Contextual Modal Types for Algebraic Effects and Handlers

NIKITA ZYUZIN, IMDEA Software Institute, Spain
ALEKSANDAR NANEVSKI, IMDEA Software Institute, Spain

Programming languages with algebraic effects often rely on effect annotations to track algebraic operations in a computation. This is particularly important in the presence of effect handlers, where handling of an effect may remove it from the annotation in the computation’s type.

In this paper we view the algebraic effect theory of a computation as a variable context, and track the effects directly in computation’s modal type with ECMTT, a novel calculus for algebraic effects and handlers. Our calculus supports computations with effects and derives from Contextual Modal Type Theory (CMTT), from which it inherits a number of important logical properties.

In contrast to type-and-effect systems, where effects are attached as annotations to a prior computational language, ECMTT tracks effects by a contextualized variant of the modal □ (necessity) operator of the intuitionistic modal logic of CMTT. In programming, the effect annotations are explicitly managed by the dedicated term constructors corresponding to the logical introduction and elimination forms for the modality. The modal foundation leads to customary logical properties of local soundness and completeness, and determines the operational semantics of ECMTT directly by β-reduction. In addition, effect handlers become a generalization of explicit substitutions, which in CMTT serve to reach one context from another.

To the best of our knowledge, ECMTT is the first system to relate algebraic effects to modal types. We also see it as a step towards providing a correspondence in the style of Curry and Howard that may transfer a number of results from the fields of modal logic and modal type theory to that of algebraic effects.

1 INTRODUCTION

Algebraic effects [Plotkin and Power 2002, 2003, 2001] represent effects in a computation as calls to operations from algebraic theories. Effect handlers [Pretnar and Plotkin 2013] specify how the operations should be interpreted when the computation using them executes. Together, algebraic effects and handlers provide a flexible way for composing effects in a computation, and for evaluating a computation into a pure value by handling all of its effects.

For example, to combine effects of state and exception in a computation it suffices to merely use the operations from the algebraic theory of state alongside the operations from the algebraic theory of exceptions. The task of interpreting the combination of effects is delegated to the point when the computation executes through a handler for the effects of both theories. This is in contrast to monads, where the semantics is provided upfront, and remains unchanged through execution.

Typically, a type system for algebraic effects keeps track of the algebraic theory of a computation through effect annotations, deriving a type-and-effect system. A call to an operation is annotated with the invoked effect, and the annotation then propagates to the type of the enclosing computation. Dually, handling removes the effect annotation.

In this paper, we propose to consider the scope of the operations used by a computation as its effect context. To this end, we adapt the tracking of contexts and operations over the terms containing them from the work on Contextual Modal Type Theory (CMTT) [Nanevski et al. 2008] that provides a generic typing discipline for programs considered in a context of variables.

In particular, CMTT derives a proof language for a contextual variant of intuitionistic modal logic S4, once the inference rules of this logic are annotated with proofs and given computational interpretation in the style of Curry-Howard correspondence. Modal logics in general reason about truth in a universe of possible worlds. In the S4 modal logic specifically, the key feature is the
propositional constructor $\square$ (called “necessity”, or “box” for short). The proposition $\square A$ is considered proved in the current world, if we can produce a proof of $A$ in every possible future world [Alechina et al. 2001; Benton et al. 1998; Pfenning and Davies 2001; Simpson 1994]. The derived computational interpretations resulted in type systems for staged computation [Davies and Pfenning 2001] and run-time code generation [Wickline et al. 1998].

The contextual variant further indexes, or grades, the necessity constructor with a context of propositions $\Psi$. The proposition $[\Psi]A$ is considered proved in the current world if we can produce a proof of $A$ in every possible future world, using only the propositions from $\Psi$ as hypotheses. The modality $\square A$ is recovered when the context $\Psi$ is empty. The computational interpretation transforms propositions to types, and considers the type $[\Psi]A$ as classifying programs of type $A$ that admit free variables from the variable context $\Psi$, and no others. The typing discipline has obtained calculi for meta-programming with open code [Nanevski and Pfenning 2005], for dynamic binding [Nanevski 2003a], for typed tactics and proof transformations in proof assistants [Pientka 2010; Stampoulis and Shao 2010; Stampoulis 2013], and has explained the notion of meta variable and related optimizations in logical frameworks [Pientka and Pfenning 2003].

Our key contribution in this paper is to show how the contextual typing discipline applies to algebraic effects, thus deriving a novel calculus for algebraic effects strongly rooted in modal logic and modal type theory. We name the resulting system Effectful Contextual Modal Type Theory, or ECMTT for short.

By connecting the disciplines of modal logic and of algebraic effects that have so far been disparate, we see this calculus as a first step towards transferring the ideas between them. For example, among other things, the work on (dependent) modal type theory has considered the polymorphism over contexts as first-class objects [Cave and Pientka 2013; Pientka 2008], which should have direct equivalent in polymorphism over effect theories [Biernacki et al. 2019; Hillerström and Lindley 2016; Leijen 2017]. Because of the foundation in modal logic, we also expect that our system will admit important logical properties and developments such as: Kripke semantics and normalization by evaluation [Bak 2017; Gratzer et al. 2019; Ilik 2013; Simpson 1994], proof search via cut-free sequent calculus (corresponding computationally to synthesizing programs with algebraic effects), equational theory, proof of strong normalization, scaling to dependent types [Ahman 2017; Gratzer et al. 2019], etc. We leave all of these considerations for future work.

1.1 Introducing contextual modality

To see how contextual types apply to algebraic effects, consider the algebraic theory of state with a single integer cell. As in related work on algebraic effects and handlers [Bauer 2018; Bauer and Pretnar 2015], this theory consists of the operations $\text{get} : \text{unit} \rightarrow \text{int}$ and $\text{set} : \text{int} \rightarrow \text{unit}$. The following program uses that theory of state, increments the state by 1, and has type $\text{int}$.  

$$ x \leftarrow \text{get} (); \_ \leftarrow \text{set} (x + 1); \text{ret} \; x : \text{int} $$

Intuitively, we model this theory as a variable context $\text{St} \triangleq \text{get} : \text{unit} \rightarrow \text{int}, \text{set} : \text{int} \rightarrow \text{unit}$, which is bound locally in the scope of the computation, and is also listed in the computation’s type:

$$ \text{incr} \triangleq \text{box St}. \; x \leftarrow \text{get} (); \_ \leftarrow \text{set} (x + 1); \text{ret} \; x : [\text{St}]\text{int} \tag{1} $$

The term constructor box is inherited from CMTT, and simultaneously binds all the variables from the provided variable context $\text{St}$. In this case, the effect operations $\text{get}$ and $\text{set}$ from $\text{St}$ become available for use within the scope of box. From the operational perspective, box thanks the enclosed programs. The boxed program does not execute until explicitly forced, and is considered

\footnote{As we shall see in Section 3, the technical details of our variable typing will differ somewhat, and will make use of several different typing judgements, but the above types for $\text{get}$ and $\text{set}$ in the context $\text{St}$ are sufficiently approximate for now.}
pure. The type $[St]A$ classifies computations that use operations from the theory $St$—but no other operations—and return a value of type $A$ upon termination. Of course, in general, we admit an arbitrary variable context (resp. algebraic theory) $Ψ$ to be bound by box and $[Ψ]A$, not just the concrete one $St$. The box constructor is the introduction form for $[Ψ]A$.

1.2 Context reachability

In a contextual type system one has to describe how the propositions from one context, say $Ψ$, can be proved from the hypotheses in another context, say $Ψ'$. When such proofs can be constructed, we say that $Ψ$ is reachable from $Ψ'$, or that $Ψ'$ reaches $Ψ$. As we shall see in Section 2, CMTT models context reachability using explicit substitutions. In ECMTT, we model context reachability somewhat differently, using effect handlers.

For example, the following is one possible handler for the algebraic theory $St$.

$$\text{handlerSt} \equiv (\text{get}(x, k, z) \to \text{cont} k z z, \text{set}(x, k, z) \to \text{cont} k () x, \text{return}(x, z) \to \text{return}(x, z))$$

As customary in languages for algebraic effects, an effect handler consists of a number of clauses showing how to interpret each effect operation upon its use in a computation. In the case of $\text{handlerSt}$, the clause for $\text{get}$ takes $x$ (of type $\text{unit}$) as the call parameter, $k$ as the continuation at the call site, and $z$ as the handler’s current state at the call site. It then calls $k$ with $z$ and $z$, thus modeling that $\text{get}$ returns the current value of the state (the first $z$), and proceeds to execute handling from the unmodified state (the second $z$). For $\text{set}$, the call parameter $x$ has type $\text{int}$, and the handler calls $k$ with $()$ and $x$, thus modeling that $\text{set}$ returns the (only) value $()$ of $\text{unit}$ type, and sets $x$ as the new state for the rest of the handling. The $\text{return}$ clause applies when the handled computation returns a value $x$ and ends in state $z$. In $\text{handlerSt}$, $x$ and $z$ are paired up and returned to the enclosing scope by $\text{return}(x, z)$.

This $\text{handlerSt}$ describes how to transform a program that uses the theory $St$ into a program with no effects, and it models state by passing it explicitly via continuation calls. Because its clauses use no effects, we can say that $\text{handlerSt}$ is a witness for $St$ reaching the empty algebraic theory (i.e., the empty context). Of course, it is perfectly possible for handler clauses to invoke operations from a non-empty theory as well. We shall see examples of this in Section 3.

1.3 Eliminating contextual modality

Following CMTT, we adopt a $\text{let}$-style constructor as an elimination form for the $[Ψ]A$ type. To illustrate how this form is used, consider the following program that handles the $St$ effects in $\text{incr}$ using $\text{handlerSt}$.

$$\text{let } \text{box } u = \text{incr} \text{ in handle } u \text{ handlerSt } 0$$

The reduction of this program binds the variable $u$ to the term inside $\text{box}$ in the definition of $\text{incr}$ in (1) and proceeds with the scope of $\text{let}$, where the term is handled with $\text{handleSt}$ starting from the initial state $0$. Overall, the program evaluates to $(0, 1)$, as we will illustrate in detail in Section 5.

This reduction for $\text{let}$-box is quite different from the one associated with monads and monadic bind. Unlike with monads, the body of $\text{incr}$ is not evaluated when $\text{incr}$ is bound to $u$, but is evaluated later, when $u$ is handled. In particular, if $u$ itself does not appear in the scope of $\text{let}$-box, or

---

In this paper, we don’t consider handler variables. Thus, when we write $\text{handlerSt}$ in the code, the reader should assume that the definition of $\text{handlerSt}$ is simply spliced in. Similarly for algebraic theories, e.g., $St$. Quantifying over variable contexts and explicit substitutions has been done in the related work on (dependent) contextual modal types [Cave and Pientka 2013], and should directly transfer to our setting with algebraic theories and effect handlers. We thus forego such addition here to focus on the more fundamental connections between modalities and algebraic effects.
$u$ appears boxed, then the computation bound to $u$ is not evaluated at all. For example, the following program which boxes over the empty algebraic theory (represented by the empty context $\cdot$), reduces to a box thunk, where the box prevents the handling of $\text{incr}$ from executing.

\[
\text{let } \text{box } u = \text{incr in box } \cdot \text{ handle } u \text{ handlerSt} 0
\]

This kind of reduction and let constructs are associated with comonads, and indeed the $[\Psi]$ modality of CMTT has been assigned a comonadic semantics [Gabbay and Nanevski 2013]. Similar reduction has also been considered in other modal calculi for (co)effects [Gaboardi et al. 2016; Nanevski 2003b, 2004; Orchard et al. 2019]. Therefore, while we do not consider the categorical semantics or the equational theory for our variant of $[\Psi]$A here, one of the contributions of this paper is observing that the comonadic elimination form applies to handling of algebraic effects as well.

## 2 REVIEW OF CONTEXTUAL MODAL TYPE THEORY

The typing rules of CMTT rely on a two-context typing judgment (Figure 1). The context $\Gamma$ contains the variables of the ordinary lambda calculus $x : A$, which we refer to as value variables, as they bind values in a call-by-value semantics. The context $\Delta$ contains modal variables $u :: A [\Psi]$ that are annotated with a type $A$, but also with a context $\Psi$ of value variables. Such a modal variable stands for a term that may depend on the (value) variables in $\Psi$, but no other value variables.

The term box $\Psi$. $e$ captures this dependence. It binds $\Psi$ in the scope of $e$, but also prevents $e$ from using any value variables that may have been declared in the outside context. This is formalized in the rule $[\square]I$ where, reading the rule upside-down, the context $\Gamma$ from the conclusion is removed from the premise. This means, in particular, that the following term is well-typed\(^3\)

\[
\vdash \text{box } x : \text{int}, y : \text{int}. \ (x + y) : [x : \text{int}, y : \text{int}] \text{int}
\]

while a term that under the box uses value variables other than those bound by box cannot be ascribed a type

\[
\not\vdash \lambda z : \text{int}. \text{box } x : \text{int}, y : \text{int}. \ (x + y + z)
\]

In Section 4 we will use a similar rule for ECMTT to capture that a term may contain effect operations from the algebraic theory $\Psi$, but not from an outside algebraic theory $\Gamma$.

However, box does not restrict the use of modal variables, as the premise and the conclusion of the $\square I$ rule share the $\Delta$ context. To introduce a modal variable into $\Delta$ one uses the

\[
\text{let } \text{box } u = e_1 \text{ in } e_2
\]

construct (rule $\square E$), which binds $u$ to the unboxed body of $e_1$ in the scope of $e_2$. For example, eliding the types and commas from iterated variable binding as customary in $\lambda$-calculus, if $e_1 = \text{box } x \ y. \ (x + y)$, then $u$ is bound to $x + y$, which is a term with free variables $x$ and $y$. In the scope of $e_2$, $u$ will be declared in $\Delta$ as $u :: int [x : \text{int}, y : \text{int}]$.

