Abstract—Service federation in 5G/B5G networks enables
service providers to orchestrate network services across multiple
domains where admission control is a key issue. For each demand,
without knowing the future ones, the admission controller either
determines the domain to deploy the demand or rejects it in
order to maximize the long-term average profit. In this paper, at
first, under the assumption of knowing the arrival and departure
rates of demands, we obtain the optimal admission control
policy by formulating the problem as a Markov decision process
that is solved by the policy iteration method. As a practical
solution, where the rates are not known, we apply the Q-Learning
and R-Learning algorithms to approximate the optimal policy.
The extensive simulation results show the learning approaches
outperform the greedy policy, and while the performance of Q-
Learning depends on the discount factor, the optimality gap of
the R-Learning algorithm is at most 3-5% independent of the
system configuration.

sion Control, Markov Decision Process, Policy Iteration, Q-
Learning, R-Learning

I. INTRODUCTION

5G and beyond networks are expected to cost-effectively
support a wide range of services with diverse quality require-
ments. To this end, enabler technologies including Network
Function Virtualization (NFV), Software Defined Networking
(SDN), and massive MIMO as well as key architectural
principles like network slicing, softwarization, and multi-
domain orchestration are incorporated in the architecture of
the networks [1], [2].

Multi-domain orchestration enables the service provider, as
an administrative domain, to increase its business profit via
collaboration with other domains in a federated environment.
The federation contract between the local domain, which is the
consumer, and other domains provides extra resources for the
local domain at the cost of the federation. The resources are
used to deploy requested network services, i.e., a network slice
composed of a set of Virtual Network Functions (VNFs) and
virtual interconnecting links, in other domains. The consumer
domain may decide to deploy a demand in the provider
domains for different reasons such as the lack of sufficient
local resources, load-balancing, and cost-efficiency.

The admission controller of the local domain is responsible
to decide whether to locally accept the given demand, to
deploy it in a provider domain, or even to reject the demand.
in this paper, we consider business profit as the objective
of the admission control, and assume that there is only one
provider domain that rejects the demands beyond the agreed
federation quota specified in the contract. Under these assump-
tions, the admission controller should decide where to deploy
the requested services which arrive one-by-one over time to
maximize the profit of the local domain without knowing the
future demands. This problem is referred to as the Admission
Control for Service Federation (ACSF) throughout this paper.

This problem is challenging and trivial approaches like
greedily attempting to accept every demand do not provide the
optimal solution, which is justified by the simulation results.
The admission controller should carefully manage the local
resources as well as the federation quota to maximize the
profit. While various admission control policies and algorithms
in 5G networks have already been proposed [3], they consid-
ered single domain networks and consequently are not directly
applicable to the ACSF problem. This is the gap that we aim
to address in this paper.

Recently, AI/ML approaches have been extensively used
to manage and optimize communication networks [4]–[7].
Reinforcement learning is an appropriate solution to tackle
the ACSF problem via learning the optimal admission control
policy over time. The reinforcement learning based admission
control solutions have already been developed in other contexts
rather than the service federation problem [8]–[11]. In this
paper, we utilize a special category of reinforcement learning,
named average reward learning, to approximate the optimal
policy that maximizes the average profit of the local domain.
More specifically, we make the following contributions to the
ACSF problem:

• The ACSF problem is formulated as a Markov Decision
  Process (MDP), which is solved by the Policy Iteration
  Dynamic Programming (DP) method to obtain the theo-
  retical performance bound.

• An average reward based learning algorithm is developed
to approximate the optimal policy.

• Through the extensive simulations, the effects of the
different parameters including the local and provider
domain capacity, federation cost as well as offered load
are investigated.

• We show that the traditional and most commonly used Q-
  Learning algorithm does not perform well in ACSF due
to dependency on the discount factor.

The remainder of this paper is organized as follows. In
Section II we review the related work to the ACSF problem.
The assumptions, system models as well as the MDP formu-
ulation of the ACSF problem are presented in Section [III]. The model will be solved by the Policy Iteration (PI) algorithm in Section [IV]. We present the learning approaches in Section [V] and evaluate them through extensive simulations in Section [VI]. Finally, in Section [VII] we will conclude this paper and discuss future research directions.

