(Dated: June 4, 2021)

We study the dynamics of a driven non-Hermitian superconducting qubit which is perturbed by quantum jumps between energy levels, a purely quantum effect with no classical correspondence. The quantum jumps mix the qubit states leading to decoherence. We observe that this decoherence rate is enhanced near the exceptional point, owing to the cube-root topology of the non-Hermitian eigenenergies. Together with the effect of non-Hermitian gain/loss, quantum jumps can also lead to a breakdown of adiabatic evolution under the slow-driving limit. Our study shows the critical role of quantum jumps in generalizing the applications of classical non-Hermitian systems to open quantum systems for sensing and control.

Dissipation is ubiquitous in nature; as in radioactive decay of an atomic nucleus and wave propagation in absorptive media, dissipation results from the coupling of these systems to different environmental degrees of freedom. These dissipative systems can be phenomenologically described by non-Hermitian Hamiltonians, where the non-Hermitian terms are introduced to account for the dissipation. The non-Hermiticity leads to a complex energy spectrum with the imaginary part quantifying the loss of particles/energy from the system. The degeneracies of a non-Hermitian Hamiltonian are known as exceptional points (EPs), where both the eigenvalues and the associated eigenstates coalesce [1,2]. The existence of EPs has been demonstrated in many classical systems [3–11] with applications in laser mode management [12,13], enhanced sensing [13,20], and topological mode transfer [21,24].

Recent experiments with single electronic spins [24,26], superconducting qubits [27], and photons [28,30] have motivated research into uniquely quantum effects in non-Hermitian dynamics. Two approaches have been taken to study non-Hermitian dynamics in the quantum regime. The first is to simulate these dynamics—through a process known as Hamiltonian dilation—by embedding a non-Hermitian Hamiltonian into a larger Hermitian system [25,26,30]. A second approach is to directly isolate the non-Hermitian dynamics from a dissipative quantum system [27]. To understand this approach, recall that dissipative quantum systems are usually described by a Lindblad master equation that contains two dissipative terms: the first is a term that describes quantum jumps between the energy eigenstates of the system, and the second is a term that yields coherence non-unitary evolution [31,32]. By suppressing the former term, the resulting evolution is described by an effective non-Hermitian Hamiltonian. This can be achieved through post-selection to eliminate trajectories that contain quantum jumps (Fig. 1(a)) [27]. However, additional sources of energy dissipation or pure dephasing can alter this non-Hermitian evolution [33,35]. The combina-

\[
\frac{\partial \rho_{\text{tot}}}{\partial t} = -i[H_e, \rho_{\text{tot}}] + \sum_{k=e,f} [L_k \rho_{\text{tot}} L_k^\dagger - \frac{1}{2} \{L_k^\dagger L_k, \rho_{\text{tot}}\}],
\]

where \( \rho_{\text{tot}} \) denotes a 3 \times 3 density operator. The jump operators \( L_e = \sqrt{\gamma_e} |e\rangle \langle e| \) and \( L_f = \sqrt{\gamma_f} |f\rangle \langle f| \) describe the energy decay from \( |e\rangle \) to \( |g\rangle \) and from \( |f\rangle \) to \( |e\rangle \), respectively. Here we only consider a drive at the \{ \langle |e\rangle, \langle f| \} \} submanifold, and in the rotating frame \( H_e = J(|e\rangle \langle f| + |f\rangle \langle e|) + \Delta/2(|e\rangle \langle e| - |f\rangle \langle f|) \), where \( \Delta \)
Here, the qubit dynamics is captured by two hybrid-Liouville superoperators $\mathcal{L}_0 \rho \equiv -i(\mathcal{H}_{\text{eff}} \rho - \rho \mathcal{H}_{\text{eff}}^\dagger)$ and $\mathcal{L}_1 \rho \equiv L_f \rho L_f^\dagger$. Compared to the Liouvillian superoperator defined by Eq. (1), the hybrid-Liouville superoperator does not lead to a completely positive and trace-preserving map [35]. In contrast to the non-Hermitian Hamiltonian approach based on a Hilbert space of dimension $N = 2$, this hybrid-Liouville formalism is based on a Liouville space of dimension $N^2 = 4$. In the Liouville space, $\rho$ is represented as a 4 × 1 vector, and $\mathcal{L}_{0,1} = 0_4$ is represented as a 4 × 4 non-Hermitian matrix. Because $\mathcal{L}_0$ encodes the evolution due to $\mathcal{H}_{\text{eff}}$, it also exhibits an EP (denoted as ‘hLEP’) at $J = (\gamma_e - \gamma_f)/4$ and $\Delta = 0$. One key difference is that three eigenvectors of $\mathcal{L}_0$ coalesce at the EP, implying that a second-order Hamiltonian EP corresponds to a third-order hLEP [40].