Because $u$ may be bound to a term with free variables from its associated context $\Psi$, one can use $u$ in a program only after providing a definition for all of the variables in $\Psi$. These definitions are given by explicit substitutions (rule $e\text{sub}$) that guard the occurrences of $u$ (rule $m\text{var}$). For example, the following term, in which $u$ is guarded by the explicit substitution $(x \rightarrow 5, y \rightarrow 2)$, is well-typed and evaluates to 7.

\[
\text{let } \text{box } u = \text{box } x \ y. \ (x + y) \text{ in } u \ (x \rightarrow 5, y \rightarrow 2)
\]  

\(^3\)In examples, we freely use standard types such as $\text{int}$ and product types, integer constants, and functions such as $+, \cdot$, pairing and projections, without declaring them in the syntax and the typing rules. They pose no formal difficulties.
Modal variable context
\[ \Delta ::= \cdot | \Delta, u :: A[\Psi] \]
Value variable context
\[ \Gamma, \Psi ::= \cdot | \Gamma, x : A \]

\[
\frac{x : A \in \Gamma}{\Delta; \Gamma \vdash x : A} \quad \text{VAR} \quad \frac{u :: A[\Psi] \in \Delta}{\Delta; \Gamma \vdash u[\sigma] : A} \quad \text{MVAR}
\]

\[
\frac{\Delta; \Gamma, x : A \vdash e : B}{\Delta; \Gamma \vdash \lambda x : A. e : A \rightarrow B} \quad \rightarrow I \quad \frac{\Delta; \Gamma \vdash e_1 : A \rightarrow B}{\Delta; \Gamma \vdash e_1 \circ e_2 : A} \quad \rightarrow E
\]

\[
\frac{\Delta; \Psi \vdash e : A}{\Delta; \Gamma \vdash \text{box } \Psi. e : [\Psi]A} \quad \square I \quad \frac{\Delta; \Gamma \vdash e_1 : A_1 \quad \cdots \quad \Delta; \Gamma \vdash e_n : A_n}{\Delta; \Gamma \vdash (x_1 \rightarrow e_1, \ldots, x_n \rightarrow e_n) : x_1 : A_1, \ldots, x_n : A_n} \quad \text{ESUB}
\]

Fig. 1. Typing rules of CMTT.

Because box does not restrict the use of modal variables, the following term, in which \( u \) occurs within a box, is also well-typed, with type \( \square \text{int} \), and it evaluates to box \((5 + 2)\).

\[
\text{let } \text{box } u = \text{box } x \cdot y \cdot (x + y) \text{ in } \text{box } \langle u \langle x \rightarrow 5, y \rightarrow 2 \rangle \rangle
\]

(3)

We emphasize that binding box \( \Psi. e_1 \) to a modal variable \( u \) via the \( \beta \)-redex

\[
\text{let } \text{box } u = \text{box } \Psi. e_1 \text{ in } e_2
\]

does not by itself cause the evaluation of \( e_1 \). Whether \( e_1 \) is evaluated depends on the occurrences of \( u \) in \( e_2 \). For instance, in the example term (3), \( u \) is thunked under a box. Thus, upon substituting \( u \) with \( x + y \), the explicit substitution \((x \rightarrow 5, y \rightarrow 2)\) executes to produce box \((5 + 2)\), after which the evaluation stops (i.e., boxed terms are values). In contrast, in the example term (2), \( u \) is not thunked, thus the evaluation proceeds for one more step to obtain 7. Moreover, \( e_2 \) may contain several occurrences of \( u \), some thunked and some not, and each guarded by a different explicit substitution. For example, the following is a well-typed term

\[
\text{let } \text{box } u = \text{box } x \cdot y \cdot (x + y) \text{ in }
\]

\[
(u \langle x \rightarrow 5, y \rightarrow 2 \rangle),
\]

\[
\text{box } x \cdot u \langle x \rightarrow 3, y \rightarrow x \rangle + u \langle x \rightarrow x^2, y \rightarrow u \langle x \rightarrow 2x, y \rightarrow 1 \rangle \rangle + x,
\]

\[
\text{box } x \cdot y \cdot u \langle x \rightarrow y, y \rightarrow x \rangle
\]

which evaluates to the triple

\[
(7, \text{box } x \cdot (3 + x) + (x^2 + (2x + 1)) + x, \text{box } x \cdot y \cdot y + x)
\]

of type \( \text{int} \times [x : \text{int}]\text{int} \times [x : \text{int}, y : \text{int}]\text{int} \). As mentioned in Section 1, this property of the \( \beta \)-reduction for \( \square \) is in contrast to monadic bind, which executes the bound computation before proceeding.

In general, local soundness for \( \square \) in CMTT is formalized as the \( \beta \)-reduction

\[
\text{let } \text{box } u = \text{box } \Psi. e_1 \text{ in } e_2 \mapsto_\beta e_2[e_1 // u]
\]

\[\text{When binding the empty variable context } \cdot, \text{ we abbreviate } [\cdot]A \text{ as } \square A \text{ and } \text{box } \cdot \cdot e \text{ as box } e.\]
where $e_2[ e;//u ]$ is a modal substitution. We elide its definition here (it can be found in [Nanevski et al. 2008]), but do emphasize its key property. Namely, upon modally substituting $e$ for $u$ in $u\langle\sigma\rangle$, the result is not the expression $e\langle\sigma\rangle$, but the expression obtained after directly applying the substitution $\sigma$ to $e$. We retain this design in ECMTT, where we develop a similar notion of modal substitution, except with context $\Psi$ generalized to an algebraic theory, and explicit substitutions replaced by effect handlers. In particular, handling in ECMTT will apply to terms with free variables, which will let us incorporate handling into $\beta$-reduction in Section 5.

We close the review of CMTT by noting that local completeness for $\Box$ in CMTT is formalized as the following $\eta$-expansion

$$e : [\Psi]A \leftrightarrow_\eta \text{let } \text{box } u = e \text{ in box } \Psi. u \langle \text{id}_\Psi \rangle$$

where $\text{id}_\Psi$ is the identity substitution for $\Psi$; that is, if $\Psi = x_1 : A_1, \ldots, x_n : A_n$, then $\text{id}_\Psi \equiv (x_1 \to x_1, \ldots, x_n \to x_n)$. ECMTT will introduce a definition of an identity effect handler and appropriately adapt the above $\eta$-expansion.

3 OVERVIEW OF ECMTT BY EXAMPLES

To support algebraic effects and handlers, we diverge from CMTT in several important aspects. We summarize these divergences in the syntax of ECMTT in Figure 2. In particular:

1. We introduce a category of (effectful) computations. These are terms that explicitly sequence bindings of algebraic operations and continuation calls, and terminate with a return of a purely-functional result. Our formulation is based on the judgmental presentation of monadic computations by Pfenning and Davies [2001]. The category of expressions is inherited from CMTT, and retains the purely-functional nature.

2. The context of value variables changes into effect context. It now contains effect operations $\text{op} \div A \Rightarrow B$ and continuations $k \div A \Rightarrow B$, each typed with a special new judgment. The modal type $[\Psi]A$ now classifies computations that use algebraic operations from the effect context $\Psi$, not purely-functional expressions as in CMTT.

3. The value variables move to the modal context. The intuition is that values, being purely-functional, can be regarded as computations in the empty effect theory. Thus, the typing $x : A$ can be considered as a special case of the modal typing $x :: A[-]$.

4. We replace explicit substitutions with handlers, and more generally, handling sequences, as we shall see. Similar to explicit substitutions, an effect handler binds a computation to each algebraic operation in a context $\Psi$. In each binding, a handler further provides access to the argument $x$ of the algebraic operation, and to the current continuation $k$, and to its current state $z$. A handler also provides a return binding that applies when handling $\text{ret } e$ terms.

We next illustrate ECMTT through concrete programming examples.

3.1 Effect contexts, algebraic theories and operations

Similarly to CMTT, the box constructor in ECMTT binds all the free variables in the underlying term, and it also blocks access to the free variables from the surrounding context. But in ECMTT, these free variables are algebraic operations (henceforth, simply operations), and the term under the box is a computation, not an expression. For example, we can box a computation that reads and returns the state using the algebraic theory $\text{St} \equiv \text{get } \div \text{unit } \Rightarrow \text{int} \div \text{set } \div \text{int } \Rightarrow \text{unit}$ from the introduction, as follows.$^5$

$$\text{box } \text{St} \cdot x \leftarrow \text{get } (); \text{ ret } x$$

$^5$Except, this time, we type the algebraic operations in $\text{St}$ with the actual variable judgment from ECMTT.
Modal context
\[ \Delta ::= \cdot \mid \Delta, u :: A[\Psi] \mid \Delta, x :: A \]

Effect context
\[ \Gamma, \Psi ::= \cdot \mid \Gamma, op \vdash A \Rightarrow B \mid \Gamma, k \bowtie A \Rightarrow B \]

Types
\[ A, B, S ::= P \mid A \rightarrow B \mid [\Psi] A \]

Expressions
\[ e ::= x \mid \lambda x : A. e \mid e_1 e_2 \mid \text{box } \Psi. c \mid \text{let } \text{box } u = e_1 \text{ in } e_2 \]

Computations
\[ c ::= \text{return } e \mid x \leftarrow s; \ c \mid \text{let } \text{box } u = e \text{ in } c \]

Statements
\[ s ::= \text{op } e \mid \text{cont } k e_1 e_2 \mid \text{handle } u [\Theta] h e \]

Handlers
\[ h ::= \text{return}(x : A, z : S) \rightarrow c \mid h, \text{op}(x, k, z) \rightarrow c \]

Handling sequences
\[ \Theta ::= \bullet \mid \Theta, (h, e, x, c) \]

Fig. 2. The syntax of ECMTT. In effect contexts, \( op \) ranges over algebraic operations, and \( k \) over continuations. \( \Psi \) ranges over effect contexts that are algebraic theories (i.e., that contain only algebraic operations and no continuations). \( P \) ranges over base types, including at least the singleton type \text{unit} with value (\( ) \).

Here, we apply the operation \text{get} on the argument of type \text{unit}, record the result in \( x \) and return \( x \) right away. The typing judgement \( \vdash \) for operations (i.e., variables) is new, and we use it to ensure that an operation can only be invoked in a computation, not in an expression, as expressions are purely-functional. We illustrate this typing discipline in detail in Section 4.

Importantly, box only binds contexts that contain operations (i.e., variables typed by \( \vdash \)), even though the new effect context \( \Gamma \) in ECMTT can also hold continuation variables (typed by \( \bowtie \)). We refer to the operation-only context as algebraic theory and we use \( \Psi \) to range over such contexts.

In the above example, \text{get} () is a statement, with \text{get} an operation and () its argument. Formally, statements are used with sequential composition, analogous to monadic bind
\[ x \leftarrow s; \ c \]
which binds the result of \( s \) to \( x \) and continues with \( c \). ECMTT features other forms of statements as well (e.g., continuation application and handling of modal variables), which we discuss later in this section. When the result of the statement is immediately returned, we abbreviate the computation into the statement alone. For example, we abbreviate the above term simply as
\[ \text{box } St. \text{ get} () \]

Of course, we retain the idea from CMTT that box prevents the use of outside operations. For example, the following term will not be well-typed (as we shall see in the typing rules of Section 4), because the inside box declares the empty algebraic theory as current. Thus it rules out calls to the operations from the outside theory \( St \) within the scope of the inside box.
\[ \text{box } St. \text{ box (get())} \]

3.2 Modal context, value variables and handling of modal variables

In ECMTT we move the value variables into the modal context \( \Delta \), reserving the context \( \Gamma \) for operations and continuations. This implements our intention that modal types in ECMTT track effects, not the use of value variables as in CMTT. Moving value variables into \( \Delta \) has the additional benefit that they now survive boxing. For example, consider the computation \text{incr} from the introduction, but this time we want to increment the state not by 1, but by a user-provided integer \( n \). We achieve this by \( \lambda \)-binding \( n \), and then invoking it under box.
\[ \text{incr}_n \equiv \lambda n : \text{int}. \text{box } St. x \leftarrow \text{get} (); y \leftarrow \text{set} (x + n); \text{ret } x \]
The resulting term $\text{incr}_n$ is an expression (i.e., it is purely functional), as it is a function whose body, being boxed, is itself an expression. Applying $\text{incr}_n$ to an integer reveals the boxed computation underneath. As in CMTT, `let-box` eliminates the box, and binds the computation to a modal variable, as in the following example

```
let box u = incr n in handle u handlerSt 0
```

which proceeds to handle the incrementing computation with `handlerSt` from the introduction.\(^6\)

Of course, we could have used any other handler for the theory $St$, just like we could guard a modal variable $u :: A[\Psi]$ in CMTT with any explicit substitution $\sigma$ that defines the variables from $\Psi$.

An important term that becomes expressible by moving variables into $\Delta$ is the following coercion of a value $\mu$ into a computation in a given theory $\Psi$, commonly known as \textit{monadic unit}.

\[
\lambda x:A. \text{box } \Psi. \text{ret } x
\]

### 3.3 Handlers

Effect handlers are similar to explicit substitutions in that they replace operation variables with computations that define them. But handlers also have important differences as well. In particular, operation clauses of a handler can manipulate the control flow of the target program by providing access to the current (delimited) continuation of the operation call. This facilitates a wide variety of effects [Pretnar 2015; Pretnar and Plotkin 2013], as we shall illustrate. In addition to continuations, our handlers provide access to \textit{handler state} which is shared between handler clauses, and can be updated through continuations. In the parlance of algebraic effects, we thus provide \textit{deep parameterized handlers} [Hillerström et al. 2020].

#### 3.3.1 Return clause. A handler in ECMTT always has a \textit{return} clause, which applies when the handled computation terminates with \textit{ret e}. The clause specifies how the handler processes $e$, together with the ending handler state of the computation. To illustrate, consider the following simple handler that consists only of a \textit{return} clause that produces a pair of the final result and state:

\[
\text{simple} \triangleq \text{return}(x, z) \rightarrow \text{ret } (x, z)
\]

This handler handles no operations; thus its theory is empty, and it only applies to computations over the empty theory. For example, we can run \text{simple} on \text{ret} 42 with initial state 5 as follows.

```
let box u = box (ret 42) in handle u simple 5
```

In the \textit{return} clause of \text{simple}, the \text{ret} value of 42 is bound to $x$ and 5 is bound to $z$ to further return (42, 5). If we used a handler with a \textit{return} clause that makes no mention of $x$ and $z$, e.g.,

\[
\text{simple} \triangleq \text{return}(x, z) \rightarrow \text{ret } 7
\]

then the same program returns 7 regardless of the initial state supplied to \text{handle} for $u$.