II. RELATED WORK

In this section, we review the most related work to the ACSF problem and highlight the differences between this paper and the previous works.

Service federation is an ingredient component of the 5G and beyond networks architecture [1], [2]. The problem of service federation is formulated as a Integer Linear Programming model in [12], which is extended in the subsequent works to consider energy efficiency [13], [14] and network services latency [15]. From the implementation point of view, service federation was studied in [16] and [17]. The service federation component was developed as a part of the 5G-TRANSPORT (5GT) [18] platform that is capable of deploying network services spanning across multiple transport networks and realizes the federation vision via addressing the shortcomings in the ETSI specifications [19]. These theoretical researches as well as the practical developments do not attempt to address the admission control in service federation; i.e., they assume that the service has already be accepted and attempt to efficiently deploy it.

Using reinforcement learning (RL) for admission control has been the topic of previous works. Adaptive call admission control (CAC) in multimedia networks using RL approaches was studied in [8]. In the case of links with variable capacity, the CAC problem using RL solutions was investigated in [20]. In [9], the authors utilized the RL solution for CAC in CDMA networks. In [10], the admission control problem in cellular networks, and in [21] the slice admission control problem were formulated as MDP. Network slice admission control in single domain networks was studied in [11], [22]. While these works approach the admission control using RL solutions, they cannot be applied directly to the service federation problem since they consider single domain networks.

In the most recent work [23], we applied the Q-Learning method to the service federation problem. In this paper, we extend the work by formulating the problem as an MDP to obtain the optimal solution as well as proposing a new average-reward learning algorithm that surpasses the Q-Learning algorithm.

III. SYSTEM MODEL AND PROBLEM FORMULATION

In this section, after discussing the assumptions and system model, the ACSF problem is formulated.

A. Assumptions and System Model

In this paper, service federation between a local consumer domain and a provider domain is considered, where as mentioned, each requested service is a network slice composed of a set of VNFs and virtual interconnecting links. It is assumed that in the consumer domain, only one type of the resources (e.g., CPU) is the limited resource; the corresponding capacity is denoted by \( LC \). The domain provides set \( T \) types of services. Each type \( t \in T \) is denoted by \((w_t, r_t)\) in the service catalog, where \( w_t \) is the total amount of required resource by the VNFs of the service type, and \( r_t \) is the revenue that the provider gains if it accepts a demand of the type.

The provider domain reserved a resource quota for service federation. The amount of the quota, denoted by \( PC \), is agreed in the federation contract between the domains. Moreover, it also specifies federation cost \( \phi_i \) which is the cost of deploying an instance of the service type \( t \) in the provider domain. The cost should be paid by the consumer domain. Demands beyond \( PC \) will be rejected.

Over the time, customers request instances of the services. The total offered load is classified into a set of traffic classes \( I \). Each class \( i \in I \) is specified by tuple \((\lambda_i, \mu_i, w_i, r_i, \phi_i)\) where \( \lambda_i \) and \( \mu_i \) are respectively the arrival and departure rates of the demands of the class, which are assumed to be a Poisson process, and \( w_i, r_i, \phi_i \) are specified by the type of the requested service in the class. Accordingly, each demand \( \delta_i \) of class \( i \) is determined by \((\tau^i_s, \tau^i_e, w_i, r_i, \phi_i)\) where the \( \tau^i_s \) and \( \tau^i_e \) are the start and end time of the demand which are respectively specified by \( \lambda_i \) and \( \mu_i \).

Upon the arrival of the demand of class \( i \), the admission controller of the local domain should determine which domain to deploy the demand or reject it. To accept the demand in the local domain, the domain allocates \( w_i \) units of the local resources to the demand and earns \( r_i \) units of money. In the case of the federation, the demand is deployed in the provider domain; so, no resource is consumed in the local domain and it earns \( r_i - \phi_i \) units of money. If the demand is rejected, no resource is used and no revenue is made.