In addition, the non-Hermitian qubit can also suffer from pure dephasing, described by a jump operator $L_o = \sqrt{\gamma_o/2}\sigma_z$. Its effect includes two aspects: on one hand, it modifies $\mathcal{H}_{\text{eff}}$ (and subsequently $\mathcal{L}_0$) by adding a term $-i\gamma_o I/4$ ($I$ denotes an identity operator), which only shifts the overall loss and does not affect the position of EP in the parameter space; on the other hand, it provides another perturbation of quantum jumps, the effect of which can be included in $\mathcal{L}_1$ [41].

Before proceeding to our experiments, we summarize the possible scenarios of non-Hermitian dynamics of an open quantum system. Depending on the post-selection efficiency $\eta$ of quantum jumps through all possible channels, the resulting non-Hermitian dynamics is described by: (i) a Liouvillian superoperator with $\eta = 0$, i.e., no post-selection; (ii) a hybrid-Liouville superoperator with $0 < \eta < 1$, i.e., imperfect post-selection; (iii) an effective non-Hermitian Hamiltonian with $\eta = 1$, i.e., perfect post-selection [35]. In the semiclassical limit, the quantum jumps are neglected, that is, equivalent to $\eta = 1$; subsequently, the dynamics of a dissipative classical system can be described by an effective non-Hermitian Hamiltonian [34].

We first investigate the quantum-jump-induced decoherence in the $\mathcal{PT}$-symmetry unbroken regime. Figure 2(a) shows the complex eigenvalues $\lambda$ of the hybrid-Liouville superoperator ($\mathcal{L}_0 + \mathcal{L}_1$) in the unbroken regime, with the real and imaginary parts indicated as projections. Note that the role of the imaginary/real parts of Hamiltonian and hybrid-Liouville spectra are reversed because the ‘$-i$’ term in Eq. (2) is absorbed into the hybrid-Liouville superoperator. The perturbative effect of quantum jumps ($\mathcal{L}_1$) lifts the degeneracy of the third-order hLEP of $\mathcal{L}_0$ and generates a new second-order hLEP (see [41] for further details). By lifting the degeneracy, this perturbation leads to decoherence, whose rate is determined by the real part of the eigenvalue difference.

The effect of the perturbation is enhanced by proximity to the EP due to the cube-root topology of the third-order degeneracy of $\mathcal{L}_0$ [35] [41].
To experimentally measure the decoherence rates in the vicinity of the hLEP, we initialize the circuit in the $|f\rangle$ state and then apply a microwave drive with amplitude $J$. We take $10^4$ measurements per time point and only keep the results with the transmon remaining in the $\{|e\}, |f\rangle\}$ submanifold for analysis. We record the final $|f\rangle$ population as a function of time. These dynamics are characterized by damped oscillatory behavior of the population as shown in Fig. 2(b). We extract the decoherence rate and oscillation frequency for different values of $J$ as shown in Fig. 2(c). The observed damping rates and oscillation frequencies are in good agreement with the real and imaginary parts of hybrid-Liouvillian spectra, respectively. In particular, we note that by proximity to the hLEP, the dissipation is dramatically enhanced over its background rate (i.e., the rate when far from the hLEP).