#### 3.3.2 Updating handler state. Handler state is modified by invoking continuations in operation clauses with new state values. To illustrate, consider an extension of \text{simple} with an operation $\text{op} \div \text{unit} \Rightarrow \text{int}$.

\[
\text{simple}^* \triangleq (\text{op}(x, k, z) \rightarrow \text{cont } k 1 (z + 4), \\
\text{return}(x, z) \rightarrow \text{ret } (x, z))
\]

The handler clause for \text{op} shows how \text{simple}^* interprets occurrences of $\text{op } e$ in a handled term: it binds the argument $e$ to $x$, the current continuation up to the enclosing box to $k$, the current handler

\(^6\)While the formal syntax for handling is handle $u [\Theta] h e$, by convention we elide $[\Theta]$ when $\Theta$ is empty, as it is here. We explain the need and the use of $\Theta$ in Section 3.5.
state to z, and proceeds with the clause body. In the clause body, the application \text{cont} k 1 (z + 4) indicates that k continues with 1 as the return value of \text{op}, and z + 4 as the new state. If we apply \text{simple}', with initial state 5, to \text{ret} 42, then handling returns (42, 5), as before. If we apply \text{simple}' with initial state 5 to the computation below that uses \text{op} non-trivially,

\begin{align}
y_1 \leftarrow \text{op} () ;
y_2 \leftarrow \text{op} () ;
y_3 \leftarrow \text{op} () ;
\text{ret} (y_1 + y_2 + y_3)
\end{align}

then handling returns (3, 17). To see this, consider that each call to \text{op} is handled by returning 1, and therefore all \( y_i \) hold 1. Each call to \text{op} also increments the initial state by 4. Thus, at the end of handling, when the \text{return} clause is invoked over \text{ret} \( (y_1 + y_2 + y_3) \), \( x \) and \( z \) variables of the \text{return} clause will bind 3 and \( 5 + 4 + 4 + 4 = 17 \), respectively, to produce (3, 17).

We can now revisit the handler for \text{St} from the introduction.

\[
\text{handlerSt} \equiv (\text{get}(x, k, z) \rightarrow \text{cont} k z z, \\
\text{set}(x, k, z) \rightarrow \text{cont} k () x, \\
\text{return}(x, z) \rightarrow \text{ret} (x, z))
\]

Because \text{get} is handled by invoking \text{cont} \( k z z \), it is apparent that the handler interprets \text{get} as an operation that returns the value of the current state \( z \) and continues the execution without changing this state. On the other hand, \text{set} \( x \) is handled by invoking \text{cont} \( k () x \); thus, the handler interprets \text{set} as returning () and changing the current state to \( x \), as one would expect.

3.3.3 Uncalled continuations. If an operation clause of a handler does not invoke the continuation \( k \), this aborts the evaluation of the handled term. For example, let us extend \text{simple}' with an operation \text{stop} \div \text{unit} \Rightarrow \text{int} \) that immediately returns a pair of 42 and the handler state.

\[
\text{simple}' \equiv (\text{op}(x, k, z) \rightarrow \text{cont} k 1 (z + 4), \\
\text{stop}(x, k, z) \rightarrow \text{ret} (42, z), \\
\text{return}(x, z) \rightarrow \text{ret} (x, z))
\]

If invoked on example (5) with the same initial state 5, \text{simple}' returns (3, 17) as before, since (5) does not make calls to \text{stop}. If we changed the middle call from \text{op} to \text{stop} as in

\begin{align}
y_1 \leftarrow \text{op} () ;
y_2 \leftarrow \text{stop} () ;
y_3 \leftarrow \text{op} () ;
\text{ret} (y_1 + y_2 + y_3)
\end{align}

then handling reaches neither the last \text{op}, nor \text{ret} \( (y_1 + y_2 + y_3) \). It effectively terminates after handling \text{stop}, to return (42, 9), as instructed by the \text{stop} clause of the handler. The state 9 is obtained after the initial state 5 is incremented by 4 through the handling of the first call to \text{op}.

Eliding continuations makes it possible to handle a theory of exceptions [Pretnar 2015]

\[
\text{Exn} \equiv \text{raise} \div \text{unit} \Rightarrow \bot
\]

A handler for \text{Exn}, such as the following one

\[
\text{handlerExn} \equiv (\text{raise}(x, k, z) \rightarrow \text{ret} 42, \\
\text{return}(x, z) \rightarrow \text{ret} x)
\]

cannot invoke \( k \) in the clause for \text{raise}, because \( k \) requires the result of \text{raise} as an input, which must be a value of the uninhibited type \( \bot \). As such an argument cannot be provided, the handler must terminate with some value when it encounters \text{raise}, thus precisely modeling how exceptions are handled in functional programming.
3.3.4 Non-tail continuation calls. So far, our example handlers either invoked the continuation variable $k$ as the last computation step (tail call), or did not invoke $k$ at all. In ECMTT, $k$ may be invoked in other ways as well.

To illustrate, consider the following handler for the theory $op, stop \rightarrow unit \Rightarrow int$ from before. The handler invokes $k$ in non-tail calls, to count the occurrences of $op$ and $stop$ in the handled term.

$$\text{handlerCount} = (op(x, k, z) \rightarrow y \leftarrow \text{cont } k \ 1 \ z; \ \text{ret } (\pi_1 \ y + 1, \pi_2 \ y),$$

$$stop(x, k, z) \rightarrow y \leftarrow \text{cont } k \ 1 \ z; \ \text{ret } (\pi_1 \ y, \pi_2 \ y + 1)$$

$$\text{return} (x, z) \rightarrow \text{ret } (0, 0))$$

To explain $\text{handlerCount}$, first consider the $\text{return}$ clause. Return clauses apply when handling values; as values are pure, they cannot call operations. Thus the $\text{return}$ clause of $\text{handlerCount}$ returns $(0, 0)$ to signal that a value contains 0 occurrences of both $op$ and $stop$.

Next consider the operation clauses. Each clause executes $\text{cont } k \ 1 \ z$ to invoke the current continuation $k$—which holds the handled variant of the remaining computation—with argument 1 and current state $z$.\footnote{Both 1 and $z$ are irrelevant for the execution of the example, but they make the example typecheck.} The obtained result, bound to $y$, is a pair containing the number of uses for $op$ and $stop$ in the the remaining computation. Each clause then adds 1 for the currently-handled operation to the appropriate projection of $y$. For example, handling (6) returns $(2, 1)$, as expected.

3.3.5 Multiply-called continuations. A handler clause in ECMTT may also invoke $k$ several times; in the literature such continuations are usually called multi-shot [Bruggeman et al. 1996]. This feature is useful for modeling the algebraic theory of non-determinism

$$\text{NDet} \equiv \text{choice} \rightarrow unit \Rightarrow bool$$

in which the operation $\text{choice}$ provides an unspecified Boolean value, as in the following program.

$$y \leftarrow \text{choice}(); \text{if } y \text{ then ret 4 else ret 5}$$

(7)

A handler for $\text{NDet}$ chooses how to interpret the non-determinism. For example, the handler below enumerates all the possible options for $\text{choice}$ and collects the respective outputs of the target program into a list. Here $\{x\}$ is a list with single element $x$, and $++$ is list append.

$$\text{handlerNDet} \equiv (\text{choice}(x, k, z) \rightarrow y_1 \leftarrow \text{cont } k \ \text{true } z; \ y_2 \leftarrow \text{cont } k \ \text{false } z; \ \text{ret } (y_1 ++ y_2),$$

$$\text{return}(x, z) \rightarrow \text{ret } \{x\})$$

Applying the handler to (7) returns the list $[4, 5]$.

3.4 Operations in handler clauses

Our example handlers so far used no outside operations, and thus handled into the empty theory. But in ECMTT handlers can handle into other theories as well. For example, the following is an alternative handler for $St$ which throws an exception whenever the state is set to 13; thus it uses the operation $\text{raise}$ and handles $St$ into the theory $\text{Exn}$.

$$\text{handlerExplosiveSt} \equiv (\text{get}(x, k, z) \rightarrow \text{cont } k \ z \ z, \text{set}(x, k, z) \rightarrow \text{if } x = 13 \text{ then raise } () \text{ else cont } k \ () \ x,$$

$$\text{return}(x, z) \rightarrow \text{ret } (x, z))$$

Using $\text{handlerExplosiveSt}$ to handle $\text{incr}_a$ 1 results in a computation from the theory $\text{Exn}$. The type system in Section 4 will require us to make the dependence on $\text{Exn}$ explicit. For example,
the following function \textit{explode} takes input \( m \) and builds a box thunk with \( \text{Exn} \). Within it, we use \textit{handlerExplosiveSt} over \( u \) with \( m \) as the initial state, and return the first projection of the result.

\[
\text{explode} = \lambda m. \text{let} \ b = \text{incr}_n 1 \text{ in}
\begin{align*}
\text{box Exn.} \ &x \leftarrow \text{handle} \ b \ \text{handlerExplosiveSt} \ m; \\
\text{ret} \ (\pi_1 x)
\end{align*}
\]

If we evaluate \( \text{explode} 0 \), we obtain \( \text{box Exn. ret 0} \) as follows. The unboxed body of \( \text{incr}_n 1 \) is first passed to \textit{handlerExplosiveSt} for handling with initial state 0. This results in the pair \((0, 1)\) indicating that \( \text{incr}_n 1 \) read the initial state, and returned the value read together with the incremented state. As we shall formalize in Section 5, the binding of the pair to \( x \) is immediately reduced, and the first projection is taken, to obtain \( \text{ret 0} \), which is finally thunked with box \( \text{Exn} \).

On the other hand, if we evaluate \( \text{explode} 12 \), then we obtain \( \text{box Exn. raise()} \), because the handling for the unboxed body of \( \text{incr}_n 1 \) with \textit{handlerExplosiveSt} terminates with \( \text{raise}() \) upon trying to set the state to 13.

We can proceed with handling by \textit{handlerExn} from initial state \( () \), as in

\[
\text{let} \ b = \text{explode} 0 \text{ in handle } b \ \text{handlerExn} ()
\]

where the \textit{return} clause of \textit{handlerExn} returns 0. Or, if we change the initial state to 12,

\[
\text{let} \ b = \text{explode} 12 \text{ in handle } b \ \text{handlerExn} () \tag{8}
\]

then the \textit{raise} clause of \textit{handlerExn} returns 42.

3.4.1 Identity handler. Given a theory \( \Psi \), the identity handler \( \text{id}_\Psi \) handles \( \Psi \) into itself, or more generally, into any theory that includes the operations of \( \Psi \). Following the definition of identity substitution of CMTT from Section 2, the identity handler is not an ECMTT primitive, but a meta definition, uniformly given for each \( \Psi \).

\[
\text{id}_\Psi \equiv (op_i(x, k, z) \rightarrow y \leftarrow op_i x; \ \text{cont} k y z, \ \text{return}(x, z) \rightarrow \text{ret} x)
\]

Each operation \( op_i \) of \( \Psi \) is handled by invoking it with the same argument \( x \) with which \( op_i \) is encountered, and passing the obtained result to the awaiting continuation. The \textit{return} clause also just further returns the encountered value. The handler state \( z \) is merely propagated by operation clauses, and thus doesn’t influence the computation. For convenience, we will thus consider that in \( \text{id}_\Psi \) the variables \( z \) are of type \text{unit}, and always invoke \( \text{id}_\Psi \) with initial state \( () \). Using the identity handler, we provide the ECMTT variant of \( \eta \)-expansion for modal types in analogy to that of CMTT in Section 2.

\[
e : [\Psi]A \rightarrow_\eta \text{let} \ b = e \text{ in box } \Psi. \ \text{handle} \ b \ \text{id}_\Psi()
\]

3.4.2 Combining theories. Suppose that we are given the function \textit{safeDiv} that implements division and raises an exception if the divisor is 0.

\[
\text{safeDiv} = \lambda x. \ \text{int.} \ \lambda y. \ \text{int. box Exn.} \ \text{if} \ y = 0 \ \text{then} \ \text{raise()} \ \text{else} \ \text{ret} \ (x/y)
\]

Obviously, the body of \textit{safeDiv} abstracts over the \textit{Exn} theory. Suppose that we now wanted to use \textit{safeDiv} in a program that also operates over state, i.e., over theory \( St \). One way to do so would be to handle the calls to \textit{safeDiv} by a handler, such as \textit{handlerExn} for example, that catches the exception and returns a pure value. But identity handlers provide another way as well. We can combine the theories of \( St \) and \( Exn \) on the fly into a common theory\footnote{We assume here that the combined theories don’t share operation names, and can thus be concatenated without clashes and variable shadowing, as indeed is the case for \( St \) and \( Exn \).}, and then simply delay
resolving exceptions to the common theory.

\[
divFromState \triangleq \text{box } St, \text{Exn. } y \leftarrow \text{get } ();
\]
\[
\text{let box } u = \text{safeDiv } 42 \text{ y in }
\text{handle } u \text{ idExn } ();
\]

For example, \( \text{divFromState} \) reads the current state into \( y \) and invokes \( \text{safeDiv} \) on 42 and \( y \), re-raising an eventual exception by handling with \( \text{idExn} \). The program \( \text{divFromState} \) explicitly boxes over both \( St \) and \( \text{Exn} \) to signal that the theories are combined into a common context.

### 3.5 Handling sequences

The reduction of computations in ECMTT requires a way to express how handlers compose. To see this, consider the following example, which slightly reformulates (8).

\[
\text{let box } o = \text{box } \text{Exn. (let box } u = \text{incr } 1 \text{ in }
\]
\[
x \leftarrow \text{handle } u \text{ handlerExplosiveSt } 12;
\]
\[
\text{ret } (\pi_1 x))
\]
\[\text{in handle } v \text{ handlerExn } ()
\]

This term reduces by first binding \( o \) to the whole computation under the \( \text{Exn} \) box. This immediately triggers handling of the boxed computation by \( \text{handlerExn} \), before any reduction in the computation itself. Therefore we must be able to handle all the subterms of the computation, including

\[
\text{handle } u \text{ handlerExplosiveSt } 12
\]

which already contains handling by \( \text{handlerExplosiveSt} \). Intuitively, we seek a way to compose the two handlers and produce an expression of the form

\[
\text{handle } u \ (\text{handlerExn } \circ \text{handlerExplosiveSt}) \ 12
\]

which records that eventual substitutions of \( u \) must first execute \( \text{handlerExplosiveSt} \) over the substituted term, followed by \( \text{handlerExn} \).

One may think that composing \( \text{handlerExn} \) and \( \text{handlerExplosiveSt} \) requires simply applying \( \text{handlerExn} \) to all the clauses of \( \text{handlerExplosiveSt} \); unfortunately, this is not correct.\(^9\) To illustrate, let us repeat the definition of \( \text{handlerExplosiveSt} \) from Section 3.4.

\[
\text{(get}(x, k, z) \rightarrow \text{cont } k \ z \ z,
\]
\[
\text{set}(x, k, z) \rightarrow \text{if } x = 13 \text{ then } \text{raise } () \text{ else cont } k \ () \ x,
\]
\[
\text{return}(x, z) \rightarrow \text{ret } (x, z))
\]

Seemingly, we could replace \( \text{raise } () \) in the \text{set}-clause with \( \text{ret } 42 \) as prescribed by \( \text{handlerExn} \), but that results in a handler which returns a pair in the \text{return} clause, and an integer in the \text{set}-clause. As will be evident from the typing rules in Section 4, such handler is ill-typed, as the return types must be consistent across all clauses.