In the ACSF problem, it is assumed that there is a set \( D \) of demands which arrive one-by-one over the time. At the arrival time of a demand, the admission controller is not aware of the future demands, moreover, it does not know the expected lifetime of the given demand. The objective is to find an admission control policy that maximizes the average profit of the local domain which is

\[
\frac{1}{|D|} \sum_{i \in I} \left( \sum_{\delta_i \in \mathcal{L}} r_i + \sum_{\delta_i \in \mathcal{F}} (r_i - \phi_i) \right),
\]

where \( \mathcal{L} \) and \( \mathcal{F} \) are respectively the set of the demands which are deployed in the local consumer domain and in the federated provider domain.

It should be noted that the most commonly used greedy policy is not the optimal solution. Define \( LC \) and \( PC \) as the currently available local and provider domain capacities respectively. The greedy policy is as follows. The given demand \( \delta_i \) is accepted in the consumer domain if \( w_i \leq LC \), it is deployed in the federated domain if \( w_i > LC \) and \( w_i \leq PC \), and it is rejected if \( w_i > LC \) and \( w_i > PC \). This policy does not provide the optimal solution since it does not differentiate between demands. It may consume resources to admit resource-intensive long-running and low-profit demands
while the resources can be used to accept high-profit short-running demands in the future. We will justify this statement in Section VI. In the following sections, we aim to find policies that do better than the greedy policy and even perform optimally.

### B. MDP Model of ACSF

In this section, under the assumption of knowing $\lambda_i$ and $\mu_i$ for every class $i \in I$, the ACSF problem is formulated as a Markov decision process, which will be solved optimally in the next section to obtain a theoretical upper bound for the performance of practical solutions.

To formulate the problem as an MDP, it is needed to specify $S, A, P_a(s, s'),$ and $R_a(s, s')$ where $S$ is the set of the states, $A$ is the set of actions, $P_a(s, s')$ is the transition probability from state $s$ to state $s'$ if the agent takes action $a$ in the state $s$, and $R_a(s, s')$ is the reward of the action $a$ in state $s$ that leads to transition to state $s'$.

In ACSF, the state of the environment is defined as

$$s = (l, f, d),$$

where $l$ and $f$ are a vector wherein $i$-th element is the number of active/alive demands of the class $i$ in the local consumer domain and in the provider domain, respectively. Similar to $\bar{d}$, $d$ is a vector that $i$-th element is $+1$ if a demand of class $i$ is arrived, it is $-1$ if a demand of class $i$ departs the network, and 0 otherwise.

Let $S^+ = \{s \mid \exists i \text{ s.t. } d[i] = +1\}$ and similarly $S^- = \{s \mid \exists i \text{ s.t. } d[i] = -1\}$; we have

- $S = S^+ \cup S^-$ and $S^+ \cap S^- = \emptyset$.

- State $s = (l, f, 0)$ is an invalid state as there is not any arrival or departure. We only consider the states where there is an event (arrival or departure).

- State $s = (l, f, d)$ where $\exists i, j \text{ s.t. } d[i] \neq 0 \text{ and } d[j] \neq 0$ is an invalid state as two events cannot occur at the same time.

Please note that the admission controller, i.e., the agent in MDP, can only take an action in states $s \in S^+$; however, we consider states $s \in S^-$ in the MDP as these states correspond to the departure of demands wherein the capacity of the resources change. These states are used to facilitate deriving the transition probabilities, which is discussed in the following.

Actions available in each state $s$ are determined by the state, which is denoted by $A(s)$. If $s \in S^+$ where $\exists i \text{ s.t. } d[i] = +1$, i.e., a new demand of class $i$ arrives, the valid actions are reject, and if $LC \geq w_i$ then accept, and if $PC \geq w_i$ then federate. However, if $s \in S^-$ then the only valid action is an artificial action, named no_action, since in this case, the agent does not do any action and a demand departs.