We now turn to the $\mathcal{PT}$-symmetry broken regime, where the quantum jumps compete with the relative non-Hermitian gain/loss effect. In the absence of quantum jumps, the qubit has two stationary states, correspond-
ing to the two eigenstates $|\pm\rangle$ of $H_{\text{eff}}$ (Fig. 3(a)). The corresponding eigenvalues are purely imaginary. Recalling that imaginary eigenvalues correspond to gain or loss, here with $0 \geq \text{Im}[\lambda_{+}] > \text{Im}[\lambda_{-}]$, both states exhibit loss but the $|+\rangle$ state has gain relative to $|-\rangle$. Therefore, the non-Hermitian dynamics favor the $|+\rangle$ state. The eigenmatrices $\rho_{0,3}$ of $L_{0}$ with the smallest and largest damping rates represent the same states, i.e., $\rho_{0} \propto |+\rangle(|+\rangle$, $\rho_{3} \propto |-\rangle(|-\rangle$. With the perturbation of quantum jumps ($L_{1}$), the eigenmatrix $\rho_{0}$ becomes slightly mixed $\rho_{0} \rightarrow \tilde{\rho}_{0}$ and corresponds to the effective steady state of the non-Hermitian qubit, while the eigenmatrix $\rho_{3} \rightarrow \tilde{\rho}_{3}$, a state that is not physically accessible (Fig. 3(a)).

The physical intuition can be understood at the quantum trajectory level. Given a trajectory with only a single quantum jump from the $|f\rangle$ to $|e\rangle$ level, the jump places the qubit in a superposition of $|+\rangle$ and $|-\rangle$. After that, though no further quantum jumps occur, the non-Hermiticity (of $H_{\text{eff}}$) selects the eigenstate with less loss, and the renormalization of the state subsequently leads to a non-exponential decay \[31,32\]. Hence, the eigenstate $|-\rangle$ of $H_{\text{eff}}$ is unstable and will decay to a steady state in a process that involves both quantum jumps and the non-Hermitian (gain/loss) evolution. Figure 3(a) displays an illustration of one possible trajectory. Since the trajectories contain unknown number of quantum jumps, the steady state is slightly mixed rather than at the eigenstate $|+\rangle$.

This prediction is experimentally confirmed through quantum state tomography. Here, we prepare the qubit at the eigenstate $|-\rangle$ of $H_{\text{eff}}$, and measure the expectation values of the qubit Pauli operators \(\{x, y, z\} \equiv \{\langle \sigma_{x} \rangle, \langle \sigma_{y} \rangle, \langle \sigma_{z} \rangle\}\). Figure 3(b) displays these expectation values for different evolution times. We highlight several features of the evolution that are different than the dissipative evolution of a Hermitian qubit, where we expect exponential decay to steady states. The non-Hermitian evolution, perturbed by quantum jumps exhibits i) non-exponential evolution, ii) occurring on a timescale much faster than the quantum jump rate $\gamma_{f}$. This occurs due to the non-zero overlap $\langle -|f\rangle$; jumps from $|f\rangle$ to $|e\rangle$ create a mixed state. Thereafter the relative gain of the $|+\rangle$ state causes its population to grow, leading to the non-exponential population evolution. This is further confirmed by examining the evolution of the entropy, defined as $S \equiv -\sum p_{i} \log_{2}(p_{i})$, where $p_{i}$ is the eigenvalue of the density matrix $\rho$ of the qubit (Fig. 3(c)). The quantum jumps increase the entropy; this distinguishes the evolution from imperfect eigenstate preparation, which would also seed non-Hermitian evolution toward $|+\rangle$, but with decreasing entropy \[12\].

Finally, we study the qubit dynamics under slow parameter variation to reveal the effects of quantum jumps on non-Hermitian adiabatic evolution. We choose a straight parameter path with $J = 30 \text{ rad} \mu s^{-1}$ ($\gg J_{\text{EP}} = 1.5 \text{ rad} \mu s^{-1}$) and $\Delta = -30 \pi \sin(2\pi t/T) \text{ rad} \mu s^{-1}$, where $T = 4 \mu s$ is the loop period (Fig. 4(a)). The initial state at $t = 0$ is chosen to be an eigenstate of $H_{\text{eff}}$ (approximated as $|+\rangle$). Along this parameter path, the energy gap is large enough to satisfy the slow-driving condition $|T|\lambda_{+} - \lambda_{-}| \gg 1$. For $t < T/2$, the initial state follows the instantaneous eigenstate $|+\rangle$ with relative gain. At $t = T/2$, the parameter path crosses a branch cut for the imaginary Riemann surface at $\Delta = 0$. Here, the instantaneous eigenstates exhibit a loss-switch behavior; the eigenstate with relative gain becomes the eigenstate with more loss (Fig. 4(b)).

