(Dated: June 9, 2021)

The accurate computational determination of chemical, materials, biological, and atmospheric properties has critical impact on a wide range of health and environmental problems, but is deeply limited by the computational scaling of quantum-mechanical methods. The complexity of quantum-chemical studies arises from the steep algebraic scaling of electron correlation methods, and the exponential scaling in studying nuclear dynamics and molecular flexibility. To date, efforts to apply quantum hardware to such quantum chemistry problems have focused primarily on electron correlation. Here, we provide a framework which allows for the solution of quantum chemical nuclear dynamics by mapping these to quantum spin-lattice simulators. Using the example case of a short-range hydrogen bonded system, we construct the Hamiltonian for the nuclear degrees of freedom on a single Born-Oppenheimer surface and show how it can be transformed to a generalized Ising model Hamiltonian. We then demonstrate a method to determine the local fields and spin-spin couplings needed to identically match the molecular and spin-lattice Hamiltonians. We describe a protocol to determine the on-site and inter-site coupling parameters of this Ising Hamiltonian from the Born-Oppenheimer potential and nuclear kinetic energy operator. Our approach represents a paradigm shift in the methods used to study quantum nuclear dynamics, opening the possibility to solve both electronic structure and nuclear dynamics problems using quantum computing systems.

I. INTRODUCTION

The quantum mechanical treatment of electrons and nuclei is critical for a wide range of problems that are of significance to biological, materials, and atmospheric studies. For example, hydrogen transfer processes are ubiquitous in reactions critical to human health, alternative energy sources, food security and environmental remediation [1]. Yet, the detailed treatment of such problems is confounded by the presence of non-trivial quantum nuclear effects, such as hydrogen tunneling [2–6], coupled with electron correlation [7]. For the study of electron correlation in most molecular systems, several powerful approximations have been developed for classical computing platforms, and these are known to provide significant speedups compared to exponentially-scaling full-configuration interaction calculations. Indeed, chemical accuracy may be obtained for many systems using the well-known CCSD(T) method [8] that has an associated scaling cost of \(O(N^{6-7})\), where \(N\) represents the number of electrons.

More recently, algorithms to solve electron correlation problems in small molecular systems have been implemented on quantum hardware devices using trapped atomic ions, photons, nuclear spins, quantum dots, Rydberg atoms, and superconducting circuits [9–20]. The mapping of most electron correlation problems onto quantum hardware is facilitated by the Jordan-Wigner, parity, or Bravyi-Kitaev transformations [21–23], where a product of Fermionic creation and annihilation operators are transformed to a chain of Pauli spin operators. In contrast, the intrinsic spin statistics of quantum nuclear effects do not play a role under conditions prevalent in biological, materials, and atmospheric systems, such as hydrogen transfer reactions under ambient conditions. As a result, most such quantum dynamics studies are currently constructed on classical computing platforms using basis sets and on grids. Furthermore, many of these problems are known to display anomalous nuclear quantum effects [2, 24, 25] that are challenging to study due to the exponentially scaling computational cost of quantum dynamics with increasing degrees of freedom. Unlike several recent attempts on the electron correlation problem [9–20, 26–30], approximating quantum nuclear dynamics problems on quantum computing platforms has received relatively less attention [31–37]. The primary goal of this paper is to develop a set of mapping protocols to allow the study of quantum nuclear dynamics problems on quantum hardware, without considering spin statistics. We provide and analyse an approximate algorithm to map exponentially-scaling quantum nuclear dynamics problems on a single Born-Oppenheimer surface, onto a general class of Ising-model
Hamiltonians. Such Ising-type Hamiltonians may be implemented on a range of quantum computing platforms, such as ion-traps [38, 39], super-conducting coils [40], Bosonic processors with photons [41–43], solid state devices and quantum dots inside cavities [44–47], and Rydberg atoms [48, 49]. Since quantum nuclear dynamics problems under ambient conditions do not need to be encoded using a set of Fermionic or Bosonic operators, we do not write the Ising model and molecular Hamiltonian in their respective second quantized forms. Instead, we first probe the structure of the Ising Hamiltonian matrix in its exponential scaling-space of spin basis vectors. This exponential space is admittedly intractable. Yet, our analysis of the Ising Hamiltonian matrix reveals an intrinsic structure where specific blocks appear within the Ising Hamiltonian matrix, and the corresponding matrix elements are only controlled by a subset of the externally controlled field parameters that dictate the dynamics of the model. To the best of our knowledge, such a structure has never been noted, or exploited, before in the literature. This structure allows us to characterize the general class of problems that may be “computable” using such hardware systems and in this paper we further inspect the extent to which quantum chemical dynamics studies may be conducted on such systems, when the statistics of particle permutation need not be included.