As mentioned above, it is assumed that traffic class parameters $\lambda$ and $\mu$ are known that determine the transition rates. In MDP, the transition probabilities should be derived. According to the theory of competing exponentials, the probability of a transition in a state equals to the rate of the transition divided by the total transition rates in the state. The total transition rates of state $s = (l, f, d)$ is $\Lambda(s) + M(s)$ where

$$\Lambda(s) = \sum_{i \in I} \lambda_i$$

is the total arrival rate of demands in the state and $M(s) = \sum_{i \in I} (l[i] + f[i]) \mu_i$ is the total departure rate of the demands. Note that while $M(s)$ depends on $s$, $\Lambda(s)$ is independent of $s$.

Here, we assume that after making a decision in state $s = (l, f, d)$, immediately $l$ or $f$ changes to $l'$ or $f'$, i.e., the given demand is either deployed in the local domain, in the provider domain or leaves the system immediately after selecting the action and before occurring the next event. Then, the environment changes $d$ to $d'$, i.e., it brings up a new event, and consequently the state transfers from $s = (l, f, d)$ to $s' = (l', f', d')$. Under this assumption, to compute the transition probability from $s$ to $s'$, the total transmission rate of state $s'$ should be used instead of $s$ because the action in $s$ immediately determines the $l'$ or $f'$ and the rate of the next event depends on $l'$ and $f'$. So, in general, transition probability from $s$ to $s'$ will be the rate of the event divided by the total rates of the state $s'$.

To formulate the probabilities and rewards, let $e_j$ be a vector with a 1 in $i$-the element and 0 in the others. The transition probabilities and corresponding rewards are shown in Table I. The first row in the table is the case that a new demand of class $i$ arrives, so the state is $s = (l, f, e_i)$. The agent decides to reject it, hence, the reward is 0 and neither $l$ nor $f$ changes. If the next event is arrival of a demand from class $j$, then the new state $s'$ will be $(l, f, e_j)$ with probability of $\frac{\lambda_j}{\Lambda(s') + M(s')}$.

However, if the next event is departure of a demand of class $j$, the next state will be $s'' = (l, f, -e_j)$, the rate of this event is $(l'[j] + f'[j]) \mu_j$ which is shown in the second row of the table. The remaining rows of the table can be interpreted in this way. Theses transition probabilities and corresponding rewards are utilized in Section VI to find the optimal policy.

### IV. Optimal Policy by Dynamic Programming

In the previous section, the ACSF problem is formulated as an MDP that represents complete information of the environment dynamics. In this section, by utilizing the information via Dynamic Programming (DP), the optimal solution of the problem is found.

Policy Iteration (PI) algorithm is one of the DP approaches that iteratively solves the Bellman optimality equations [24]. It is depicted in Algorithm 1 where the parameter $\theta$ determines the precision and $\gamma$ is the reward discount factor. In the policy iteration loop, the given policy $\pi$ is evaluated by updating the state values $V(s)$ using the transition probabilities and rewards until to the given precision; then in the policy improvement loop, for each state, the old action $\bar{a}$ is compared against the new action obtained from the updated $V(s)$; if they are not the same then these two loops are iterated.

To solve the ACSF problem using the PI algorithm, an important issue needs to be addressed properly. The optimal policy found by this algorithm in fact optimizes $V(s)$ which is the discounted state values. Therefore, the policy is optimal with respect to the discount factor $\gamma$. Different values of $\gamma$ can/may lead to different policies. For example, if $\gamma = 0$ then the policy only aims to maximize the one-step/immediate

14:            stable \(\leftarrow false\)
15: return \(\pi\)

reward \(R_a(s, s')\) which is exactly the greedy policy does, and consequently, in this case, the optimal policy will be greedy policy.

In ACSF, the objective is to maximize the average profit defined by (1), which is, indeed, the average reward rather than the discounted reward optimized by the PI algorithm. While some DP methods have been proposed in the literature to find the optimal average reward policy, it is also known that by \(\gamma \rightarrow 1\), maximizing the discounted reward approximates the average reward [25]. So, in the ACSF problem, we set \(\gamma \approx 1\) to approximate the optimal policy. Note that \(\gamma\) must be less than 1 and setting \(\gamma = 1\) make the algorithm unstable as \(V(s) \rightarrow \infty\).

