforms.

An additional benefit of this technique is that the augmentations are applied as an intermediate part of the perception pipeline - and thus can also be applied to replicate the effects of adverse weather during real-world testing on an otherwise un-weatherproofed vehicle, deferring and reducing the need to protect the sensitive, potentially expensive on-board equipment from the actual effects of the weather - and thus accelerating development and reducing cost. With some further work, parameter values could be matched remarkably well between simulation and augmented real-world, thus an approximate value of the parameter can be found using whichever dataset has been labelled.

More work on validation and numeric confirmation of results is certainly necessary. Subject to data acquisition, future work will also examine a broader range of conditions, e.g. snow, heavy rain, etc. An improved perception pipeline with higher mAP both in real-world and simulated data is being developed using the techniques outlined here, and will form the basis of an iterative test suite to be refined and enhanced in further generations of the autonomous control system. Finally, thus far the experimental testing in poor weather has been applied strictly to simulated driving; in future the enhanced perception will be used to control the vehicle in a live autonomous racing environment, which will provide, it is hoped, the ultimate test of the perception pipeline's capabilities.

6 Conclusions
This study provides the following conclusions:

- A methodology has been developed to apply synthetic weathering effects to real or simulated data using simple noise models.
- The algorithms are low-latency (under 8 ms) and can be integrated into an autonomous racing vehicle running in real time on hardware that is suitable for on-board use within the vehicle.
- A quantitatively accurate degradation of the perception system performance can be required with adjustment of a single parameter for emulation of each weather condition.
- Similar parameter values can be used to simulate the effects of adverse weather conditions in both augmented-reality real-world driving and simulated driving.
- Use of this system allows for real-world testing in adverse weather, even when actual weather conditions are favourable.
- Use of simple techniques to artificially worsen perception can be used to aid the development of robust downstream systems for autonomous vehicle control.