Worse still, if, unlike \( \text{handlerExn} \), the outside handler actually calls its continuations, it is not clear what exactly the continuations should capture. For correct behavior, the continuations must capture the term being handled, but here we are trying to handle a clause of another handler, rather than a term to which both handlers apply. Thus we cannot use one handler inside the clauses of the other for composition.

We resolve the problem by introducing the \textit{handling sequence} \( \Theta \) into the syntax.

\[
\text{handle } u \ [\Theta] \ h \ e
\]

\(^9\)Incidentally, such direct approach works in CMTT for composing explicit substitutions [Nanevski et al. 2008], but handlers are much more involved than explicit substitutions.
The term stands for applications of handlers from the list $\Theta$, in sequence from left to right, on a term bound to $u$, followed by the handler $h$ running on the result, using initial state $e$. However to preserve handler applications, $\Theta$ cannot merely be a list of handlers. It must also record the initial state of handling and the computation that follows its statement for each handler in the list. Thus, for example, the immediate $\beta$-reduction of example (9) will be

\[
\text{let box } u = \text{incr}_n 1 \text{ in} \\
\text{handle } u [\text{handlerExplosiveSt}, 12, x. \text{ret} (\pi_1 x)] \text{ handlerExn ()}
\]

recording that $\text{ret} (\pi_1 x)$ is the immediate continuation of $	ext{handle}$ $u$ $\text{handlerExplosiveSt}$ 12 in (9).

Finally, the need for handler sequences arises only when expressing the intermediate results of program reduction, and we do not expect that a user of our system will ever write them by hand. The simplified syntax without $\Theta$ suffices for source code examples.

### 4 TYPING

ECMTT uses the following variable judgements:

- $x : A \in \Delta$ : expressions of type $A$
- $u :: A[\Psi] \in \Delta$ : computations of type $A$ in an algebraic theory $\Psi$
- $op \div A \Rightarrow B \in \Gamma$ : operations with input type $A$ and output type $B$
- $k \div A \Rightarrow B \in \Gamma$ : continuations with input type $A$, state type $S$, and output type $B$

We also have a separate judgement for each of the syntactic categories:

\[
\begin{align*}
\Delta; \Gamma \vdash e : A & \quad e \text{ is an expression of type } A \\
\Delta; \Gamma \vdash c \div A & \quad c \text{ is a computation of type } A \\
\Delta; \Gamma \vdash s \div sA & \quad s \text{ is a statement of type } A \\
\Delta; \Gamma \vdash h \div A[\Psi] \Rightarrow B & \quad h \text{ is a handler for computations of type } A \text{ in an algebraic theory } \Psi \text{ that uses state parameter of type } S \text{ and handles into computations of type } B \\
\Delta; \Psi \vdash \Theta \div A[\Psi'] \Rightarrow B & \quad \Theta \text{ is a handling sequence for computations of type } A \text{ in an algebraic theory } \Psi' \text{ that produces computations of type } B
\end{align*}
\]

We show the typing rules of ECMTT on Figure 3. Let us review their key parts:

1. The variable typing rules $\text{VAR}$, $\text{OP}$, $\text{CONT}$ and $\text{MVAR}$ are grouped first. The rule $\text{MVAR}$ guards a modal variable $u$ with a handling sequence $\Theta$, handler $h$, and initial state $e$. It ensures that the context $\Psi$ of $u$ matches the range theory of $\Theta$, and that the context $\Psi'$ of $h$ matches the range theory of $h$. Thus, the handling of $u$ proceeds by $\Theta$, then $h$. The judgment for handling sequences formalizes this intermediary role of $\Theta$ by using theory $\Psi'$ for its effect context, as opposed to the more general effect context $\Gamma$.

2. The rules dealing with function and modal types are almost unchanged from CMTT. The only distinctions are that $\Box I$ now boxes computations instead of expressions, and that we also have a rule $\Box E$-COMP that eliminates modal types into computations. The latter is a standard feature of $\text{let}$-forms in calculi with multiple judgments [Pfenning and Davies 2001].

3. The $\text{RET}$ rule coerces pure expressions into computations, while the $\text{BIND}$ rule sequentially composes a statement $s$ with a computation $c$. Notice that the term $\text{ret } e$ is a computation, not a statement. Thus, strictly speaking, the syntax $x \leftarrow \text{ret } e; c$ is not valid in ECMTT.
This is not a restriction in programming, as the intended behavior can be introduced as a syntactic sugar via boxing.\(^{10}\)

\(^{10}\)One solution is \(x \leftarrow \text{ret } c; c \equiv \text{let box } u = \text{box } (\text{ret } e) \text{ in } x \leftarrow \text{handle } u \text{ id } () ; c\), and there are others.
(4) The rules \texttt{RETH} and \texttt{OPH} deal with building handlers. \texttt{RETH} is the base case, giving a handler for the empty theory \( \cdot \) which thus contains only the \texttt{return} clause. \texttt{OPH} is the inductive case, adding a clause for a new operation \texttt{op} to a handler \( h \), thus extending \( h \)'s theory \( \Psi \) with \( \texttt{op} \div A \Rightarrow B \). We add new clauses to the right, but retain the syntax from Section 3, where the \texttt{return} clause is presented as the last in a handler.

(5) The rules \texttt{EMPH} and \texttt{SEQH} deal with building handling sequences. \texttt{EMPH} gives an empty sequence, and \texttt{SEQH} adds a handler clause to \( \Theta \), ensuring proper sequencing, i.e., that the theory \( \Psi' \) of the added handler \( h \) matches the effect context of \( \Theta \).

4.1 Examples

We illustrate the typing rules of ECMTT by showing a few example typing judgments and derivations. We assume the theories of state and exceptions from Section 3.

\[
\begin{align*}
\text{St} &\equiv \text{get} \div \text{unit} \Rightarrow \text{int}, \text{set} \div \text{int} \Rightarrow \text{unit} \\
\text{Exn} &\equiv \text{raise} \div \text{unit} \Rightarrow \bot 
\end{align*}
\]

(1) \( \vdash \text{box St. get () : [St]int} \)

(2) \( \vdash \lambda n. \text{box St. (x } \leftarrow \text{ get () ; y } \leftarrow \text{ set (x + n) ; ret x) : int } \rightarrow [\text{St}]\text{int} \)

(3) \( \not\vdash \text{box St. (get ()) } \)

(4) \( \vdash \text{handlerSt } \div \text{int[St]} \Rightarrow \text{int } \times \text{int} \)

(5) \( \vdash \text{handlerExn } \div \text{int[Exn]} \Rightarrow \text{unit} \)

(6) \( \text{Exn} \vdash \text{handlerExplosiveSt } \div \text{int[St]} \Rightarrow \text{int } \times \text{int} \)

(7) \( \text{Exn} \vdash (\text{handlerExplosiveSt,12,x. ret } (\pi_1 x)) \div \text{int[St]} \Rightarrow \text{int} \)

(8) \( u :: \text{int[St]} :: \vdash \text{handle u [(handlerExplosiveSt,12,x. ret } (\pi_1 x))] \text{ handlerExn } (\cdot) \div \text{int} \)

(9) \( \text{If } \Psi \subseteq \Psi', \text{ then } \Psi' \vdash \text{id}_\Psi + A[\Psi] \Rightarrow A \)

(10) \( \text{If } \Psi \subseteq \Psi', \text{ then } \vdash \lambda e. \text{let } \text{box u } = e \text{ in } \text{box } \Psi'. \text{ handle u id}_\Psi (\cdot) : [\Psi]A \to [\Psi']A \)

(11) \( \vdash \lambda x. \text{box } \Psi. \text{ret x : A } \to [\Psi]A \)

(12) \( \vdash \lambda f. \lambda x. \text{let } \text{box u } = f \\
\text{ box v } = x \\
\text{ in } \text{box } \Psi. a \leftarrow \text{handle u id}_\Psi (\cdot); \\
\text{ b } \leftarrow \text{handle v id}_\Psi (\cdot); \\
\text{ ret (a b) : [\Psi]A } \to [\Psi]A \)

(13) \( \vdash \lambda x. \text{let } \text{box u } = x \text{ in } \\
\text{ box } \Psi. a \leftarrow \text{handle u id}_\Psi (\cdot); \\
\text{ let box v } = a \text{ in } \text{handle v id}_\Psi (\cdot) : [\Psi][\Psi]A \to [\Psi]A \)

4.1.1 Typing computations. Derivation (1) shows that we can invoke an operation declared in the current theory. The derivation expands the syntactic sugar whereby the computation consisting of a statement \( s \) actually abbreviates \( x \leftarrow s; \text{ret x} \).

\[
\frac{
\begin{array}{c}
\text{get } \div \text{unit} \Rightarrow \text{int } \in \text{St} \\
\text{St} \vdash (\cdot) : \text{unit} \\
\text{ Let } x : \text{int}; \text{St} \vdash x : \text{int} \\
\var{\text{VAR}} \\
\text{St} \vdash x \leftarrow \text{get () ; ret x } \div \text{int} \\
\text{Let } \text{box St. get () : [St]int} \\
\end{array}
}{
\text{\textcircled{l} \text{BIND}}}
\]
On the other hand, we can try to derive (3) as follows

\[ \not \vdash \text{get}() : \text{int} \]
\[ \not \vdash \text{box (get()) : [\cdot | \text{int}] int} \]
\[ \not \vdash \text{box St. box (get()) : [St | \cdot | \text{int}] int} \]

but the derivation tree cannot be completed because \text{get} does not appear in the effect context available at the top.

4.1.2 Typing handlers. Next consider the derivations (4-6). In the handler typing judgment, the declared components \( A[\Psi] \Rightarrow B \) should be understood as an input that guides the rest of derivation, and determines the types of the variables bound in operation clauses. For example, let us show why (4) holds. Recall the definition of \text{handlerSt}.

\[ \vdash (\text{get}(x, k, z) \rightarrow \text{cont } k \ z \ z, \]  
\[ \text{set}(x, k, z) \rightarrow \text{cont } k () x, \]  
\[ \text{return}(x, z) \rightarrow \text{ret} (x, z) \div \text{int}[St] \Rightarrow \text{int } \times \text{int} \]

in the typing of the \text{return} clause we have to assume \( x : \text{int} \), as \text{int} is the declared input type of the handler, and \( z : \text{int} \), as \text{int} is the declared type of handler state. The clause returns a pair of type \( \text{int } \times \text{int} \), which matches the result type of the handler, by rule \text{RETH}.

Similarly, in the typing of the \text{get} clause, we must assume

- \( x : \text{unit} \), as \text{unit} is the input type of \text{get in St}.
- \( k \vdash \text{int} \Rightarrow \text{int } \times \text{int} \). The first \text{int} is the result type of \text{get in St}. The second \text{int} is the declared type of handler state. The result type of \text{get} matches the declared result type of the handler.
- \( z : \text{int} \) because \text{int} is the declared type of handler state.

Under these assumptions, \( \text{cont } k \ z \ z \) has type \( \text{int } \times \text{int} \) by rule \text{CONT}, matching the result type of the handler by rule \text{OPH}.

4.1.3 Typing handling sequences. The starting point for derivation (7) is the judgment (6) of \text{handlerExplosiveSt}. In sequence (7), we are providing 12 as the initial state, thus matching the type \( \text{int} \) of handler state of \text{handlerExplosiveSt}. We are also providing continuation \( x, \text{ret} (\pi_1 x) \), which modifies the output type \( \text{int } \div \text{int} \) of \text{handlerExplosiveSt} into the output type \( \text{int} \) of the sequence (7).

This modification of the output type of (7) into \( \text{int} \) is essential to typecheck (8). By the typing rule \text{OPH}, the output type of a sequence must match the input type of the extending handler, and in our case, \( \text{int} \) is \text{handlerExn input type by derivation (5)}.

4.1.4 Generic modal typing derivations. Derivation (9) is easy to establish by induction on \( \Psi \). Then derivation (10) shows that we can coerce a computation from theory \( \Psi \) into a larger theory \( \Psi' \). In the special case when \( \Psi' = \Psi \), the derivation establishes the validity of \( \eta \)-expansion for modal types, i.e., local soundness. We show derivation (10) in some detail below, assuming derivation (9) and weakening in \( \Gamma \) and \( \Delta \). We also elide the first steps involving \( \lambda \), as they are standard.

\[ \Delta, u :: A[\Psi]; \Psi' \vdash \text{id}_\Psi \div A[\Psi] \Rightarrow A \]
\[ \Delta, u :: A[\Psi]; \Psi' \vdash () :: \text{unit} \]  

\[ \Rightarrow \]  
\[ \Delta; \Gamma \vdash ; e : [\Psi] A \]
\[ \Delta; \Gamma \vdash \text{let } box u = e \text{ in box } \Psi', \text{handle } u \text{ id}_\Psi () :: [\Psi'] A \]
\[ \Delta; \Gamma \vdash \text{MVAR} \]

\[ \Delta; \Gamma \vdash \text{MINVAR} \]

\[ \Delta; \Gamma \vdash \text{MINVAR} \]
Derivations (11-13) show that the modal type $[Ψ]A$ satisfies the usual functions required of monads in programming. Derivation (11) shows that a value of type $A$ can be coerced into a computation of type $[Ψ]A$. Derivation (12) shows that a function application is stable under algebraic theory; that is, if a function and the argument share the algebraic theory, so will the result. This is property $K$ of modal logic. Finally, derivation (13) shows that iterated modalities can be coalesced. This is property $C4$ of modal logic.

5 REDUCTIONS AND SUBSIDIARY OPERATIONS

As in CMTT, $β$-reduction of modal types is the key notion in ECMTT. This, together with $β$-reduction on function types, is the basis for the operational semantics of our language (we present it in Figure 6).

```
let box u = box Γ. c₁ in c₂ →β e₂[c₁//u]
let box u = box Γ. c in e →β e[c//u]
```

The reduction depends on modal substitutions $c₂[c₁//u]$ (resp. $e[c//u]$), which substitute a computation for a modal variable $u$ in a computation (resp. expression). We define modal substitution in the Appendix A, and in this section illustrate it on an example, along with a number of subsidiary operations (Figure 4) that modal substitution invokes. These operations are:

- **Monadic substitution** $\{c'/x\}c$ sequentially composes $c'$ before $c$, using variable $x$ as the connection. The definition follows closely a similar notion from Pfenning and Davies [2001].
- **Continuation substitution** $c[x.y. c'/k]$ replaces the continuation variable $k$ in $c$ with a computation $c'$ that binds variables $x$ and $y$.
- **Handling** $⟨c⟩^h$ applies the handler $h$ over computation $c$, using $e$ as the current state.
- **Handling sequencing** $⟨c | Θ⟩$ applies the handling sequence $Θ$ to the computation $c$.
- **Expression substitutions** $c[e/x]$ and $e'[e/x]$ replace an expression $e$ for variable $x$ into computation $c$ and expression $e'$ respectively. The last two are standard notions, so we use them without an explicit definition.