The results of quantum state tomography are shown in Fig. 4(c). At $t = 2 \mu s$, adiabatic evolution would return the qubit to the state $|+\rangle$. The qubit returns close to this state, with slight mixing induced by the quantum jumps. For $t > T/2$ the qubit is now predominantly in the eigenstate with greater loss, seeding non-Hermitian
evolution toward the eigenstate \( |- \rangle \). At the end of the parameter sweep, the qubit has undergone a switch between eigenstates, induced by the small perturbation of quantum jumps. This transition is accompanied by a sharp increase in the entropy as shown in Fig. 4(d).

Similar nonadiabatic state/energy transfer has been observed when dynamically encircling an EP [21–24] as a result of non-Hermitian coupling between eigenstates and non-Hermiticity gain-loss effects [43]. To verify that our parameter variation is sufficiently slow to prevent this nonadiabatic coupling, we plot the calculated dynamics in the absence of quantum jumps in Fig. 4(c), observing that there is no eigenstate switch. This reveals how quantum jumps effectively serve as a new source of nonadiabatic coupling, breaking adiabatic evolution even when parameter variation is sufficiently slow.

Quantum jumps, even when introduced at very modest rates, produce significant effects on non-Hermitian dynamics. The dissipation induced by these jumps is greatly enhanced by proximity to the EP, with dynamics driven by non-Hermitian evolution. In addition, quantum jumps introduce a new timescale relevant to adiabatic state transport in non-Hermitian systems. Our study elucidates the role and effect of dissipation on quantum non-Hermitian evolution, highlighting how controlling these dissipation mechanisms will be critical for harnessing non-Hermiticity and complex energies in quantum information processing and quantum sensing [10, 14, 45].

[41] Supplemental information provides information about the calculation of the Liouvillian spectrum.

Supplemental Information

In these supplementary materials, we describe our experimental setup, provide calculations of the spectra of the hybrid-Liouvillean superoperators in detail, and also discuss the decoherence effect led by quantum jumps.

A. EXPERIMENTAL SETUP

Our setup consists of a transmon superconducting circuit dispersively coupled to a three-dimensional copper microwave cavity. The transmon is composed of a pair of Josephson junctions in a SQUID geometry shunted by a capacitor. It is fabricated through double-angle evaporation and oxidation of aluminium on silicon substrate. The transmon transition frequency can be adjusted by tuning a d.c. magnetic flux through the SQUID loop. Through a bath engineering technique, the density of states of the electromagnetic field near the transition frequency is nonuniform, allowing us to tune the dissipation rates of the transmon energy levels. In experiments, the transition frequencies are about $\omega_{ge}/2\pi = 5.71$ GHz, $\omega_{ef}/2\pi = 5.41$ GHz, with the corresponding charging energy $E_c/h = 270$ MHz and the Josephson energy $E_J/h = 16.6$ GHz.

The transmon circuit is dispersively coupled to the microwave cavity (with the dressed resonance frequency $\omega_c/2\pi = 6.684$ GHz and decay rate $\kappa_c/2\pi = 5$ MHz) at a rate $g/2\pi = 65$ MHz, with the coupling rates for $|e\rangle$ and $|f\rangle$ levels given by $\chi_c/2\pi = -2$ MHz and $\chi_f/2\pi = -11$ MHz. We achieve high-fidelity, single-shot readout of the transmon state in the energy eigenbasis by probing the microwave cavity with a weak signal and detecting its phase shift, assisted by a Josephson parametric amplifier with over 20 dB gain and instantaneous bandwidth of 50 MHz. The readout fidelity for $|g\rangle$, $|e\rangle$, $|f\rangle$ are about 77%, 78%, 98%, respectively (Fig. 5). In quantum state tomography, a $\pi/2$ pulse is used to rotate the qubit about $X$ and $Y$ axes, followed by readout in the energy eigenbasis. The duration of $\pi$ pulses used in the sequence are $\tau_{ge} = 34$ ns and $\tau_{ef} = 30$ ns, respectively. Each data set acquired with $10^4$ repetitions per time point, of this approximately 100-200 successful postselections contribute to the tomography.