The mapping algorithm is illustrated in Figure 1. An example of a quantum nuclear problem is shown in Figure 1a, where we depict a system containing a short-strong hydrogen bond with anharmonic vibrational behavior along the donor-acceptor axis. This problem is prototypical and is representative of a broad range of systems that occur during hydrogen transfer reactions [2] and in hydrogen-bonded systems that are known to have significance in many critical processes [1]. We precompute the Born-Oppenheimer potential using electronic structure calculations and obtain a discrete version of the quantum nuclear Hamiltonian. To map this Hamiltonian onto a spin-lattice Ising-type model, the key insights in this paper are as follows: (i) A projected subspace of a specific unitary transformation of the diagonal elements of the quantum nuclear Hamiltonian (related to the Born-Oppenheimer potential) maps to and defines the local magnetic fields applied on each lattice site of an Ising model Hamiltonian. (ii) A similarly projected subspace of a related unitary transformation of the off-diagonal elements of the quantum nuclear Hamiltonian (related to the nuclear kinetic energy operator) defines and is mapped onto the inter-site coupling terms in the Ising model. Thus, we take a critical step towards solving quantum nuclear dynamics problems, and more generally problems that may not obey Fermi statistics, by mapping them to Ising-type Hamiltonians realizable on ion-trap quantum hardware. This is done without using a circuit model. The matrix elements, of the nuclear Hamiltonian that describe the molecular dynamics, inform the choice of local magnetic fields applied on each lattice site and laser pulse intensities that dictate the inter-site coupling, and govern the dynamics of the ion-trap quantum computing platform. In this manner we provide a direct map of the two quantum systems.

The paper is organized as follows: In Section II, we inspect the block structure of the Ising Hamiltonian which informs the general class of problems that may be computable on hardware architectures used to realize such Ising-type Hamiltonians. Following this, we then introduce the quantum nuclear Hamiltonian matrix on a single Born-Oppenheimer surface in Section III and a class of Givens rotations [50] based matrix transformations in Section III A to represent the quantum nuclear Hamiltonian matrix in a form that is commensurate with the transformed form of the Ising model Hamiltonian in Section II. This transformation leads to our approximate mapping protocol that is outlined in Section IV. Numerical results for the anharmonic molecular vibrations of the shared proton in a symmetric short-strong hydrogen bonded system are provided in Section V. These include explicit numerical propagation of both the molecular dynamics problem as well as the spin lattice dynamics governed by Ising-type Hamiltonian where the Ising Hamiltonian parameters are chosen based on the mapping protocol in Section IV. The results match exactly for the case of three-qubits and error estimates beyond three-qubits are given in Section IV. Conclusions are given in Section VI.

II. BLOCK STRUCTURE OF ISING-TYPE HAMILTONIAN MATRICES OBTAINED FROM APPROPRIATE CLASSIFICATION OF THE COMPUTATIONAL BASIS

Ising-type Hamiltonians can be implemented on a range of available quantum computing platforms [38–49], which makes these one of the most commonly-used quantum computing models today [39, 51]. However, for specificity, we will illustrate our mapping protocols for ion-trap based quantum architectures, where ions form defect-free arrangements and can support quantum coherence times longer than 10 minutes [52]. Interactions between ions map to interactions between effective quantum spin states and quantum-harmonic-oscillator bath states – each of which can be precisely controlled and programmed using laser light [53]. Site-resolved detection of each ion’s spin state can be achieved with near-unit fidelity [54]. These features have made trapped ions the leading platform for establishing atomic frequency standards [55] and one of the leading candidates for performing quantum simulations and quantum computations on such interacting spin systems. [39, 56–61]

For ion-trap quantum hardware, the generalized Ising Hamiltonian is represented by a spin-lattice of qubits,
These now provide us with a "computational basis" set of permutations on the computational basis vectors to determine the Ising model used to control the dynamics of lattice spin-states.