While the PI algorithm can find the optimal policy, in most practical circumstances, the arrival and departure rates of the demands are not known; moreover, the number of states exponentially grows in terms of \([2, LC,\) and \(PC\). Hence, the DP methods are not practical solutions. We will use them to obtain the theoretical performance bound for evaluating the practical solutions presented in the following sections.

V. Practical Solution via Learning

In this section, learning approaches are applied to the ACSF problem to deal with the issues of the DP approaches. These approaches instead of finding the optimal policy by exploiting the transition probabilities, learn the policy via interaction with the environment over time; therefore, they need neither the transition probabilities nor enumerating all the possible states.

A. Q-Learning

Q-Learning is one of the well-known reinforcement learning algorithms that use the concept of temporal difference to iteratively solve the Bellman optimality equations [24]. This algorithm keeps tracking a table of values of each action in each state, denoted by \(Q(s, a)\). Details of the algorithm are depicted in Algorithm 2 [24]. At state \(s\), the agent selects an action which is determined by the values \(Q[s, \cdot]\) and the exploration strategy. Then it observes the next state \(s'\), gets reward \(R_a(s, s')\) from the environment, and consequently updates the \(Q[s, a]\) as following

\[
Q[s, a] = (1 - \alpha)Q[s, a] + \alpha \left( R_a(s, s') + \gamma \max_{a'} Q[s', a'] \right),
\]

where \(\alpha\) is the learning rate. In this algorithm, \(n\) is the number of learning episodes and \(m\) is the number of demands in each episode.

The general Q-Learning algorithm is customized for the ACSF problem as follows. Action in each state is chosen by the \(\epsilon\)-greedy strategy that acts greedy with probability \(\epsilon\), i.e., selects the action with the maximum value; and with probability \((1-\epsilon)\), it selects a random action from \(\mathcal{A}(s)\). At the beginning of each episode, the values of parameters \(\alpha\) and \(\epsilon\) are decayed to rely more on the learned \(Q\) values over time. In the beginning, the large value of \(\alpha\) causes the agent to learn faster and the large value of \(\epsilon\) allows it to explore more. But later, decreasing these parameters in subsequent episodes forces the agent to pay more attention to the \(Q\) values that it has learned.
Algorithm 2 Q-Learning(n, m, α, γ, ϵ)
1: Arbitrary initialize $Q(s, a) \in \mathbb{R} \forall s \in S, \forall a \in A(s)$
2: for n times do
3: $α ← 0.99α$
4: $ε ← 0.99ε$
5: Reinitialize the environment
6: $s ←$ environment state (0, 0, d)
7: for m times do
8: $a ←$ action from $A(s)$ by ε-greedy strategy
9: $R_a(s, s') ←$ reward from the environment
10: $s' ←$ environment state
11: $R_a(s, s') ←$ reward from the environment
12: $Q[s, a] ← (1 - α)Q[s, a] + α\Big(R_a(s, s') +
\gamma \max_{a'}Q[s', a']\Big)$
13: $s ← s'$
14: $π(s) ← \arg\max_a Q[s, a] \forall s \in S$
15: return $π$

Unlike the parameters $α$ and $ϵ$, the proper setting of $γ$ is not straightforward. Similar to the PI algorithm, $γ = 0$ turns Q-Learning to the greedy policy; however, unlike PI, setting $γ → 1$ does not work well. In this case, the value of the next step, $\max_{a'}Q[s', a']$, significantly contributes in the value update equation of the algorithm; and consequently, the agent underestimates the importance of the immediate rewards $R_a(s, s')$. In the ACSF problem, it means that the agent undervalues the immediate profit of accepting demands in comparison to the value of the next state; and consequently, it tends to deploy the demands in the provider domain. This tendency is problematic in the case of large capacities where all demands can/should be locally accepted. The effect of $γ$ is evaluated in Section VII.

B. R-Learning

As discussed, discounting the rewards, which is needed in the Q-Learning algorithm, is problematic in the ACSF problem. To alleviate the issues, in this section, we apply the R-Learning algorithm [25] on the ACSF problem.