FIG. 5. Histogram of integrated single-shot readout signal, with the three states well separated.

B. MATRIX REPRESENTATION AND SPECTRA OF HYBRID-LIOUVILLIAN SUPEROPERATORS

The dynamics of the three-level quantum system in our study is described by a Lindblad master equation

$$\frac{\partial \rho_{\text{tot}}}{\partial t} = -i[H_c, \rho_{\text{tot}}] + \sum_{k=e,f} [L_k \rho_{\text{tot}} L_k^\dagger - \frac{1}{2} \{L_k^\dagger L_k, \rho_{\text{tot}}\}],$$

(4)

where $\rho_{\text{tot}}$ denotes a $3 \times 3$ density operator. The Lindblad dissipators

$$L_c = \sqrt{\gamma_e} |g\rangle \langle e|$$

and $L_f = \sqrt{\gamma_f} |e\rangle \langle f|$ describe the energy decay from $|e\rangle$ to $|g\rangle$ and from $|f\rangle$ to $|e\rangle$, respectively. A microwave drive is applied to the $\{|e\rangle, |f\rangle\}$ submanifold, and in the rotating frame $H_c = J(|e\rangle \langle f| + |f\rangle \langle e|) + \Delta/2(|e\rangle \langle e| - |f\rangle \langle f|)$, where $\Delta$ is the frequency detuning (relative to the $|e\rangle - |f\rangle$ transition) of the microwave drive that couples the states at rate $J$.

In the absence of $L_f$, non-Hermitian evolution in the $\{|e\rangle, |f\rangle\}$ submanifold can be isolated by eliminating quantum jumps from the $|e\rangle$ level. The resulting dynamics is governed by

$$\frac{\partial \rho}{\partial t} = -i[H_c, \rho] - \frac{1}{2} \{L_c^\dagger L_c, \rho\} \equiv \mathcal{L}\rho,$$

(5)
where $\rho$ denotes a $2 \times 2$ density operator and we define $H_{\text{eff}} = H_c - iL_{c}^\dagger L_c/2$ and $L\rho = -i(H_{\text{eff}}\rho - \rho H_{\text{eff}}^\dagger)$.

To study the hybrid-Liouvilian spectra and exceptional points, we first represent the hybrid-Liouvillian superoperator in a matrix form \[34, 35\], given by

$$L_{\text{matrix}} = -i(H_c \otimes I - I \otimes H_c^T) - \frac{L_{c}^\dagger L_c \otimes I}{2} - \frac{I \otimes L_c^\dagger L_c}{2},$$ \hspace{1cm} (6)

where $\otimes$ represents a Kronecker product operation and $T$ represents the transpose. Accordingly, the density operator is written in a vector form,

$$\rho = \begin{pmatrix} \rho_{ee} & \rho_{ef} \\ \rho_{fe} & \rho_{ff} \end{pmatrix} \rightarrow \begin{pmatrix} \rho_{ee} \\ \rho_{ef} \\ \rho_{fe} \\ \rho_{ff} \end{pmatrix}. \hspace{1cm} (7)$$

When the frequency detuning of microwave drive $\Delta = 0$,

$$L_{\text{matrix}} = \begin{pmatrix} -\gamma_c & iJ & -iJ & 0 \\ iJ & -\gamma_c/2 & 0 & -iJ \\ -iJ & 0 & -\gamma_c/2 & iJ \\ 0 & -iJ & iJ & 0 \end{pmatrix}, \hspace{1cm} (8)$$

and accordingly,

$$H_{\text{eff}} = \begin{pmatrix} -\gamma_c/2 & J \\ J & 0 \end{pmatrix}. \hspace{1cm} (9)$$