where (a) the energy gap between the states at each qubit, \( i \), and their relative orientations, are controlled by local effective magnetic fields, \( \{ B_i^x, B_i^y, B_i^z \} \), and (b) the spin-spin coupling between different lattice sites, \( i \) and \( j \), is controlled using laser pulses, also spatially non-isotropic, and represented as \( \{ J_{ij}^x, J_{ij}^y, J_{ij}^z \} \). Thus, the most general Hamiltonian achievable within the ion trap quantum hardware at low temperatures is

\[
\mathcal{H}_{IT} = \sum_{\gamma}^{N-1} \sum_{i=1}^{N} J_{ij}^x \sigma_i^\gamma \sigma_j^\gamma + \sum_{\gamma}^{N} \sum_{i=1}^{N} B_i^\gamma \sigma_i^\gamma \tag{1}
\]

where \( \gamma \in \{x, y, z\} \), and \( N \) is the number of qubits (or ion-sites). The quantities \( \{ \sigma_i^\gamma \} \) are the Pauli spin operators acting on the \( i^{th} \) lattice site along the \( \gamma \)-direction of the Bloch sphere.

In this paper, we map the Born-Oppenheimer nuclear Hamiltonian onto Eq. (1), thus allowing the two quantum systems to undergo analogous quantum dynamics. Towards this, the parameters \( \{ B_i^\gamma; J_{ij}^\gamma \} \) are "programmed" as per the elements of the classically determined Born-Oppenheimer nuclear Hamiltonian matrix. To arrive at such a map, we first examine the intrinsic symmetries that are present within such generalized Ising Hamiltonians.

The ion-trap Hamiltonian, \( \mathcal{H}_{IT} \), is naturally represented in a basis of \( 2^N \) spin states, where for example, \( \{ |↑↑⟩, |↑↓⟩, |↓↑⟩, |↓↓⟩ \} \) form a basis for a 2-qubit system. These now provide us with a "computational basis" with programmable handles, \( \{ B_i^\gamma; J_{ij}^\gamma \} \). To gauge the set of mappable problems, we introduce a general set of permutations on the computational basis vectors to reveal a novel block structure of the Ising Hamiltonian matrix. Specifically, the \( 2^N \) spin states are partitioned into two sets that are created by the span of even and odd total spin raising operators. Towards this, the basis vectors created from using an even number of lattice-site spin raising operators, \( \{ S^{+2n} \} \) acting on the full down-spin state, \( |2^N - 1⟩ \equiv |↓↓⋯⟩ \), yield the set, \( \{ |2^N - 1⟩; S_i^+ S_j^+ 2^N - 1; S_i^+ S_j^+ S_k^+ S_l^+ |2^N - 1⟩; ⋯ \} \), that are grouped as part of one block of the ion-trap Hamiltonian. See the set of vectors in Figure 2a, and
the treatment of systems that may have a similar block structure. Similarly, the off-diagonal matrix elements within each block are determined by the laser field parameters, \( \{ J_{ij}^x, J_{ij}^y \} \). While the structure derived here is completely general, it is illustrated in Figure 3 for a 3-qubit system. The diagonal elements of the matrix, not shown in Figure 3 to maintain clarity, contain linear combinations of \( \{ B_i^x, B_i^y \} \).

For larger number of qubits, the block structure is recursive form and this aspect is further elaborated in Appendix A. This block-form of the Ising-type Hamiltonian and the associated structure in Figure 3, is a significant general result in this paper, and as we find below, this analysis is critical towards mapping arbitrary problems.

III. THE GRID BASED QUANTUM NUCLEAR HAMILTONIAN COMPUTED ON CLASSICAL HARDWARE

The quantum nuclear Hamiltonian for the molecular system, \( \mathcal{H}_{Nuc} \), is constructed on classical hardware, for the purpose of this paper. In the grid basis representation \( \{ x \} \), the Hamiltonian matrix elements are given by,
For diagonal potentials, the potential energy operator, \( \hat{V} \), is diagonal in the coordinate representation. The potential energy in the above equation is obtained from electronic structure calculations, that may also be performed on quantum hardware, independently, in future. The kinetic energy in the coordinate representation and hence fast Fourier transforms are commonly employed [62]. In this paper, we employ an analytic distributed approximating functional (DAF) [63, 64] representation for the coordinate space version of the kinetic energy operator in Eq. (2):

\[
K(x, x') = K(|x - x'|) = \frac{-\hbar^2}{4m\sigma^2} \exp \left\{ -\frac{(x - x')^2}{2\sigma^2} \right\}
\]

\[
\sum_{n=0}^{M_{DAF}/2} \left( -\frac{1}{4} \right)^n \frac{1}{n!} H_{2n+2} \left( \frac{x - x'}{\sqrt{2\sigma}} \right).
\]

