Abstract We propose a new kind of qubits composed of electric dipolar molecules. The electric dipolar molecules in an external uniform electric field will take simple harmonic oscillations, whose quantum states belonging to the two lowest energy levels act as the states |0>, |1> of a qubit. The qubits’ excited states have a very long mean life time more than 70ms. We can perform quantum computations by manipulating the qubits of electric dipolar molecules just like those of neutral atoms. When the qubits are used for quantum computations, the dipolar moments’ orientations will harmonically oscillate along an external electric field and they will not change the directions: along or against the electric field, so the qubits can be large-scalely manufactured in graphene system.

Key Words: electric dipolar molecules, scalable qubits, nitrogen-doped graphene oxide

I Introduction
For a physical system to be viable in the long run, it should exhibit most or all of the elements (DiVincenzo criteria): well-defined qubits that allow for initialization into well-characterized, long-lived quantum states with the capability of high-fidelity state-dependent readout; a means to deterministically and controllably entangle individual qubits without decoherence; and the ability to transfer entanglement remotely[1]. There are several species of qubits to be used in quantum computations, for instance trapped ions[2], superconducting quantum circuitries[3], linear optics[4], semiconductor quantum dots[5,6], nitrogen vacancy centers in diamond[7] and neutral atoms[8] et al. No matter which species of qubits are manipulated, the scaling up to larger number of qubits is a central challenge. As there prevalently exist electric dipolar moments in the current quantum devices[9,10,11], the electric dipolar moments may be employed in quantum computing. De Mille proposed the novel qubits composed of ultracold diatomic molecules, whose electric dipolar moments can orient along or against an external electric field[12]. The protocol is interesting, however, the ultracold diatomic molecules in the protocol have to be cooled and trapped, which obstructs the scalability of qubits. In this paper we propose a new kind of qubits composed of electric dipolar molecules in solid. The paper is organized as follows: in section II the qubit of dipolar molecule are introduced, in section III the mean lifetime of the qubit is evaluated, in section IV Rydberg blockade and CNOT quantum gate are presented, in section V physical realization of scalable qubits is proposed based on graphene, in section VI the conclusions are given.

II the qubit of dipolar molecule

Given the moment of inertia of an electric dipolar molecule \( J \), the electric dipolar moment \( \vec{p} \), an external uniform electric field strength \( \vec{E} \), as shown in Fig.1, the molecule’s potential in the electric field reads \( V = -\vec{p} \cdot \vec{E} = -pE \cos \theta \).
If the oscillation angle $\theta$ is smaller than 0.1, i.e. about $5^\circ$, and the potential is expanded to $\theta^4$ terms in the Taylor series, then the potential has the form of a 1D harmonic oscillator, i.e.,

$$V = \frac{pE}{2} \left( \theta^2 - \frac{\theta^4}{12} \right),$$

where the constant term $-pE$ is neglected. The stationary Schrödinger's equation for the dipolar molecule’s anharmonic oscillator is written as

$$\left[ -\frac{\hbar^2}{2J} \frac{d^2}{d\theta^2} + \frac{pE}{2} \left( \theta^2 - \frac{\theta^4}{12} \right) \right] \psi(\theta) = E\psi(\theta)$$

Given the intrinsic frequency $\omega_0 = \sqrt{pE/J}$, we numerically obtain the eigenvalues of a hydrochloric molecule with moment of inertia $J \approx 2.5 \times 10^{-47} \text{kg} \cdot \text{m}^2$ [13], which is shown in Fig. 2. The nonlinearity of the energy levels of dipolar molecules resembles that of Josephson junctions in superconducting qubits. The quantum states $\psi_0$, $\psi_1$ belonging to the two lowest energy levels act as the states $|0\rangle, |1\rangle$ of a qubit. Given the external uniform electric field strength $E = 300V/m$, we obtain the intrinsic frequency $\omega_0 \approx 6 \text{GHz}$ of a hydrochloric molecule with the dipolar moment $p \approx 1 \text{Debye}$.
III the long mean lifetime of the qubit