The eigenvalues of $H_{\text{eff}}$ and $L_{\text{matrix}}$ are provided in Fig. 6. The hybrid-Liouvilian spectra is ordered as $\text{Re}[\lambda_0] \geq \text{Re}[\lambda_1] \geq \text{Re}[\lambda_2] \geq \text{Re}[\lambda_3]$. Due to the ‘$-i$’ term in Eq. (1), the real and imaginary parts of hybrid-Liouvilian spectra should be compared to the imaginary and real parts of the spectra of $H_{\text{eff}}$, respectively. Both spectra show an EP at $J = \gamma_c/4$.

![Figure 6](image-url)

**FIG. 6.** Eigenvalues of the hybrid-Liouvilian superoperator $L_0$ (a) and the effective non-Hermitian Hamiltonian $H_{\text{eff}}$ (b) at different drive amplitudes $J$. The parameters used are $\gamma_c = 6.25 \mu s^{-1}$, $\gamma_f = 0$, $\gamma_\phi = 0$, and $\Delta = 0$. The curves have been slightly offset for clarity.

We now consider the effect of the jump operator $L_f$. It affects the qubit dynamics in two aspects. First, it modifies the effective non-Hermitian Hamiltonian $H_{\text{eff}}' = H_{\text{eff}} - iL_f^\dagger L_f/2$, and the corresponding hybrid Liouvillian is denoted...
as \( \mathcal{L}_0 \) (See Table I). Second, the quantum jumps abruptly change the qubit state, the effect of which is described by the hybrid-Liouvillian superoperator \( \mathcal{L}_1 \rho = L_f \rho L_f^\dagger \) which has no Hamiltonian counterpart. The matrix form of \( \mathcal{L}_1 \) can be calculated by using \( \mathcal{L}_1^{\text{matrix}} = L_f \otimes L_f \) (See Table I). Figure 7 presents the hybrid-Liouvillian spectra with \( (\mathcal{L}_0 + \mathcal{L}_1) \) and without \( (\mathcal{L}_0) \) considering quantum jumps. The eigenvalues of \( \mathcal{L}_0 \) are given by

\[
\lambda_{0,1} = -\left(\frac{\gamma_e + \gamma_f}{2}\right) \\
\lambda_{2,3} = -\left(\frac{\gamma_e + \gamma_f}{2}\right) \pm \left(\frac{1}{2}\right) \sqrt{\left(\gamma_e - \gamma_f\right)^2 - 16J^2}
\]

with \( \gamma_e = 6.25 \text{ ms}^{-1} \), \( \gamma_f = 0.25 \text{ ms}^{-1} \), \( \phi = 0 \), and \( \Delta = 0 \).

With the effect of quantum jumps \( (\mathcal{L}_1) \), the eigenvalues of \( \mathcal{L}_0 + \mathcal{L}_1 \) are given by

\[
\lambda_0 = -\frac{\gamma_e + \gamma_f}{2} - \frac{M}{6N^{1/3}} + \frac{1}{6}N^{1/3} \\
\lambda_1 = -\left(\frac{\gamma_e + \gamma_f}{2}\right) \\
\lambda_{2,3} = -\frac{\gamma_e + \gamma_f}{2} + \frac{(1 \mp i\sqrt{3})M + (-1 \mp i\sqrt{3})N^{2/3}}{12N^{1/3}}
\]

with \( M = 48J^2 - 3(\gamma_e - \gamma_f)^2 \) and \( N = 216\gamma_f J^2 + \sqrt{216}\gamma_f J^2 \mp M^2 \).