The details of the algorithm are shown in Algorithm 3. Due to the similarities between the Q-Learning and R-Learning algorithms, we omit the explanation of the common steps and only emphasize the differences. Contrary to the Q-Learning, the state-action values, $Q[s, a]$, are not the expected discounted reward. The key idea of the R-Learning algorithm is that in the infinite horizon and ergodic MDPs, the average reward, which is denoted by $ρ$ in the algorithm, is independent of the state. Therefore, the algorithm by $Q[s, a]$ keeps tracking the difference between $ρ$ and the expected average reward of action $a$ in state $s$. The $Q[s, a]$ value is updated according to the difference between the value and the expected average reward $ρ$ and the immediate reward $R_a(s, s')$ and also the value of the next step as follows.

$$Q(s, a) ← (1 - α)Q[s, a] + α\Big(R_a(s, s') - ρ\Big) + \max_{a'}Q[s', a']$$

This was not happen in PI because the rewards are scaled by the $P_a(s, s')$

Algorithm 3 R-Learning(n, m, α, β, ϵ)
1: Arbitrary initialize $Q[s, a] \in \mathbb{R} \forall s \in S, \forall a \in A(s)$
2: $ρ ← 0$
3: for n times do
4: $α ← 0.99α$
5: $ϵ ← 0.99ϵ$
6: $β ← 0.99/β$
7: Reinitialize the environment
8: $s ←$ environment state (0, 0, d)
9: for m times do
10: $a ←$ action from $A(s)$ by ε-greedy strategy
11: $Action a is performed by the environment$
12: $s' ←$ environment state
13: $R_a(s, s') ←$ reward from the environment
14: $Q[s, a] ← (1 - α)Q[s, a] + α\Big(R_a(s, s') - ρ\Big) + \max_{a'}Q[s', a']$
15: if $Q[s, a] = \max_a Q[s, a]$ then
16: $ρ ← (1 - β)ρ + β\Big(R_a(s, s') - \max_a Q[s, a] + \max_{a'}Q[s', a']\Big)$
17: $s ← s'$
18: $π(s) ← \arg\max_a Q[s, a] \forall s \in S$
19: return $π$

VI. SIMULATION RESULTS

In this section, we evaluate the performance of the reinforcement learning approaches in comparison to the greedy policy in terms of the average profit $\Pi$, and the optimality gap which is defined $(AP_{DP} - AP_{Alg})/AP_{DP}$ where $AP_{DP}$ and $AP_{Alg}$ are respectively the average profit of DP and the given algorithm. In the following, the effect of the capacity of the local domain, as well as provider domain, the effect of federation cost, and also, offered load will be investigated.

In these simulations, $γ = 0.99$ in PI, and $n = 200$, $m = 4000$, and $ϵ = 0.9$ in the learning algorithms. The default configuration of the domains and traffic classes are shown in Table II. The following results are the average of 10 experiments.

A. The Effect of the Number of Episodes

The Q-Learning and R-Learning algorithms learn the policy over time via interaction with the environment. The number of the episodes determines the length of the learning period. The performance of the algorithms with respects to the number of the episode $n$ are shown in Figures 1a and 1b.

The results show that after a number of episodes, both Q-Learning and R-Learning converge. The RL algorithm outperforms QL not only in terms of optimality gap, which is
Fig. 1: The performance of the R-Learning and Q-Learning (with $\gamma = 0.5$ and $\gamma = 0.9$) with respect to the number of episodes

less than 2%, but also in terms of the number of the episode needed to converge. These results also show the dependency of the performance of Q-Learning on the discount factor $\gamma$. In this setting, while at the beginning, QL with $\gamma = 0.5$ performs better than $\gamma = 0.9$, finally QL-0.9 converges to a better result.

B. The Effect of the Local Domain Capacity

The capacity of the local domain is the vital resource that the admission controller manages; it greatly influences the achievable profit. Figures 2a and 2b show the performance of the different policies with respect to the local domain capacity $LC$.