If the qubit is in the thermal reservoir, the master equation in the interaction picture for the qubit reads

$$\frac{d\rho_{qubit}(t)}{dt} = \Gamma \left[ \sigma_+ \rho_{qubit} \sigma_- - \frac{1}{2} (\sigma_- \rho_{qubit} \sigma_+ + \rho_{qubit} \sigma_+ \sigma_-) \right]$$

with \( \sigma_+ = |1\rangle\langle 0|, \sigma_- = |0\rangle\langle 1| \). The qubit decay rate \( \Gamma \) can be derived by the Weisskopf-Wigner theory, and it is equal to the Einstein’s spontaneous emission coefficient\[14\]. The qubit decay rate is given by \( \Gamma = \frac{4(2\pi)^4 v_{eg}^2 e^2 l^2 |\theta_{eg}|^2}{3hc^3} \), where \( |\theta_{eg}|^2 = \frac{nh}{8\pi^2 Jv_{eg}} \) is the matrix element of a harmonic oscillator, \( h \) is the Planck constant, \( c \) is the light speed in vacuum, \( e \) is the electron’s charge, \( n \) is the quantum number, \( v_{eg} \) is the transition frequency from an excited state \( |1\rangle \) to a ground state \( |0\rangle \), \( l \) and \( J \) are, respectively, the length and the moment of inertia of electric dipolar molecules. The mean life time is written as \( \tau = 1/\Gamma = \frac{3Je^3}{2(2\pi)^2 v_{eg}^2 e^2 l^2 n} \). The typical parameters for hydrochloric molecules are \( J \approx 2.5 \times 10^{-47} \text{kg} \cdot \text{m}^3, l = 0.128 \text{nm}, v_{eg} \approx 10^3 \text{Hz}, n = 1 \), the mean life time \( \tau \) is evaluated about 70ms, which belongs to a very long mean life time for quantum computations. The mean life time 70ms is not only the mean life time of the excited state, but also is the coherence time of the qubit. In this paper we do not involve the depopulation time of the qubit, which should be determined by Rabi frequency.

IV Rydberg blockade and quantum gate

The energy level spaces of dipolar molecules in an external electric field will decrease as the quantum number \( n \) increases, and then the qubits of electric dipolar molecules are fully equivalent to those of neutral atoms. The qubits are coupled by the electric dipole-dipole interaction, and Rydberg blockade effect entangling two qubits still works well just as the effect entangling two neutral atoms does\[15\]. Actually electric dipolar molecules are sensitive to electric fields, so the two dipolar molecules in Rydberg states undergo a strong dipole-dipole interaction. Consider the ground state \( |0\rangle \) of a dipolar molecule coupled to its Rydberg state \( |r\rangle \) with a resonant laser with a Rabi frequency \( \Omega \). In the case of two dipolar molecules, the collective ground state \( |00\rangle \) is still resonantly coupled to the states \( |0r\rangle \) and \( |r0\rangle \) containing a single Rydberg excitation. The doubly-excited state \( |rr\rangle \) is shifted out of resonance by the strong van der Waals interaction \( U \) between the two molecules. In the limit \( U \gg \hbar \Omega \), the double excitation is energetically forbidden(Rydberg blockade). Introducing the two collective states \( |\psi_{\pm}\rangle = (|0r\rangle \pm |r0\rangle)/\sqrt{2} \), the collective ground state \( |00\rangle \) is not coupled to \( |\psi_{-}\rangle \) but coupled to \( |\psi_{+}\rangle \) with the coupling \( \sqrt{2}\Omega \). Starting from \( |00\rangle \) and applying the laser for a duration \( \pi / (\sqrt{2}\Omega) \) thus prepares the entangled state \( |\psi_{+}\rangle \)[16].
Fig. 3 Principle of a two-qubit quantum gate based on Rydberg blockade.

(a) involved levels and lasers. (b) pulse sequence. (c) truth table of the phase gate [excerpted from Ref. 16].