where, \( H_{2n+2} \left( \frac{x - x'}{\sqrt{2\sigma}} \right) \) are the even order Hermite polynomials that only depend on the spread separating the grid basis vectors, \( |x\rangle \) and \( |x'\rangle \), and \( M_{DAF} \) and \( \sigma \) are parameters that together determine the accuracy and efficiency of the resultant approximate kinetic energy operator. In this manner, the DAF presents a banded-Toeplitz representation for the kinetic energy operator, the structure of which, has a critical role in reducing the nuclear Hamiltonian to the form of \( \mathcal{H}_{IT} \), depicted in Figure 3. This is further elaborated in the following section.

### A. Unitary transformations that yield the Block structure of the nuclear Hamiltonian, for symmetric potentials, to make these commensurate with and mappable to the spin-lattice Hamiltonian, \( \mathcal{H}_{IT} \)

The nuclear Hamiltonian, \( \mathcal{H}^{Mol} \) from Eq. (2), has a banded Toeplitz structure due to the kinetic energy being expressed in terms of DAFs. In general, the Hamiltonian in Eq. (2) represents a multi-dimensional quantum dynamics problem, where the number of dimensions directly corresponds to the number of nuclear degrees of freedom. In this paper, we examine the map between the Hamiltonian in Eq. (2) for symmetric one-dimensional potentials and the Ising model Hamiltonian discussed in Section II. Routes from here to unsymmetric potentials and to problems in higher dimensions will be considered as part of future publications. In the proton transfer problem considered here, the one-dimensional potential energy surface along the hydrogen transfer axis, \( V(x) \) in Eq. (2), is a symmetric double well owing to the isoenergic donor and acceptor sites arising from the symmetry of the system (Figure 1(a)). We exploit the symmetric structure of the potential and the Toeplitz structure of the kinetic energy operator to construct a unitary transformation that block diagonalizes the nuclear Hamiltonian.

The unitary transform that leads to the block diagonalization of the nuclear Hamiltonian, similar to the structure of the Ising Hamiltonian, can be expressed as a product of Givens rotations. The effect of the Givens rotations on the grid basis states is to create superposition states of the symmetric grid basis states. The action of the product of Givens rotations is, therefore, to yield a rotation in the \( 2^N \) dimensional basis state space, by a sequence of \( 2 \times 2 \) (or one-qubit) rotations. This now divides the basis state space, in which the Hamiltonian is represented, into two sets of rotated states, created by the symmetric and anti-symmetric combinations respectively. To explain this, we introduce a uniform one-dimensional set of \( 2^N \) grid points, \( \{x_i\} \), such that the Givens transformed grid basis, \( \{\tilde{x}_i\} \), may be represented as

\[
|\tilde{x}_i\rangle = \frac{1}{\sqrt{2}} (|x_i\rangle \pm |x_{2N-i+1}\rangle), \quad 1 \leq i \leq 2^N
\]

(4)

These now form two mutually orthogonal subspaces that block diagonalize the nuclear Hamiltonian for symmetric potentials. This process is illustrated for a three-qubit system (2³-grid points) in Figure 4. The \( i^{th} \) matrix element of the resultant molecular Hamiltonian in the Givens transformed grid basis is explicitly written as

\[
\tilde{H}_{il}^{Mol} = \frac{1}{2} (H_{il}^{Mol} + \alpha_i H_{l+n-1,i}^{Mol} + \alpha_i H_{n+1-i,l}^{Mol} + \alpha_i \alpha_{l} H_{n+1-i,n+1-l}^{Mol}),
\]

(5)

where \( n = 2^N \) and \( \alpha_i = \text{sgn}[i-(n+1)/2] \). The elements of the diagonal blocks of \( \mathcal{H}^{Mol} \) (matrix on the right in Figure 4) are obtained from Eq. (5) as

\[
\tilde{H}_{il}^{Mol} = \frac{1}{2} (H_{il}^{Mol} + \alpha_i H_{l+n-1,i}^{Mol} + \alpha_i H_{n+1-i,l}^{Mol} + H_{n+1-i,n+1-l}^{Mol}) + \frac{1}{2} [V(x_i) + V(x_{n+1-l})] \delta_{i,l}
\]

(6)