5.1 Example

We illustrate all these notions by tracing the reduction steps of

```
let box u = incr₁ 1 in handle u handlerSt 0
```

We present the steps on Figure 5 and we also comment on them below.

In the first step (11), we unfold the definition of $incr₁$ and apply the $β$-reduction to reveal a modal substitution for the variable $u$ into $(x' ← handle u handlerSt 0; ret x')$. Of course, the latter computation represents the scope of the initial let-box term, expanding the syntactic sugar for statements.

In the next step (12), the modal substitution applies handling with $handlerSt$ with given state over the application of the empty handling sequence on $u$. This proceeds by the following characteristic definition case for modal substitution

```
(x' ← handle u [Θ] h e; c'[c//u]) = {⟨⟨c [Θ[c//u]]⟩⟩ h[e//u]}(c'[c//u])
```

In other words, we first substitute $c'$ for $u$ in all the subterms. As customary, we ensure that $c'$ does not contain free occurrences of variable $x'$ (thus incurring capture), by $α$-renaming $x'$ if necessary. In the expression (11), $u$ does not occur in the subterms, thus the modal substitutions are vacuous, and we directly obtain (12).

In the next step (13), the empty handling sequencing immediately resolves according to the definition in Figure 4d, and proceeds to handling with $handlerSt$. 

\[
\{ \text{ret } e/x \} c = c[e/x]
\]
\[
\{ y \leftarrow s; \ c'/x \} c = y \leftarrow s; \ \{ c'/x \} c
\]
\[
\{ \text{let } box \ u = e \ in \ c'/x \} c = \text{let } box \ u = e \ in \ \{ c'/x \} c
\]

(a) Monadic substitution.

\[
(\text{ret } e)[x.y. \ c \cdot k] = \text{ret } e
\]
\[
(x' \leftarrow \text{op } e; \ c')[x.y. \ c \cdot k] = x' \leftarrow \text{op } e; \ c'[x.y. \ c \cdot k]
\]
\[
(x' \leftarrow \text{cont } k \ e_1 \ e_2; \ c')[x.y. \ c \cdot k] = c[e_1/x][e_2/y/x']c'
\]
\[
(x' \leftarrow \text{cont } k' \ e_1 \ e_2; \ c')[x.y. \ c \cdot k] = x' \leftarrow \text{cont } k' \ e_1 \ e_2; \ c'[x.y. \ c \cdot k]
\]
when \( k \neq k' \)

\[
(\text{let } box \ u = e \ in \ c')[x.y. \ c \cdot k] = \text{let } box \ u = e \ in \ c'[x.y. \ c \cdot k]
\]
\[
(x' \leftarrow \text{handle } u \ [\Theta] \ h \ e; \ c')[x.y. \ c \cdot k] = x' \leftarrow \text{handle } u \ [\Theta] \ h[x.y. \ c \cdot k] \ e; \ c'[x.y. \ c \cdot k]
\]

(b) Continuation substitution.

\[
\langle \text{ret } e' \rangle^h_e = c[e'/x][e/z] \quad \text{where } \text{return}(x, z) \rightarrow c \in h
\]
\[
\langle y \leftarrow \text{op } e'; \ c' \rangle^h_e = c_\text{op}[e/z][e'/x'][y.z'] \langle c' \rangle^h_z \cdot k \quad \text{where } (\text{op}(x', k, z) \rightarrow c_\text{op}) \in h
\]
\[
(\text{let } box \ u = e' \ in \ c')[x.y. \ c \cdot k] = \text{let } box \ u = e' \ in \ \langle c' \rangle^h_e
\]
\[
(x' \leftarrow \text{handle } u \ [\Theta] \ h' \ e'; \ c' \rangle^h_e = x \leftarrow \text{handle } u \ [\Theta, (h', e', x', c') \ h \ e; \ ret \ x
\]

(c) Handling.

\[
\langle c' \ | \ \bullet \rangle = c'
\]
\[
\langle c' \ | \ [\Theta, (h, e, x, c)] \rangle = \{ \langle c' \ | \ \Theta \rangle \}^{h_e/x} c
\]

(d) Handling sequencing.

Fig. 4. Definition of operations auxiliary to modal substitution. The definitions are recursive but well-founded (hence, also terminating) as each operation either makes recursive calls involving strictly smaller subterms, or invokes an operation that has been defined ahead of it in the figure. As conventional, we assume that all the bound variables are \( \alpha \)-renamed to avoid capture by the operations.

Handling by \textit{handlerSt} in (13) results in the computation \(\text{ret } (0, 1)\), as we shall illustrate shortly. In the next step (14), this computation is monadically substituted for \(x' \in \text{ret } x'\) to get the final reduction result of \(\text{ret } (0, 1)\). This follows by the definition of the monadic substitution in Figure 4a. Monadic substitution \(\{c'/x\} c\) sequentially precomposes \(c'\) before \(c\). In the special case when \(c'\) is \(\text{ret } e\), it simply substitutes \(e\) for \(x\) in \(c\).

In step (15) we return to the step (13) of applying the handler \textit{handlerSt}. We proceed according to the definition of handling from Figure 4c. In particular, we obtain the expression (16) by substituting the following into the get clause of \textit{handlerSt}:
Thus, it illustrates that all of our subsidiary operations work over expressions with free variables.

The last component above, namely the handling of the remainder of the computation is depicted in lines (20-25) in Figure 5. We do not comment on it in any detail as it is similar to the rest of the example, but we just note that it obtains the result \( \text{ret} \ (y, y + 1) \) in the scope of variables \( y \) and \( z' \).

Thus, it illustrates that all of our subsidiary operations work over expressions with free variables.

We next execute the substitutions over \( z \) and \( x \) to derive step (17). Next, to obtain (18), we proceed with continuation substitution whereby the arguments 0 and 0 of \( k \) in the main expression are replaced for \( y \) and \( z' \) respectively in the expression being substituted for \( k \). The remainder of the reduction is then easy to complete.

6 SOUNDNESS

In this section we present the basic theoretical properties of ECMTT, leading to the proofs of local soundness (i.e., that \( \beta \)-reduction is well typed), local completeness (i.e., that \( \eta \)-expansion is well typed), as well as the type soundness theorems (i.e., progress and preservation) for the operational
\[
\begin{align*}
    e_1 & \mapsto e'_1 & e_2 & \mapsto e'_2 \quad e_1 e_2 & \mapsto e'_1 e'_2 \\
    \forall & e_2 \mapsto e'_2 & (\lambda x : A. e) & \mapsto e[\varnothing/x] \\
\end{align*}
\]

\[
\begin{align*}
    e_1 & \mapsto e'_1 & \text{let box } u = e_1 \text{ in } e_2 & \mapsto \text{let box } u = e'_1 \text{ in } e_2 \\
\end{align*}
\]

\[
\begin{align*}
    e & \mapsto e' & \text{let box } u = e \text{ in } c & \mapsto \text{let box } u = e' \text{ in } c \\
\end{align*}
\]

Fig. 6. Call-by-value operational semantics. The semantics considers closed terms (no free variables) in the empty effect theory (no unhandled operations). Consequently, it only evaluates computations of the form \( \text{ret } e \) and \( \text{let box } u = e \text{ in } c \), as other cases involve free variables or operations. The rules include only those for \( \beta \)-reduction, and for enforcing call-by-value/left-to-right evaluation order. The values of expression kind (ranged over by \( \varnothing \)) are \( \lambda e : A. e' \) and box \( \Psi. c \). The value of computation kind is \( \text{ret } \varnothing \).

6.1 Structural properties

To avoid writing out all 20 combinations of our variable and term judgements, we state weakening with generic binding forms. We use \( x_\Delta : J_{\text{var}} \) to stand over variable bindings in \( \Delta \), namely \( x : A \) and \( u : A \cdot \Psi \). \( x_\Gamma : J_{\text{var}} \) ranges over \( \Gamma \) variable bindings \( op \div A \Rightarrow B \) and \( k \div A \Rightarrow B \). The generic term binding \( t : J_{\text{term}} \) ranges over \( e : A, c \div A, s \div_s A, h \div A \cdot \Psi \Rightarrow B, \) and \( \Theta \div A \cdot \Psi \Rightarrow B \). We also use the generic term judgement to state the principles governing the subsidiary operations from Section 5.

**Lemma 6.1 (Weakening).** If \( \Delta; \Gamma \vdash t : J_{\text{term}} \), then

1. \( \Delta, x_\Delta : J_{\text{var}}; \Gamma \vdash t : J_{\text{term}} \).
2. \( \Delta; \Gamma, x_\Gamma : J_{\text{var}} \vdash t : J_{\text{term}} \).

**Lemma 6.2 (Expression Substitution Principle).** If \( \Delta; \Gamma \vdash e : A \) and \( \Delta, x : A; \Gamma \vdash t : J_{\text{term}} \), then \( \Delta; \Gamma \vdash t[e/x] : J_{\text{term}} \).

**Lemma 6.3 (Monadic Substitution Principle).** If \( \Delta; \Gamma \vdash c \div A \) and \( \Delta, x : A; \Gamma \vdash c' \div B \), then \( \Delta; \Gamma \vdash \{c/x\}c' \div B \).

**Lemma 6.4 (Continuation Substitution Principle).** If \( \Delta, x : A_1, y : A_2; \Gamma \vdash c' \div A_3 \), then

1. If \( \Delta; \Gamma, k \div A_1 \Rightarrow A_3 \vdash c \div B \), then \( \Delta; \Gamma \vdash c[x.y, c' \circ k] \div B \).
2. If \( \Delta; \Gamma, k \div A_1 \Rightarrow A_3 \vdash h \div C \cdot \Psi \Rightarrow C' \), then \( \Delta; \Gamma \vdash h[x.y, c' \circ k] \div C \cdot \Psi \Rightarrow C' \).
Lemma 6.5 (Handling principle). If $\Delta; \Psi \vdash c \vdash A$, and $\Delta; \Gamma \vdash h \vdash A[\Psi] \Rightarrow B$, then $\Delta; \Gamma \vdash \langle c \rangle^B h \vdash C$.

Lemma 6.6 (Handling sequencing principle). If $\Delta; \Psi \vdash c \vdash A$ and $\Delta; \Psi' \vdash \Theta \vdash A[\Psi] \Rightarrow B$, then $\Delta; \Psi' \vdash \langle c \mid \Theta \rangle \vdash B$.

Lemma 6.7 (Modal substitution principle). If $\Delta; \Psi \vdash c \vdash A$ and $\Delta, u :: A[\Psi]; \Gamma \vdash t : J_{\text{term}}$, then $\Delta; \Gamma \vdash t[c//u] : J_{\text{term}}$.

Lemma 6.8 (Identity handler). $\Delta; \Psi \vdash id_{\Psi} \vdash A[\Psi] \Rightarrow A$.

6.2 Main theorems

Theorem 6.9 (Local soundness). If $\Delta; \Psi \vdash c \vdash A$, then the following $\beta$-reductions are well-typed.

1. If $\Delta; \Gamma \vdash \text{let } u = \text{box } \Psi.c \in c' \vdash B$, then $\Delta; \Gamma \vdash c'[c//u] \vdash B$.

2. If $\Delta; \Gamma \vdash \text{let } u = \text{box } \Psi.c \in e' : B$, then $\Delta; \Gamma \vdash e'[c//u] : B$.

Theorem 6.10 (Local completeness). If $\Delta; \Gamma \vdash e : [\Psi]A$, then the $\eta$-expansion of $e$ is well-typed, i.e. $\Delta; \Gamma \vdash \text{let } u = e \in \text{box } \Psi. \text{handle } u \text{ id}_{\Psi} () : [\Psi]A$.

Theorem 6.11 (Preservation on expressions). If $\vdash e : A$ and $e \mapsto e'$, then $e' : A$.

Theorem 6.12 (Preservation on computations). If $\vdash c \vdash A$ and $c \mapsto c'$, then $c' : A$.

Theorem 6.13 (Progress on expressions). If $\vdash e : A$, then either (1) $e$ is a value, or (2) there exists $e'$ s.t. $e \mapsto e'$.

Theorem 6.14 (Progress on computations). If $\vdash c \vdash A$, then either (1) $c$ is $\text{ret } v$ where $v$ is a value, or (2) there exists $c'$ s.t. $c \mapsto c'$.

7 Extensions to ECMTT

7.1 Evaluation

In any calculus that tracks effects in types, it is desirable to relate the category of computations with no effects to the purely functional expressions. Similarly, in ECMTT we also would like to have a correspondence between the types $A$ and $\square A$. In Section 4 we presented a function (monadic unit) of type $A \rightarrow \square A$ that realizes one side of the correspondence. To establish the other side we need a function of type $\square A \rightarrow A$, known in modal logic as axiom $T$ or reflexivity [Blackburn et al. 2001], as counit for the $\square$ comonad in categorical semantics [Bierman and de Paiva 2000], and as the $\text{eval}$ function in modal type systems [Davies and Pfenning 2001].

However, currently it is impossible to express in ECMTT, because modal types can only be handled within the computation judgement. That is, we can always handle $\square A$ into $A$, but only within the scope of a box term. Thus, we can write a function for $\square A \rightarrow \square A$

$$\lambda x : \square A. \text{let } u = x \text{ in } \text{handle } u \text{ id. } () : \square A \rightarrow \square A$$

but not for $\square A \rightarrow A$. To support this, we need a mechanism to handle computations in an empty context into expressions. Thus we present an extension of ECMTT with a primitive $\text{eval}$ expression.

We extend the language with a new expression $\text{eval } [\Theta] u$ that, similarly to handling, holds a handling sequence $\Theta$ applied to $u$. This time however the typing restricts $\Theta$ to be typed in an empty effect context, or that the last clause of $\Theta$ must not use any operation:

$$e ::= \cdots | \text{eval } [\Theta] u$$
We prove the following lemma about the evaluation:

\[(u :: A[\Psi]) \in \Delta \quad \Delta; \cdot \vdash \Theta \div A[\Psi] \Rightarrow B\]

\[\Delta; \Gamma \vdash \text{eval}[\Theta] u : B\]

And then we define evaluation on empty effect context computations

\[\text{ret } e = e\]

\[\text{let } c = \text{eval}[\Theta] h e; c\]

\[\text{let } box u = e \text{ in } c\]

\[\text{let } box u = e \text{ in } [c]\]

to support substitution of \(u\) in \(\text{eval}\) with a computation.

\[(\text{eval}[\Theta] u)[c/u] = [[c | \Theta[c/u]]]\]

We prove the following lemma about the evaluation:

**Lemma 7.1 (Eval Principle).** If \(\Delta; \cdot \vdash c \div A\), then \(\Delta; \Gamma \vdash [c] : A\).

And in the result we can write the \(\text{eval}\) function:

\[\text{evalf} \equiv \lambda x : \Box A. \text{let } box u = x \text{ in } \text{eval} [\bullet] u : \Box A \rightarrow A\]

On the formal side, the addition of \(\text{eval}\) does not affect any of the definitions from Figure 4, and the modal substitution is the only definition that we change. Accordingly, the changes to the soundness proofs are also minimal. The modal substitution principle for \(\text{eval}\) readily follows from **Eval Principle** and **Handling Sequencing Principle.** And the progress and preservation theorems do not need to consider this case explicitly because \(\text{eval}\) expression is not a closed term.