As it is seen, the performance of the R-Learning algorithm is excellent independent of $LC$. When the local domain has not sufficient resource to accept all the offered load, i.e., $LC < \sum (w_i \lambda_i / \mu_i)$, the intelligent decisions by the reinforcement learning algorithms greatly improve the performance in comparison to the greedy policy. In the case of very large capacities, all demands can be locally accepted, so the greedy algorithm is also the optimal policy. Again, the performance of the QL algorithm is affected by the discounting factor. As it is seen, a single value of $\gamma$ is not the best choice for all cases. In cases of small capacities, large $\gamma$ is better, but in the large capacities, it should be small. Obtaining the optimal value of the $\gamma$ is out of the scope of this paper and left for future work.

C. The Effect of the Provider Domain Capacity

Besides the local domain capacity, the quota reserved by the provider domain for federation is the second resource that the admission controller should utilize efficiently. In this section, the performance of the policies with respect to this parameter is studied. The results are shown in Figures 3a and 3b.

As it is seen, the results are almost similar to the results of the local domain capacity. Again, the performance of the R-Learning algorithm is excellent independent of $PC$. When the total capacity of the local and provider domain is not sufficient to admit (either in the local domain or in the provider domain) all the offered load, some demands should be rejected. The greedy approach cannot differentiate between the demands that causes the low-profit demands to use the resources which could be allocated for the high-profit demands; and as a result, there is a considerable gap in optimality. However, the intelligent decisions by the reinforcement learning algorithms improve the performance. Contrary to the local domain capacity, the greedy policy cannot use all the provider domain capacity effectively and there is a 10% optimality gap even in the case of very large $PC$. Again, the performance of the QL algorithm is determined by the discounting factor and a single $\gamma$ is not the best choice for all the cases.

D. The Effect of the Federation Cost

As mentioned, for each service type $t$ that agreed in the federation contract, the provider domain charges the consumer domain equals to $\phi_t$ per demand that is deployed in the provider domain. The admission controller should take this cost into account. For example, if the federation cost is very high, the optimal decision would be reject the demand. In this section, the admission control policies are evaluated with respect to the cost that is scaled by $\zeta$. Figures 4a and 4b show the average profit and the gap of the policies with respect to $\zeta$.

These results show that by increasing the federation cost, as expected, the profits of all policies decrease. The optimality gap of R-Learning is independent of the scale $\zeta$ that implies it considers the federation cost properly in the admission control process. The Q-Learning algorithm attempts to maintain the gap however it does not perform as good as R-Learning. The optimality gap of the greedy policy increases by enlarging $\zeta$ since the non-optimal decisions by the greedy policy incur more cost in the case of larger $\zeta$.
discounted rewards while the latter attempts to maximize the average reward. The extensive simulations show the excellent performance of the R-learning independent of system configuration.

For future work, the next steps would be obtaining the optimal value of $\gamma$, taking into account the capacity of the intra-domain links, considering more complicated federation contracts, and multiple provider domains. These changes will cause the exponential growth of the state space that justify applying the Deep Reinforcement Learning (DRL) solutions.

**E. The Effect of the Offered load**

The total offered load is another parameter that affects on the performance of the admission controller. In this section, by scaling the arrival rates of demands as $\ell \lambda$, the performance of the algorithms is investigated. The results are shown in Figures 5a and 5b.

In these results, it is seen that in the case of very small $\ell$, where all demands can be locally accepted as $L \lambda \ll \ell \sum (w_i \lambda_i / \mu_i)$, the greedy policy performs well. However, by increasing the offered load, some demands should be sent to the provider domain and eventually rejected. In these cases, the learning algorithms outperform the greedy policy by making smart decisions. Similar to the other results, the RL algorithm has a near-optimal performance. These results show that the appropriate value of the discounting factor $\gamma$ in Q-Learning also depends on the offered load. This makes finding the optimal value of $\gamma$ more challenging since it is assumed that $\lambda_i$ and $\mu_i$ are unknown.

**VII. Conclusion and Future Work**

In this paper, we investigated the ACSF problem, where a set of network service requests arrive one-by-one to the local domain, the admission controller of the domain should decide whether to locally accept the demand, to deploy it in the federated provider domain, or even to reject the demands. The optimal policy under the assumption of knowing the arrival and departure rates of the demands was obtained via solving the MDP model by the policy iteration algorithm. As a practical solution, we applied the Q-Learning and R-Learning algorithms to the problem where the former maximizes the
