Abstract—This paper reports the impacts of temperature variation on the inference accuracy of pre-trained all-ferroelectric FinFET deep neural networks, along with plausible design techniques to abate these impacts. We adopted a pre-trained artificial neural network (NN) with 96.4% inference accuracy on the MNIST dataset as the baseline. As an aftermath of temperature change, the conductance drift of a programmed cell was captured by a compact model over a wide range of gate bias. We observe a significant inference accuracy degradation in the analog neural network at 233 K for a NN trained at 300 K. Finally, we deployed binary neural networks with "read voltage" optimization to ensure immunity of NN to accuracy degradation under temperature variation, maintaining an inference accuracy of 96.1%.

I. INTRODUCTION

Recent advents in the research on hafnium zirconium oxide (HZO) based ferroelectric (FE) materials have paved the way for using FE-FETs for computing in memory (CIM) with an attempt to alleviate memory bandwidth limitation induced performance bottleneck in von-Neumann architecture [1]. Pronounced ferroelectricity in single-layer thin film of HZO [2], fast switching, high on/off ratio, excellent linearity, bi-directional operation and good endurance are the key technological factors, which makes FE-FETs superior to other emerging non-volatile memory technologies. Nevertheless, significant temperature-induced threshold voltage ($V_{th}$) shift in FE-FETs pose a challenge towards practical applications [3,4]. Despite the random variation-tolerant nature of deep neural networks (DNN), the CIM architecture, where the analog current sum determines computational output, is susceptible to systematic variation in its basic device building block.

This work’s cornerstone is to mitigate the impact of temperature-change induced variations in FE-FET-based CIM operation without affecting device scaling, power consumption, and latency. The choice of FE-FinFET as synaptic devices instead of planar FE-FET ensures compatibility with perpetual device scaling trend. The paper begins with a discussion of fabrication and characterization of deeply scaled FE-FinFETs, where we characterize and construct statistical compact models for temperature effects. Subsequently, we investigate DNN applications focusing on the offline training scenario, where pre-trained weights are programmed to FE-FinFET devices. The model is subsequently applied to a DNN pre-trained with the CIMulator [5] software platform to evaluate inference accuracy degradation. Based on the findings, we propose a novel application strategy to minimize the impacts of temperature variation.

II. DEVICE FABRICATION AND CHARACTERIZATION

We have fabricated FE-FinFET using self-aligned gate-first process on silicon-on-insulator (SOI) using an improved version of the process described in [3, 6], with thinner FE layer (5nm) and better-optimized fin pattern. Fig. 1(a) shows the schematic illustration and Fig. 1(b) shows the TEM cross-section of the fabricated FE-FinFET with 15 nm top fin width ($T_{fin}$) and 5.8 nm FE layer ($T_{FE}$).

![Fig. 1. (a) Device schematic (b) TEM cross section of fabricated device. The average fin width is 18nm and the fin height is 28nm. The thickness of the FE layer (HZO) is 5.8nm.](image)

The binary program-erase operation is shown in Fig. 2(a). Program and erase operations are achieved by applying a 100 ns pulse of amplitude 4.5V and -4.5V respectively at the gate terminal. The drain terminal is kept at 0V during the program operation, and the read operation is performed by applying a non-disturbing dc sweep at gate voltage while keeping the drain terminal at a constant 100mV. The multi-level characteristics are also evaluated by partially switching the ferroelectric layer's dipoles by fast and low voltage pulses. 100ns-wide pulses with constant amplitude (2V) are...
applied for programming; pulses of opposite polarity (-2V) are applied for erasing. The resulting remnant polarization alters the inversion charge concentration in the channel, resulting in modulation in channel conductance and the threshold voltage [7]. Figure 2(b) depicts the channel conductance modulation and multi-level states measured from a single FE-FinFET cell with 20nm TiN and 50nm gate length (Lg). The device shows excellent linearity and symmetry with a nonlinearity factor [8] of -0.84 for long-term potentiation (LTP) and long-term depression (LTD).