### 7.2 Fixed Points

Currently, there is no way to write loops in ECMTT. In that it is more similar to a system for logical inference than a programming language. We can however also add loops through recursion to ECMTT. For this, we introduce a fixed point operator and update operational semantics accordingly. The idea is that a recursive function \(f\) should have the type \(A \rightarrow [\Psi]B\), allowing it to use effect operations from \(\Psi\). The reduction in operational semantics then substitutes \(f\) with a function in which the boxed body recursively redefines \(f\).

\[e ::= \cdots \mid \text{let } \text{fix } f (x : A) = \text{box } \Psi. c \text{ in } e\]

\[c ::= \cdots \mid \text{let } \text{fix } f (x : A) = \text{box } \Psi. c_1 \text{ in } c_2\]

\[\Delta, f : A \rightarrow [\Psi]B, x : A; \Psi \vdash c \div B \quad \Delta, f : A \rightarrow [\Psi]B; \Gamma \vdash e : C\]

\[\Delta; \Gamma \vdash \text{let } \text{fix } f (x : A) = \text{box } \Psi. c \text{ in } e \div C\]

\[\Delta, f : A \rightarrow [\Psi]B, x : A; \Psi \vdash c_1 \div B \quad \Delta, f : A \rightarrow [\Psi]B; \Gamma \vdash c_2 \div C\]

\[\Delta; \Gamma \vdash \text{let } \text{fix } f (x : A) = \text{box } \Psi. c_1 \text{ in } c_2 \div C\]

\[\text{let } \text{fix } f (x : A) = \text{box } \Psi. c \text{ in } e \mapsto e[\lambda x : A. \text{box } \Psi. \text{let } \text{fix } f (x : A) = \text{box } \Psi. c \text{ in } c/f]\]

\[\text{let } \text{fix } f (x : A) = \text{box } \Psi. c_1 \text{ in } c_2 \mapsto c_2[\lambda x : A. \text{box } \Psi. \text{let } \text{fix } f (x : A) = \text{box } \Psi. c_1 \text{ in } c_1/f]\]
Thus \textbf{let} \textbf{fix} allows us to write programs that use recursion, for example a program that computes 3!

\begin{verbatim}
let fix fact (n: int) = box · ·
  if n = 0 then 1 else n * (eval_f (fact (n - 1))) in
eval_f (fact 3)
\end{verbatim}

and reduces to 6 as we expect.

In Appendix A we present the definitions for all our subsidiary operations extended with eval and let-fix, and we also include these cases in the proofs in Appendix B.

8 RELATED AND FUTURE WORK

\textbf{Type-and-effect systems for algebraic effects.} Many languages for algebraic effects and handlers include effect systems to track operations. Among them are \texttt{λ eff} \cite{Kammar et al. 2013}, which puts collection of available operations \(E\) in the typing judgement for computations \(Γ \vdash E M : C\), similarly as we do with effect contexts, and \texttt{Eff} \cite{Bauer and Pretnar 2014, 2015; Karachalias et al. 2020}, \texttt{Links} \cite{Hillerström and Lindley 2016, 2018; Hillerström et al. 2020}, \texttt{Helium} \cite{Biernacki et al. 2019}, \texttt{Frank} \cite{Convent et al. 2020}, and \texttt{Koka} \cite{Leijen 2014}, which put the annotation on the computation’s type.

In \texttt{Eff}, the type \(\texttt{!} \Delta\) specifies that a computation might invoke operations from \(\Delta\), which is a collection of operations. \texttt{Links}, \texttt{Helium}, and \texttt{Koka} rely on a more involved effect annotation called effect rows, although their primary role—to track the use of operations—is similar to the one in \texttt{Eff}. \texttt{Links} for example similarly specifies their computation type as \(\texttt{!} \Delta\) but there is an effect row of a computation. Notably, effect row languages support a notion of row polymorphism, that allows a programmer to write computations polymorphic over effect theories.

ECMTT differs from these languages in the key property that it manipulates effect annotations explicitly through introduction and elimination forms of the modal type \(\Psi\)\(\Delta\). Thus, the ECMTT type-and-effect system is in fact just a type system, as the effect annotations are built directly into the modal types. This leads to an operational semantics determined solely by \(\beta\)-reduction, although \(\beta\)-reduction itself now includes handling. More importantly, we can consider the modal (effectful) types as propositions, thus, in the future, obtaining a Curry-Howard style interpretation for algebraic effects and handlers.

On the other hand, these systems support more advanced features in handlers than ECMTT, for example shallow \cite{Hillerström and Lindley 2018} and recursive \cite{Bauer and Pretnar 2015} handlers, or asynchronous effects, as in \texttt{λ eff} \cite{Ahman and Pretnar 2021}. We leave considering these features for ECMTT also for future work.

\textbf{Scaling to dependent types.} Ahman \cite{2017} develops a dependently typed calculus for algebraic effects based on call-by-push value approach. In this paper we do not consider dependent types, but we expect that the foundation of ECMTT in modal logic will offer us some conceptual simplification when scaling to dependent types, as we can build on the recent work on modal type theories. In particular, CMTT itself has been lifted to dependent types \cite{Nanevski et al. 2008}, albeit in a somewhat restricted form, with abstraction over modal variables, but no explicit modality. More recently, Gratzer et al. \cite{2019} have developed a variant of Martin-Löf type theory with a non-contextual \(\Box\) modality, while using an alternative elimination form unbox \cite{Davies and Pfenning 2001} instead of \texttt{let-box} to avoid commuting conversions.

The work related to the Beluga system \cite{Cave and Pientka 2013; Pientka 2008, 2010} has provided extensions to CMTT with abstraction over first-class contexts and explicit substitutions. In the future, we plan to study these extensions and consider how they apply to the setting of algebraic effects. In particular, we expect them to provide an alternative to row polymorphism, and
potentially a different solution to the problem of combining different uses of the same effect in a program [Biernacki et al. 2020].

Currently, ECMTT admits only free algebraic theories; i.e. those with no equations between operations. Luksic and Pretnar [2020] add support for equations in Eff through the extension of the annotations to \( \Delta/\mathcal{E} \), where \( \mathcal{E} \) stands for the set of equations. Ahman [2017] supports equations and also treats them as a special annotation over the computation types. We expect that the scaling to dependent types will immediately allow us to support equations, or any arbitrary propositions over operations. Indeed, in dependent type theories, propositions are merely types, and thus can easily be added to a context \( \Psi \) representing an algebraic theory in a modal type.

**Relationship to comonads and modal logic and calculi.** As illustrated in Section 5, our formulation of ECMTT employs the \texttt{let} box \( u = e_1 \in c_2 \) constructor. When \( e_1 \) itself is a value—thus, by typing, necessarily of the form box \( \Psi \), \( c_1 \)—the reduction modally substitutes \( c_1 \) for \( u \) in \( c_2 \). However, whether \( c_1 \) evaluates depends on the occurrences of \( u \) in \( c_2 \). This is in contrast to the elimination rule for monads (i.e., the monadic bind), where the bound computation immediately executes.

This kind of reduction seems characteristic of comonadic calculi. For example, CMTT itself has been given comonadic semantics in [Gabbay and Nanevski 2013]. More generally, comonadic calculi for coeffects [Gaboardi et al. 2016; Orchard et al. 2019] also employ constructs with similar behavior, in turn inspired by the elimination rule for exponentials in linear \( \lambda \)-calculus. However, to the best of our knowledge, these calculi have not been applied to algebraic effects and handling. On a related note, CMTT has been applied to staged computation and meta programming [Davies and Pfenning 2001; Nanevski and Pfenning 2005], and recently Poulsen et al. [2021] proposed that staging could be useful in giving a modular treatment to algebraic effects, albeit also without utilizing modal logic.

Nanevski [2004] presents modal calculi similar to CMTT, where the graded \( \Box \) modality tracks effects that depend on the execution environment but do not change it. These are handleable effects; examples include exceptions and delimited continuations [Nanevski 2003b], and dynamic binding [Nanevski 2003a]. In contrast, ECMTT supports algebraic effects whose execution may change the environment (e.g., witness the theory \( St \) of state in Section 3), and requires a significantly more general notion of handling. Another distinction is that ECMTT models effects simply as contexts of operations, whereas loc. cit. use much more involved freshness and binding disciplines inspired by Nominal logic [Pitts 2003].

That said, as we show in the examples (11-13) in Section 4, the modality \( [\Psi]A \) exhibits the functions with the types that are in programming usually associated with monads. Moreover, the typing \( \Box A \to A \) of the comonadic counit becomes available with the addition of the evaluation construct in Section 7. In the future we will study the equational theory of ECMTT, with the goal of clarifying the exact categorical nature of our modality. A useful step in this direction will be the work on categorical semantics of operations in scope [Piróg et al. 2018].

We also plan to study how graded \( \Diamond \) modality (called "possibility", or "diamond") can be used in ECMTT. In [Nanevski 2003a], it was proposed that the proof terms for \( (\Psi) \) correspond to installing a default handler for a number of effect names. Afterwards, these effects do not need to be explicitly handled, as the default handler applies. We expect that similar behavior will usefully extend to algebraic effects in ECMTT.

Finally, the type system of ECMTT makes sense as a logic as well, i.e., when one erases the terms and just considers the types as propositions. In the future we plan to study this logic in its own right (e.g., its Kripke semantics, its sequent calculus, etc.) and derive correspondence with ECMTT in the style of Curry and Howard.
9 CONCLUSION

We have presented the design of ECMTT, a novel contextual modal calculus for algebraic effects and handlers. We start from the idea that an algebraic theory can be represented as a variable context, and apply the graded modal necessity type $[\Psi]A$ to classify computations of type $A$ that may invoke effects described by the algebraic theory (equivalently, context) $\Psi$. The notion of handling naturally arises as a way to transform $\Psi$ into another theory. To the best of our knowledge, this is the first calculus that relates algebraic effects to modal types.

ECMTT is organized around $\beta$-reduction and $\eta$-expansion for its type constructors. Defining these requires developing interesting technical concepts such as identity handlers and modal substitutions that encompass handling. We illustrated the system on a number of examples, and established the basic soundness properties.

A FULL DEFINITIONS OF SUBSIDIARY OPERATIONS (INCLUDING EVAL AND LET-FIX)

A.1 Modal substitution

\[ x[c//u] = x \]
\[ (\lambda x : A. e)[c//u] = \lambda x : A. e[c//u] \]
\[ (t_1 t_2)[e//u] = t_1[e//u] t_1[e//u] \]
\[ (let box u' = e_1 in e_2)[c//u] = let box u' = e_1[c//u] in e_2[c//u] \text{ s.t. } u \neq u' \]
\[ (eval [\Theta] u)[c//u] = \llbracket \llparenthesis c | \Theta[c//u] \rrparenthesis \rrbracket \]
\[ (let fix f (x:A) = box \Psi. c' in e)[c//u] = \]
\[ \quad let fix f (x:A) = box \Psi. c'[c//u] in e[c//u] \]
\[ (\text{ret } e)[c//u] = \text{ret } e[c//u] \]
\[ (x \leftarrow p e; c')[c//u] = x \leftarrow p e[c//u]; c'[c//u] \]
\[ (x \leftarrow \text{cont } k e_1 e_2; c')[c//u] = x \leftarrow \text{cont } k e_1[c//u] e_2[c//u]; c'[c//u] \]
\[ (\Theta[h e; c'][c//u] = \llbracket (\llparenthesis c | \Theta[c//u] \rrparenthesis)[h[c//u]/e[c//u]]/x' \rrparenthesis \rrbracket \]
\[ \quad (x' \leftarrow \text{handle } u' [\Theta] h e; c')[c//u] = \]
\[ \quad \quad x' \leftarrow \text{handle } u' [\Theta[c//u]] h[c//u] e[c//u]; c'[c//u] \text{ where } u \neq u' \]
\[ (let box u' = e in c')[c//u] = let box u' = e[c//u] in c'[c//u] \text{ where } u \neq u' \]
\[ (let fix f (x:A) = box \Psi. c_1 in c_2)[c//u] = \]
\[ \quad let fix f (x:A) = box \Psi. c_1[c//u] in c_2[c//u] \]
\[ (\bullet)[c//u] = \bullet \]
\[ (\Theta, (h, e, x', c'))[c//u] = \Theta[c//u], (h[c//u], e[c//u], x', c'[c//u]) \]
\[ (\text{return}(x:A, z:S) \\ c')[c//u] = \text{return}(x:A, z:S) \\ c'[c//u] \]
\[ (h, p(y, k, z) \\ c')[c//u] = h[c//u], p(y, k, z) \\ c'[c//u] \]
A.2 Monadic substitution

\[ \{ \text{ret } e/x \} c = c[e/x] \]
\[ \{ y \leftarrow s; c'/x \} c = y \leftarrow s; \{ c'/x \} c \]
\[ \{ \text{let } \text{box } u = e \text{ in } c'/x \} c = \text{ let } \text{box } u = e \text{ in } \{ c'/x \} c \]
\[ \{ \text{let fix } f \ (x:A) = \text{box } \Psi. c_1 \text{ in } c_2/y \} c = \text{let fix } f \ (x:A) = \text{box } \Psi. c_1 \text{ in } \{ c_2/y \} c \]