The quantum jumps \( (\mathcal{L}_1) \) as a perturbation lift the eigenvalue degeneracy at the third-order Liouvillian EP (i.e., \( M = 0 \)). On one hand, the splitting of the real part of eigenvalues leads to decoherence, determined by the eigenvalue difference \( \Re[\lambda_0 - \lambda_{2,3}] \). On the other hand, the nonzero imaginary parts of \( \lambda_{2,3} \) lead to oscillatory behavior. For
small $\gamma_f$ limit,

\[
\text{Re}[\lambda_0 - \lambda_{2,3}] = \frac{3}{4} (\gamma_e^2 \gamma_f)^{1/3},
\]

\[
\text{Im}[\lambda_{2,3}] = \frac{\sqrt{3}}{4} (\gamma_e^2 \gamma_f)^{1/3}.
\]

Both effects are enhanced due to the cube-root topology of the hLEP (Fig. 8).

Similarly, we can include the effect of pure dephasing in the submanifold, described by a jump operator $L_\phi = \sqrt{\gamma_\phi / 2} \sigma_z$ with dephasing rate $\gamma_\phi$ (see Table I and Fig. 9).

![FIG. 9. Hybrid-Liouvillian spectra $\lambda_i=0,1,2,3$ at different drive amplitudes $J$ with (solid curves) and without (dashed curves) quantum jumps from the pure dephasing of the $|e\rangle - |f\rangle$ submanifold. The parameters used are $\gamma_e = 6.25 \mu s^{-1}$, $\gamma_\phi = 0.5 \mu s^{-1}$, $\gamma_f = 0$, and $\Delta = 0$. The curves have been slightly offset for clarity.](image)

TABLE I. Matrix form of the hybrid-Liouvillian superoperators $\mathcal{L}_0$ and $\mathcal{L}_1$ under the dissipation of spontaneous emission of the $|f\rangle$ level at a rate $\gamma_f$ and the pure dephasing of the $|e\rangle - |f\rangle$ submanifold at a rate $\gamma_\phi$.

C. DECOHERENCE IN NON-HERMITIAN DYNAMICS WITH QUANTUM JUMPS

The $\mathcal{PT}$ symmetry breaking transition of a non-Hermitian qubit has been reported in Ref. [27], manifested as a transition of population dynamics from exhibiting exponential decay in the broken regime to anharmonic sinusoidal oscillations in the unbroken regime. The quantum jumps within the qubit lead to decoherence, eventually resulting in a steady state. As shown in Fig. 2 of the main text, the decoherence effect manifests as a decaying oscillation in the unbroken regime. Here we provide the connection between this decay rate and the hybrid-Liouvillian spectra.

The dynamics of the density matrix $\rho(t)$ (except at the EP) can be written as

\[
\rho(t) = \sum_{i=0,1,2,3} c_i(0) e^{\lambda_i t} \rho_i,
\]
where $\lambda_i (\rho_i)$ is the eigenvalue (eigenvector) of the hybrid-Liouvilian superoperator, and $c_i(0)$ is determined by the initial state. Given the initial state $|f\rangle$, $c_1(0) = 0$; therefore the eigenvalue $\lambda_1$ does not affect the dynamics. The evolution for the population at each level $\{|e\rangle, |f\rangle\}$ can be obtained from $\rho(t)$, that is, $P_e(t) = \rho_{ee}(t)$ and $P_f(t) = \rho_{ff}(t)$. The population in the $\{|e\rangle, |f\rangle\}$ submanifold then can be calculated from $P^n_e = P_e/(P_e + P_f)$ and $P^n_f = P_f/(P_e + P_f)$.

In the absence of quantum jumps, the four eigenvalues have the same real part (corresponding to the decay rate) in the unbroken regime, subsequently leading to undamped oscillation for $P^n_e$ and $P^n_f$. The oscillation frequency is determined by the imaginary part of the eigenvalue $\lambda_2$ (equivalently $\lambda_3$, since $\text{Im}[\lambda_2] = -\text{Im}[\lambda_3]$). The quantum jumps lift the degeneracy, and the eigenvalues no longer have the same real part (see Fig. 7). Therefore, the components in Eq. [17] feature different decay rates: the eigenvector $\rho_0$ with the smallest decay rate corresponds to the effective steady state, and the relaxation rate to the effective steady state is determined by $\text{Re}[\lambda_0 - \lambda_2]$, which is enhanced near the hLEP. In our study, the experimental results are fit to an exponentially decaying sine function, which is a good approximation to the theoretical model.