Fig. 2. (a) Binary program-erase characteristics. The low resistance state has been obtained by programming the device with a 4.5V pulse of 100ns width. The high resistance state has been obtained with a -4.5V pulse of 100ns width. (b) Gradual change of channel conductance during analog program and erase operations obtained by applying ±2V pulse of 100ns at gate terminal. The drain terminals were kept at 0V during program and erase operations. The read operations has a similitude with the technique described in [7]. A constant 100mV was applied at drain terminal during read operation. The channel conductance was extracted at constant 1V gate voltage.

III. IMPACT OF TEMPERATURE CHANGE

Temperature change in real scenarios causes mobility and carrier concentration to fluctuate, leading to change in \(G_{th}\) and \(V_{th}\) for FE-FinFET synaptic devices, thus altering the NN weights they represent. The temperature dependence of the FE-FinFET is characterized by first programming the device to a fixed (low or high resistance) state at room temperature (300K), measuring \(L_{g}V_{gs}\) with a non-destructive \(V_{gs}\) range, reducing the temperature, and measuring again. The impacts of temperature on mobility and threshold voltage are modeled with the following expressions [9]:

\[
\mu(T) = \mu(300K) \left( \frac{T}{300} \right)^{UTE}
\]

\[
V_{th}(T) = V_{th}(300K) + KT1 \left( \frac{T}{300K} - 1 \right)
\]

The evolution of \(V_{th}\) with the change of temperature for the low-resistance state (LRS, programmed using a +4.5V pulse) is accurately captured (Fig. 3(b)). The same expressions are used for the high-resistance state (HRS) as well, with good agreement with measured data. Fig. 4 shows the measured and modeled change in \(G_{th}\) as a function of temperature, which highlights the dependence of ON/OFF ratio on \(V_{g,read}\). It is evident that to ensure a high ON/OFF ratio; the device should be in the subthreshold region at all temperatures in HRS, which is key to the proper operation of binarized neural networks (BNN).

Fig. 4. Characterization and modeling the conductance drift as a result of temperature change for different read voltage.

We further applied the calibrated model to consider a realistic scenario (Fig. 5(a)), where BNN was trained at room temperature and driven to a lower temperature to perform inference without re-calibration. We observe a significant drop in NN accuracy (10%) for \(V_{g,read}=1.25V\) when a temperature change occurs. This is because of the significant ON/OFF ratio change when the operation regions of HRS synapses go from...
strong inversion at 300K to weak inversion at 233K. Although one of our previous works [3] shows that re-calibration at 233K may restore accuracy, the overhead associated with it may not be suitable for real applications. On the other hand, $V_{g,read}$ of 0.75V, ensures requisite ON/OFF ratio (HRS stays in the sub-threshold region). The inference accuracy remains unfazed amidst temperature change only when $V_{g,read}$ is 0.75V. For all other cases, a significant accuracy drop is noted with at least one state switching from strong inversion to sub-threshold (Fig.5 (b)). The aforementioned $V_{g,read}$ optimization ensures preserving the digital nature (high ON/OFF ratio) of NN weights. Accurate modeling of $G_{ch}$, all the way from sub-threshold to strong inversion, is crucial for the optimization of bias condition to ensure proper NN operation.

The results of this study leads to a possible "dynamic read voltage" scheme, where $V_{g,read}$ is chosen according to the present junction temperature. We expect such scheme to alleviate the impact of temperature variation and expand the overall design margin.

IV. CONCLUSION

We have fabricated, characterized, and evaluated the performance of deeply scaled FE-FinFETs for neuromorphic computing in the presence of temperature variation. The digital nature of the binarized neural network, with the "0" state programmed deep in sub-threshold and "1" state in strong inversion, is key to robust DNN inference. On the other hand, the apparent channel conductance shift of FE-FET as an aftermath of temperature change may render neural network inaccurate due to its analog nature. A proper choice of "read voltage" is of paramount importance to ensure the "0" state stays deep in the sub-threshold region for maintaining the ON/OFF ratio for the LRS-HRS state. This study also suggested dynamic read voltage scheme to maintain inference accuracy in the presence of temperature variation.