A.3 Continuation substitution

\[ (\text{ret } e)[x.y. c\cdot k] = \text{ret } e \]
\[ (x' \leftarrow \text{op } e; c')[x.y. c\cdot k] = x' \leftarrow \text{op } e; c'[x.y. c\cdot k] \]
\[ (x' \leftarrow \text{cont } k e_1 e_2; c')[x.y. c\cdot k] = \{ c[e_1/x][e_2/y] / x' \} c' \]
\[ (x' \leftarrow \text{cont } k' e_1 e_2; c')[x.y. c\cdot k] = x' \leftarrow \text{cont } k' e_1 e_2; c'[x.y. c\cdot k] \text{ when } k \neq k' \]
\[ (\text{let } \text{box } u = e \text{ in } c')[x.y. c\cdot k] = \text{ let } \text{box } u = e \text{ in } c'[x.y. c\cdot k] \]
\[ (\text{let fix } f \ (x':A) = \text{box } \Psi. c_1 \text{ in } c_2)[x.y. c\cdot k] = \]
\[ \text{let fix } f \ (x':A) = \text{box } \Psi. c_1 \text{ in } c_2[x.y. c\cdot k] \]
\[ (x' \leftarrow \text{handle } u \ [\Theta \ h \ e; c'])[x.y. c\cdot k] = \]
\[ x' \leftarrow \text{handle } u \ [\Theta \ h[x.y. c\cdot k] e; c'[x.y. c\cdot k] \]

A.4 Handling

\[ \langle \text{ret } e' \rangle^h_e = e'[x/e][e/z] \text{ where return}(x,z) \rightarrow c \in h \]
\[ \langle y \leftarrow \text{op } e'; c' \rangle^h_e = c_{op}[e/z][e'/x'] [y.z'. \langle c' \rangle^h_e \cdot k] \text{ where } (\text{op}(x',k,z) \rightarrow c_{op}) \in h \]
\[ \langle \text{let fix } f \ (x:A) = \text{box } \Psi. c_1 \text{ in } c_2 \rangle^h_e = \text{ let fix } f \ (x:A) = \text{box } \Psi. c_1 \text{ in } \langle c_2 \rangle^h_e \]
\[ \langle \text{let box } u = e' \text{ in } c' \rangle^h_e = \text{ let box } u = e' \text{ in } \langle c' \rangle^h_e \]
\[ \langle x' \leftarrow \text{handle } u \ [\Theta \ h \ e'; c'] \rangle^h_e = x \leftarrow \text{handle } u \ [\Theta, (h', e', x'. c') ] h \ e; \text{ ret } x \]

A.5 Handling sequencing

\[ \langle e' \bullet \rangle = c' \]
\[ \langle c' \ | \ \Theta, (h, e, x. c) \rangle = \{ \langle c' \ | \ \Theta \rangle \}^h_e/x \} c \]

A.6 Eval

\[ \llbracket \text{ret } e \rrbracket = e \]
\[ \llbracket x \leftarrow \text{handle } u \ [\Theta \ h \ e; c] \rrbracket = \text{eval } [\Theta, (h, e, x. c)] u \]
\[ \llbracket \text{let box } u = e \text{ in } c \rrbracket = \text{ let box } u = e \text{ in } \llbracket c \rrbracket \]
\[ \llbracket \text{let fix } f \ (x:A) = \text{box } \Psi. c_1 \text{ in } c_2 \rrbracket = \text{let fix } f \ (x:A) = \text{box } \Psi. c_1 \text{ in } \llbracket c_2 \rrbracket \]
B THEOREMS AND PROOFS

B.1 Structural properties

To avoid writing out all 20 combinations of our variable and term judgements, we state weakening with generic binding forms. We use \( x_\Delta : J_{\text{var}} \) to stand over variable bindings in \( \Delta \), namely \( x : A \) and \( u :: A[\Psi] \). \( x_\Gamma : J_{\text{var}} \) ranges over \( \Gamma \) variable bindings \( op \div A \Rightarrow B \) and \( k \div A \Rightarrow B \). The generic term binding \( t : J_{\text{term}} \) ranges over \( e : A, c \div A, s \div A, h \div A[\Psi] \Rightarrow B, \) and \( \Theta \div A[\Psi] \Rightarrow B \). We reuse the generic term judgement to also state the principles governing the subsidiary operations from Section 5.

**Lemma B.1 (Weakening).** If \( \Delta; \Gamma \vdash t : J_{\text{term}}, \) then

1. \( \Delta, x_\Delta : J_{\text{var}}; \Gamma \vdash t : J_{\text{term}}. \)
2. \( \Delta; \Gamma, x_\Gamma : J_{\text{var}} \vdash t : J_{\text{term}}. \)

**Proof.** The cases follow by mutual induction over the premise typing judgements and our assumption on the distinctness of named variables.

**Lemma B.2 (Expression Substitution Principle).** If \( \Delta; \Gamma \vdash e : A \) and \( \Delta, x : A; \Gamma \vdash t : J_{\text{term}}, \) then \( \Delta; \Gamma \vdash t[e/x] : J_{\text{term}}. \)

**Proof.** By mutual induction on the expansions of the second premise. We present the interesting cases for expressions:

**Case** \( e' = x. \) The goal is to show \( \Delta; \Gamma \vdash e : B, \) while we assume \( \Delta, x : A; \Gamma \vdash x : B \) and we have \( x : B \in \Delta, x : A \) by inversion. Thus we know \( B = A \) and the goal follows by assumption.

**Case** \( e' = y. \) We need to show \( \Delta; \Gamma \vdash y : B, \) while we know \( y : B \in \Delta, x : A \) by inversion. The goal follows by the \( \text{var} \) rule, where showing \( y : B \in \Delta \) is straightforward.

**Case** \( e' = \lambda y : B_1. e''. \) We need to show \( \Delta; \Gamma \vdash \lambda y : B_1. e''[e/x] : B_1 \rightarrow B_2 \) for some \( B_1 \) and \( B_2, \) with \( x \neq y \) given. By inversion on \( e', \) we know that \( \Delta, x : A, y : B_1; \Gamma \vdash e'' : B_2 \) by the \( \rightarrow I \) rule we need to show \( \Delta, y : B_1; \Gamma \vdash e''[e/x] : B_2 \) which follows by induction.

**Lemma B.3 (Monadic Substitution Principle).** If \( \Delta; \Gamma \vdash c \div A \) and \( \Delta, x : A; \Gamma \vdash c' \div B, \) then \( \Delta; \Gamma \vdash \{c/x\}c' \div B. \)

**Proof.** By induction on \( c. \) Cases are:

**Case** \( c = \text{ret} e. \) The goal \( \Delta; \Gamma \vdash c'[e/x] \div B \) follows by the substitution lemma B.2.

**Case** \( c = y \leftarrow s; \) \( c'. \) The goal \( \Delta; \Gamma \vdash y \leftarrow s; \) \( \{c''/x\}c' \div B \) follows by the rule \( \text{BIND}, \) weakening, and induction.

**Case** \( c = \text{let} \) \( \text{box} u = e \) \( \text{in} c''. \) The goal \( \Delta; \Gamma \vdash \text{let} \) \( \text{box} u = e \) \( \text{in} \) \( e''[e/x]c' \div B \) follows by the rule \( \text{E}, \) weakening, and induction.

**Case** \( c = \text{let} \) \( \text{fix} f \) \( (x : A') = \text{box} \Psi. \) \( c_1 \) \( \text{in} \) \( c_2 \) follows analogously to the case above.

**Lemma B.4 (Continuation Substitution Principle).** If \( \Delta, x : A_1, y : A_2; \Gamma \vdash c' \div A_3, \) then

1. \( \text{If} \) \( \Delta; \Gamma, k \div A_1 \xrightarrow{A_1} A_3 \div c \div B, \) \( \text{then} \) \( \Delta; \Gamma \vdash c[x,y,c' \cdot k] \div B. \)
2. \( \text{If} \) \( \Delta; \Gamma, k \div A_1 \xrightarrow{A_1} A_3 \div h \div C[\Psi] \xrightarrow{S} C', \) \( \text{then} \) \( \Delta; \Gamma \vdash h[x,y,c' \cdot k] \div C[\Psi] \xrightarrow{S} C'. \)

**Proof.** By mutual induction on the first premise of each branch. The interesting case is the continuation statement, where the continuation is the one being substituted:
**Case** $c = x' \leftarrow \text{cont } k \ e_1 \ e_2\colon c''$. The goal is to show $\Delta; \Gamma \vdash \{c'[e_1/x][e_2/y]/x'\}c'' \div B$, while by inversion on $c$ we assume $\Delta, x'\colon A_3; \Gamma \vdash c'' \div B, \Delta; \Gamma \vdash e_1 : A_1$, and $\Delta; \Gamma \vdash e_2 : A_2$. We first derive $\Delta; \Gamma \vdash c'[e_1/x][e_2/y] \div A_3$ by the substitution principle (Lemma B.2). Then the goal follows by the monadic substitution principle (Lemma B.3).

□

**Lemma B.5 (Handling Principle).** If $\Delta; \Psi \vdash c \div A$, and $\Delta; \Gamma \vdash h \div A[\Psi] \Rightarrow C$, and $\Delta; \Gamma \vdash e : B$, then $\Delta; \Gamma \vdash \langle c \rangle^B_h \div C$.

**Proof.** By induction on $c$. The cases are:

**Case** $c = \text{ret } e'$. By the definition of handling we need to show $\Delta; \Gamma \vdash c'[e'/x][e/z] \div C$ s.t. $\text{return}(x, z) \rightarrow c' \in h$ and $\Delta, x:A, z:B; \Gamma \vdash c' \div C$. By inversion on typing of $c$ we know that $\Delta; \Psi \vdash e' : A$. Thus we show the goal with the assumption $\Delta; \Gamma \vdash e : B$ and the substitution principle (Lemma B.2).

**Case** $c = x' \leftarrow \text{op } e'; c'$. By the definition of handling, we need to show:

$$\Delta; \Gamma \vdash c_{\text{op}}[e/z][e'/x][x', z'] \cdot (c')^h_z \cdot k \div C$$

where $(\text{op}(x, k, z) \rightarrow c_{\text{op}}) \in h$ since $\text{op}$ is in $\Psi$ by typing. Thus by inversion on the typing of $c$, we have $\text{op} \div A_1 \Rightarrow A_2 \in \Psi$ for some $A_1$ and $A_2$, $\Delta; \Psi \vdash e' : A_1$, and $\Delta, x' : A_2; \Psi \vdash c' \div A$. Also, by the typing of the handler operation clauses, we know: $\Delta, x : A_1, z : B; \Gamma, k + A_2 \Rightarrow C \vdash c_{\text{op}} \div C$.

For substitution of $z$ and $x$ we apply Lemma B.2, and for $k$ we use Lemma B.4. The expression variable substitutions immediately follow, but the continuation substitution changes the goal to $\Delta, x' : A_2, z' : B; \Gamma \vdash (c')^h_z \div C$ which we show by induction on $c'$ weakening.

**Case** $c = \text{let } \text{box } u = e' \in c_n$. The goal is to show $\Delta; \Gamma \vdash \text{let } \text{box } u = e' \in \langle c_n \rangle^h_e \div C$ and it immediately follows by the $\land \text{E}$ rule, and induction.

**Case** $c = \text{let } \text{fix } f \ (x' : A') = \text{box } \Psi'. c_1 \in c_2$ follows analogously to the case above.

**Case** $c = x' \leftarrow \text{handle } u \ [\Theta] \ h' e' ; c'$. The goal is to prove

$$\Delta; \Gamma \vdash x \leftarrow \text{handle } u \ [\Theta, (h', e', x', c')] \ h e; \ \text{ret } x \div C$$

and by the inversion on the typing of $c$ we know that $u :: A_1[\Psi_1] \in \Delta, \Delta; \Psi_2 \vdash \Theta \div A_1[\Psi_1] \Rightarrow A_2, \Delta; \Psi \vdash h' \div A_2[\Psi_2] \Rightarrow A_3, \Delta; \Psi \vdash e : S_{h'}, \text{ and } \Delta, x' : A_3; \Psi \vdash c' \div A$ for some types $A_1, A_2, A_3$ and algebraic theories $\Psi_1, \Psi_2$.

Thus we use the $\text{seq}$ rule to add $h'$ into the sequence. We obtain: $\Delta; \Psi \vdash \Theta, (h', e', x', c') \div A_1[\Psi_1] \Rightarrow A$. Then with the $\text{mvar}$ we get $\Delta; \Gamma \vdash \text{handle } u \ [\Theta, (h', e', x', c')] \ h e \div C$ by our typing assumptions on $h$ and $e$. Then the case follows by $\text{bind}$ and $\text{ret}$.

□

**Lemma B.6 (Handling Sequencing Principle).** If $\Delta; \Psi \vdash c \div A$ and $\Delta; \Psi' \vdash \Theta \div A[\Psi] \Rightarrow B$, then $\Delta; \Psi' \vdash \langle c \mid \Theta \rangle \div B$.

**Proof.** By induction on $\Delta; \Psi' \vdash \Theta \div A[\Psi] \Rightarrow B$. The cases are:

**Case** $\Theta = \bullet$. The goal $\Delta; \Psi \vdash c \div B$ follows from the typing of $\Theta$ and our assumptions. By the rule $\text{emph}$ the input and output types of $\Theta$ must much, and thus $B = A$. From it, we also know that $\Psi \subseteq \Psi'$ and thus we apply weakening to finish the goal.

**Case** $\Theta = \Theta', (h, e, x', c')$. By the typing of $\Theta$, we know: $\Delta; \Psi_h \vdash \Theta' \div A[\Psi] \Rightarrow A', \Delta; \Psi' \vdash h \div A'[\Psi_h] \Rightarrow A''', \Delta; \Psi' \vdash e : S$, and $\Delta, x' : A'''; \Psi' \vdash c' \div B$. The goal is to show $\Delta; \Psi' \vdash$...
\{(c | \Theta')_e^h/x'\}c' \vdash B. First, we apply the monadic substitution principle (Lemma B.3) and use our assumption on the typing of \(c'\). Then, the goal becomes \(\Delta; \Psi' \vdash (\{c | \Theta'\})_e^h \vdash A''\). Thus, by the handling principle (Lemma B.5) and our assumptions, the goal changes to \(\Delta; \Psi_h \vdash (\{c | \Theta'\}) \vdash A'\) and follows by induction.

\[\square\]

**Lemma B.7 (Eval Principle).** If \(\Delta; t \vdash c \vdash A\), then \(\Delta; \Gamma \vdash \llbracket c \rrbracket : A\).

**Proof.** By induction on \(c\).

**Case** \(c = \text{ret } e\). The goal is to show \(\Delta; \Gamma \vdash e : A\) and it follows by inversion on the typing of \(\text{ret } e\) and weakening of \(\cdot\) into \(\Gamma\).