The Rydberg blockade can be used to construct fast quantum gates with dipolar molecules. As shown in Fig. 3, the qubits are encoded in two lowest energy levels \( |0\rangle, |1\rangle \), which can be separately addressed by lasers that couple the state \(|1\rangle\) to the Rydberg state \(|\tau\rangle\). The two molecules are close enough so that Rydberg blockade prevents the excitation \(|\tau\tau\rangle\). When applying the pulse sequence shown in Fig. 3(b), if any of the qubits is initially prepared in \(|1\rangle\), then the blockade makes one of the lasers off-resonant, one and only one of the molecule undergoes a \( 2\pi \) rotation, and the wavefunction of the system gets a minus sign at the end of the sequence. If both qubits are initially in \(|0\rangle\), the laser pulses have no effect. This leads to the truth table shown in Fig. 3(c), which constructs a controlled-phase gate. The controlled-phase gate can be turned into a controlled-not (CNOT) gate using additional single-qubit gates [16]. The remarkable feature of the Rydberg gates lies in its short duration, set by the interaction energy of the two molecules. Another advantage of this protocol is that it is insensitive to the exact value of the inter-molecule interaction. From the above discussions, we know that the qubits of dipolar molecules are employed to implement quantum computing.

If the noises of room temperature are suppressed, i.e. all of the qubits are in ground states in room temperature, the corresponding external electric field strength acting on the hydrochloric molecules is about \( 10^4 V / \mu m \). Of course, the lower the temperature, the smaller the electric field strength. Actually if the condition \( k_B T < \hbar \omega_0 = \hbar \sqrt{pE / J} \) is satisfied, then the noise is suppressed. For the qubits of hydrochloric molecules, the electric field should be about \( 10^4 V / \mu m \) when the qubits work in room temperature 300K. However, if the qubits work in 3K temperature, the electric field should only be about \( V / \mu m \).

V Physical realization of scalable qubits based on graphene

Thanks to graphene, scalability of qubits becomes probable. Fig. 4 shows the nitrogen-doped graphene oxide, on which there are ‘pyridinic’ \( N \) atoms, ‘amino’ \( N \) atoms, ‘pyrrolic’ \( N \) atoms and ‘graphitic’ \( N \) atoms. If the nitrogen-doped graphene oxide in an electric field, the ‘amino’ \( N \) atoms acts as simple pendulums which harmonically oscillate. The lowest two energy states are employed as the states \(|0\rangle, |1\rangle\) of a qubit. As the qubits of electric dipolar molecules are fully equivalent to those of neutral atoms, we can evaluate the radius of Rydberg blockade. Given the principal quantum number \( n=100 \), the Rabi frequency \( \Omega = 1 MHz \) [17], the electric field \( E = 10^4 V / \mu m \), the radius
of Rydberg blockade from \( R \sim \frac{C_6}{\hbar \Omega} \) is about 1mm. The van der Waals coefficient

\[
C_6 = \left( \frac{d_1 d_2}{2} \right)^2 \frac{(4\pi \epsilon_0)}{2\delta}
\]

involves the transition dipole moment scales as \( d_1, d_2 \sim n^2 \), the Föster defect with the same scaling as the energy splitting between neighboring Rydberg states \( \delta = n^3 \). Overall the scaling of \( C_6 \) is about \( n^{11} \) [18]. As the time of gate on the qubits is about 1\( \mu \)s and the qubits possess a very long coherent time 70ms, the number of operated qubits should reach several thousands. The scalability of these qubits is realized through the scalable manipulations of graphene.

VI Conclusions

In summary, the electric dipolar molecules in an external uniform electric field are fully equivalent to neutral atoms, the new qubits can be also used for quantum computing. The qubits of dipolar molecules have several advantages compared with the qubits of neutral atoms: (1) the qubits’ excited states possesses a very long mean life time more than 70ms, which means that decoherent phenomena would not be a serious problem in quantum computing. Actually the mean life time of the qubit is evaluated from the qubit’s decay rate in thermal reservoir. (2) the orientations of dipolar moments do not need to change the directions: along or against the electric field, the qubits can be large-scalely manufactured in solid, dielectric molecules are maybe good candidates; (3) the qubits do not have to be cooled and trapped, the chip’s structures should be very simple. The nonlinear energy levels of dipolar molecule are non-degenerate, which is helpful to manipulate the qubits precisely. It seems feasible that the qubits on graphene are massively operated, the number of operated qubits reaches several thousands. Although there are other physical structures with long coherent time [20,21], our proposal of qubits incorporating long coherent time and scalability is very attractive. Of course the paper only theoretically gives a promising proposal for scalable qubits, there are many problems to be solved in practice. For instance, how is it possible to controllably create the defects in graphene? how are the qubits ensured to be the same strain, the same local environment? how are the qubits read out? how does the addressability work? These problems are left in the future work, we believe that quantum computer must occur from the various efforts.