**Case** \(c = x \leftarrow \text{op } e\); \(c'\) contradicts typing as the context of effects is empty.

**Case** \(c = x \leftarrow \text{handle } u [\Theta] h e; c\). The goal is to show \(\Delta; \Gamma \vdash \text{eval } [\Theta, (h, e, x, c)] u : A\), while we assume \(u : A'[\Psi'] \in \Delta, \Delta; \vdash h \vdash A'[\Psi'] \overset{S}{\Rightarrow} A'', \Delta; \vdash e : S\), and \(\Delta, x : A'' ; \vdash c \vdash A\). By the rule \(\text{seqh}\), we obtain \(\Delta; \vdash \Theta, (h, e, x, c) \vdash A'[\Psi'] \Rightarrow A\) and this, together with the typing of \(u\), is sufficient as a premise to the rule \(\text{eval}\) to show the goal.

**Case** \(c = \text{let } \text{box } u = e \in c\). The goal is to show \(\Delta; \Psi \vdash \text{let } \text{box } u = e \in \llbracket c \rrbracket : A\) and the goal follows with the rules \(\sqsubseteq E, \sqsubseteq E - \text{comp}\), weakening, and induction.

**Case** \(c = \text{let } \text{fix } f (x : A') = \text{box } \Psi, c_1 \in c_2\). Similarly to the case above, this case follows by the rules \(\text{fix, fix-comp, weakening, and induction}\).

\[\square\]

**Lemma B.8 (Modal Substitution Principle).** If \(\Delta; \Psi \vdash c \vdash A\) and \(\Delta, u : A[\Psi]; \Gamma \vdash t : J_{\text{term}}\), then \(\Delta; \Gamma \vdash t[c/u] : J_{\text{term}}\).

**Proof.** By mutual induction on the expansions of the second premise. The interesting cases are the substitutions for \(u\) in \(\text{handle}\) and \(\text{eval}\):

**Case** \(\Delta, u : A[\Psi]; \Gamma \vdash x' \leftarrow \text{handle } u [\Theta] h e; c' \vdash B\). According to the definition of the modal substitution, our goal is to show \(\Delta; \Gamma \vdash \llbracket (\{c | \Theta[c/u]\})_e^{h[c/u]/x'}\rrbracket(c'[c/u]) \vdash B\), and we have the assumptions \(\Delta, u : A[\Psi]; \Psi' \vdash \Theta \vdash A[\Psi] \Rightarrow A', \Delta, u : A[\Psi]; \Gamma \vdash h \vdash A'[\Psi'] \overset{S}{\Rightarrow} A'', \Delta, u : A[\Psi]; \Gamma \vdash e : S\), and \(\Delta, u : A[\Psi], x' : A'' ; \Gamma \vdash c' \vdash B\). Then, we apply the monadic substitution principle (Lemma B.3) with induction on our assumption on the typing of \(c'\). The goal becomes \(\Delta; \Gamma \vdash \llbracket (\{c | \Theta[c/u]\})_e^{h[c/u]} \rrbracket(c'[c/u]) \vdash A''\). By the handling principle (Lemma B.5), and induction over the typing of \(h\) and \(e\), the goal changes to \(\Delta; \Psi \vdash \llbracket c | \Theta[c/u] \rrbracket \vdash A'\) and follows by the theorem B.6 and induction over \(\Theta\).

**Case** \(\Delta, u : A[\Psi]; \Gamma \vdash \text{eval } [\Theta] u : B\). The goal is to show \(\Delta; \Gamma \vdash \llbracket c | \Theta[c/u] \rrbracket : B\), while we assume \(\Delta, u : A[\Psi]; \vdash \Theta \vdash A[\Psi] \Rightarrow B\). By induction on \(\Theta\), we obtain \(\Delta; \vdash \Theta[c/u] \vdash A[\Psi] \Rightarrow B\) and we use this as a premise to the handling sequencing principle lemma B.6 to obtain \(\Delta; \vdash c \vdash A[\Psi] \Rightarrow B\). Finally, we use this assumption as a premise to the eval principle lemma B.7 to show the goal.

\[\square\]

**Lemma B.9 (Identity Handler).** \(\Delta; \Psi \vdash id_\Psi \vdash A[\Psi] \overset{\text{unit}}{\Rightarrow} A\).

**Proof.** By induction on \(\Psi\).
Case $\Psi = \cdot$. The goal is to show $\Delta; \cdot \vdash \text{return}(x : A, z : \text{unit}) \rightarrow \text{ret} x \div A[\cdot] \overset{\text{unit}}{\longrightarrow} A$. The goal immediately follows by the RET and RET rules.

Case $\Psi = \Psi', \ op \div B \Rightarrow B'$. The goal is to show $\Delta; \Psi', \ op \div B \Rightarrow B' \overset{\text{id}_\Psi}{\rightarrow} \ op x; \ cont \ k \ y \ z \div A[\Psi', \ op \div B \Rightarrow B'] \overset{\text{unit}}{\longrightarrow} A$. By the rule OPH, we have to show $\Delta; \Psi', \ op \div B \Rightarrow B' \overset{\text{id}_\Psi}{\rightarrow} \ A[\Psi'] \overset{\text{unit}}{\longrightarrow} A$ which follows by weakening on the inductive hypothesis. Then, we also must show $\Delta, x : B, z : \text{unit}; \Psi', \ op \div B \Rightarrow B', k \div B' \overset{\text{unit}}{\longrightarrow} A + y \leftarrow \ op x; \ cont \ k \ y \ z \div A$ which follows by rules BIND, OP, CONT, and RET.

\[ \blacksquare \]

### B.2 Main theorems

**Theorem B.10 (Local soundness).** If $\Delta; \Psi \vdash c \div A$, then the following $\beta$-reductions are well typed.

1. If $\Delta; \Gamma \vdash \text{let} \ \text{box} \ u = \text{box} \Psi. c \ \text{in} \ c' \div B$, then $\Delta; \Gamma \vdash c'[c//u] \div B$.
2. If $\Delta; \Gamma \vdash \text{let} \ \text{box} \ u = \text{box} \Psi. c \ \text{in} \ e' : B$, then $\Delta; \Gamma \vdash e'[c//u] : B$.

**Theorem B.11 (Local completeness).** If $\Delta; \Gamma \vdash e : [\Psi]A$, then the $\eta$-expansion of $e$ is well-typed, i.e. $\Delta; \Gamma \vdash \text{let} \ \text{box} \ u = e \ \text{in} \ \Psi. \text{handle} u \ \text{id}_\Psi (\cdot) : [\Psi]A$.

**Proof.** By the $\Box E$ rule and our assumption on the typing of $e$, we need to show $\Delta, u :: A[\Psi]; \Gamma \vdash \text{box} \Psi. x \leftarrow \text{handle} u \ \text{id}_\Psi (\cdot); \text{ret} x : [\Psi]A$. Thus, by the $\Box I$ rule, we need to show $\Delta, u :: A[\Psi]; \Psi \vdash x \leftarrow \text{handle} u \ \text{id}_\Psi (\cdot); \text{ret} x : B$. By the rules RET and BIND, it suffices to show $\Delta, u :: A[\Psi]; \Psi \vdash \text{handle} u \ \text{id}_\Psi (\cdot) \div s A$. The goal follows by the rule MVAR and the identity handler lemma B.9.

**Theorem B.12 (Preservation on expressions).** If $\vdash e : A$ and $e \mapsto e'$, then $\vdash e' : A$.

**Proof.** By induction over $e \mapsto e'$. The cases are:

- **Case** $e_1 e_2 \mapsto e'_1 e_2'$. We need to show $\vdash e'_1 e_2' : A$, while assuming $e_1 \mapsto e'_1$ and $\vdash e_2 : A$. The goal follows by inversion on the second assumption, $\rightarrow E$ rule and induction.

- **Case** $v e_2 \mapsto v e'_2$. Follows analogously.

- **Case** $(\lambda x : A. e_1) e_2 \mapsto e_1 [e_2/x]$. Follows by inversion on the typing of $e$ and the expression substitution principle (Lemma B.2).

- **Case** let box $u = e_1$ in $e_2 \mapsto$ let box $u = e'_1$ in $e_2$. The goal follows by inversion on the typing of $e$, the $\Box E$ rule, and induction.

- **Case** let box $u = \text{box} \Psi. c \ \text{in} \ e \mapsto e[c//u]$. Follows by inversion on the typing of $e$ and the modal substitution principle (Lemma B.8).

- **Case** $e = \text{let} \ \text{fix} \ f (x : B) = \text{box} \Psi. c \ \text{in} \ e_1$ which reduces to

  \[ e_1 [\lambda x : B. \text{box} \Psi. \text{let} \ \text{fix} f (x : B) = \text{box} \Psi. c \ \text{in} c/f] \]

  The goal is to show $\vdash e_1 [\lambda x : B. \text{box} \Psi. \text{let} \ \text{fix} f (x : B) = \text{box} \Psi. c \ \text{in} c/f] : A$, under the assumptions that (1) $f : B \rightarrow [\Psi]C$; $\vdash e_1 : A$ and (2) $f : B \rightarrow [\Psi]C, x : B; \Psi \vdash c \div C$ for some type $C$. (These assumptions are obtained by inversion on the typing of $e : A$.)

  The proof follows immediately by applying the substitution principle (Lemma 6.2) on the variable $f$ in assumption (1). For the principle to apply, we must show that $\vdash \lambda x : B. \text{box} \Psi. \text{let} \ \text{fix} f (x : B) = \text{box} \Psi. c \ \text{in} c : B \rightarrow [\Psi]C$

  but this is easy to establish from assumption (2) by the $\rightarrow I$, $\Box I$ and Fix typing rules.

\[ \blacksquare \]

**Theorem B.13 (Preservation on computations).** If $\vdash c \div A$ and $c \mapsto c'$, then $\vdash c' : A$. 

\[ \blacksquare \]
Proof. By case analysis over \( c \mapsto c' \). The cases are:

**Case** \( \text{ret} \ e \mapsto \text{ret} \ e' \). We need to show \( \vdash \text{ret} \ e' \vdash A \), while assuming \( e \mapsto e' \). By the preservation on expressions (Theorem B.12) and inversion on the typing of \( \text{ret} \ e \) we obtain \( \vdash e' : A \). Thus the goal follows by the \( \text{ret} \) rule.

**Case** \( \text{let} \ \text{box} \ u = e \in e' \mapsto \text{let} \ \text{box} \ u = e' \in e'' \). In this case, under assumption that \( e \mapsto e' \), we need to show that \( \vdash \text{let} \ \text{box} \ u = e' \in e'' \vdash A \). By the preservation on expressions (Theorem B.12) and inversion on the typing of \( \text{let} \ \text{box} \ u = e \in e' \) we obtain \( \vdash e' : A' \) for some \( A' \). Thus the goal follows by the \( \square E \) rule.

**Case** \( \text{let} \ \text{fix} \ f \ (x : B) = \text{box} \ \Psi \ c_1 \text{ in } c_2 \). \( c_2 \) reduces to

\[
\text{let} \ \text{fix} \ f \ (x : B) = \text{box} \ \Psi \ c_1 \text{ in } c_2.
\]

This case proceeds analogously to the one for expressions.

\[\square\]

**Theorem B.14 (Progress on Expressions).** If \( \vdash e : A \), then either (1) \( e \) is a value, or (2) there exists \( e' \) s.t. \( e \mapsto e' \).

Proof. By induction on \( \vdash e : A \). Cases are:

**Case** \( e = x \) contradicts typing.

**Case** \( e = \lambda x : A. e' \) is a value.

**Case** \( e = e_1 \cdot e_2 \). By induction on \( e_1 \). If it is a value \( v_1 \), then by induction on \( e_2 \). If it is also a value \( v_2 \), then from typing and by inversion we know that \( v_1 \) must be of the form \( \lambda x : B. e' \) for some type \( B \). Thus \( e \) reduces to \( e'[v_2/x] \) by the semantic step relation. If \( e_2 \) is not a value, but there exists \( e'_2 \) s.t. \( e_2 \mapsto e'_2 \), then \( e \) reduces to \( v_1 \cdot e'_2 \) by the semantic step relation. If \( e_1 \) is not a value, but there exists \( e'_1 \) s.t. \( e_1 \mapsto e'_1 \), then \( e \) reduces to \( e'_1 \cdot e_2 \) by the semantic step relation.

**Case** \( e = \text{box} \ \Psi \ c \) is a value.

**Case** \( e = \text{let} \ \text{box} \ u = e_1 \in e_2 \). By induction on \( e_1 \), it is either a value or there exists \( e'_1 \) s.t. \( e_1 \mapsto e'_1 \). In the former case, \( e_1 \) must be of the form \( \text{box} \ \Psi \ c \) from typing and by inversion. Thus in this case \( e \) reduces to \( e_2[c/u] \) by the semantic step relation. In the latter case, \( e \) reduces to \( \text{let} \ \text{box} \ u = e'_1 \in e_2 \) by the semantic step relation.

**Case** \( e = \text{eval} \ [\Theta] \ u \) contradicts typing since \( u \) is a variable.

**Case** \( c = \text{let} \ \text{fix} \ f \ (x : B) = \text{box} \ \Psi \ c \text{ in } e \). \( c \) reduces to

\[
e[\lambda x : B. \text{box} \ \Psi. \text{let} \ \text{fix} \ f \ (x : B) = \text{box} \ \Psi. \ c \text{ in } c/f]
\]

by the reduction relation.

\[\square\]

**Theorem B.15 (Progress on Computations).** If \( \vdash c \vdash A \), then either (1) \( c \) is \( \text{ret} \ v \) where \( v \) is a value, or (2) there exists \( c' \) s.t. \( c \mapsto c' \).

Proof. By induction on \( \vdash c \vdash A \). Cases are:

**Case** \( c = \text{ret} \ e \). By inversion on \( c \), and the progress on expressions theorem B.14, two cases possible on \( e \): either it is a value, by which \( c \) is \( \text{ret} \ v \) and the first statement holds, or there exists \( e' \) s.t. \( e \mapsto e' \). Then, \( c \) reduces to \( \text{ret} \ e' \) and the second statement holds.

**Case** \( c = x \mapsto s; c' \) contradicts typing, as all statements use variables.
Case $c = \textbf{let fix } f (x : B) = \textbf{box } \Psi. \ c_1 \ \textbf{in} \ c_2$. $c$ reduces to 

$$c_2[\lambda x : B. \text{box } \Psi. \text{let } \text{fix } f (x : B) = \text{box } \Psi. \ c_1 \ \text{in} \ c_1/f]$$

by the reduction relation.

Case $c = \textbf{let box } u = e \ \textbf{in} \ c_1$. By inversion on $c$, and the theorem B.14, $e$ is either a value or there exists $e'$ s.t. $e \mapsto e'$. In the first case, $e$ must be of a form $\text{box } \Psi. \ c_b$ for some $\Psi$, by typing and inversion. Thus $c$ reduces to $c_1[c_b//u]$. In the second case, $c$ reduces to $\textbf{let box } u = e' \ \textbf{in} \ c_1$. 

$\square$