The elements of the unitary transform, \( \alpha_i \) are, in fact, the characters of the \( C_n \) point group. The right hand side of the above equation, therefore, represents a symmetry adapted transformation of the nuclear Hamiltonian, and the term \( \frac{1}{2} [V(x_i) + V(x_{n+1-l})] \), symmetrizes the potential energy surface in one-dimension. By extension, for the off-diagonal blocks of \( \mathcal{H}^{Mol} \) in Figure 4, \( \alpha_1 = -\alpha_i \).
and
\[ H_{\text{Mol}}^{\text{Mod}} = \frac{1}{2} (H_{i,l}^{\text{Mod}} - \alpha_i H_{i,n+1-l}^{\text{Mod}} + \alpha_i H_{n+1-i,l}^{\text{Mod}} - \delta_{i,n+1-l}) \]  
(7)
where the kinetic energy contribution is identically zero purely due to the Toeplitz nature of Eq. (3), and only the anti-symmetric portion of the potential, \( \frac{1}{2} [V(x_i) - V(x_{n+1-i})] \), contributes to the anti-diagonal part of \( H_{\text{Mol}}^{\text{Mod}} \). Thus for symmetric potentials such as those considered here, Eq. (7) is identically zero. This observation will become useful when we generalize the approach presented here, first to general potentials and then, to problems of higher dimensionality in future publications.

IV. MAPPING PROTOCOL FOR QUANTUM CHEMICAL DYNAMICS

The structure of the ion-trap Hamiltonian constrains the class of mappable problems. These constraints dictate the accuracy with which quantum chemical dynamics simulations can be performed on an ion-trap system given by Eq. (1). To summarize our discussion thus far, we began with a computational basis \( |\lambda\rangle \), used to describe the Ising Hamiltonian, \( H_{\text{IT}} \) in Eq. (1), and the molecular basis \( |x\rangle \), used to represent the quantum nuclear Hamiltonian, \( H_{\text{Mol}}^{\text{Mod}} \) in Eq. (2). In the interest of matching the structures of the two Hamiltonians, we first obtained a permuted computational basis: \( |\lambda\rangle \rightarrow |\tilde{\lambda}\rangle \) (Section II) and a unitary (Givens) transformed quantum nuclear basis: \( |x\rangle \rightarrow |\tilde{x}\rangle \) (Section III A). In doing so our goal becomes:
\[ \langle \tilde{x}|H_{\text{Mol}}^{\text{Mod}}|\tilde{x}\rangle \leftrightarrow \langle \tilde{\lambda}|H_{\text{IT}}|\tilde{\lambda}\rangle \]  
(8)
where we have also tersely introduced a map between the transformed quantum nuclear wavefunction bases and the permuted computational bases that represent the Ising spin lattice system as:
\[ |\tilde{x}\rangle \leftrightarrow |\tilde{\lambda}\rangle . \]  
(9)
The effectiveness of the maps in Eqs. (8) and (9) will essentially dictate the accuracy to which the dynamics captured within the ion-trap quantum simulator controlled by an Ising Hamiltonian accurately predicts the quantum nuclear dynamics. In this section, we will show that, due to the structure of the Hamiltonians discussed in the previous sections, the diagonal and off-diagonal elements of each individual diagonal block of mappable Hamiltonians, such as Eq. (2), are Hadamard transformed to provide \( \{B_i^z; J_{ij}\} \) and \( \{J_{ij}; J_{ij}^\mu\} \), respectively. Similarly the coupling between the diagonal blocks in the Ising Hamiltonian, are controlled through \( \{B_i^z; B_i^\mu\} \) and provide handles for the appropriate blocks of mappable Hamiltonians. As a consequence of the discussion in Section III A, both Hamiltonians, Eqs. (1) and (2), by construction, take the form depicted in Figure 1c and the right side of Figure 4, respectively. However, we will also see that these maps are not exact for arbitrary Hamiltonians, beyond three-qubits, and towards the end of this section we provide error-bounds to determine the extent to which the Ising Hamiltonians deviate from the molecular Hamiltonian (or any other general matrix).

Our quantum nuclear dynamics test case that will be mapped to the aforementioned Ising Hamiltonian (Section V), exploits the block structure discussed above and
we illustrate the map by studying a symmetric hydrogen bonded system displayed in Figure 1a, where a symmetric double-well potential is also shown. For these cases, as seen from Eqs. (7), (6) and the discussion in Section II and Eq. (A3) in Appendix A, the block structure of both the Hamiltonian matrices allows the two blocks of each Hamiltonian matrix (Ising and molecular) to be propagated independently, and, potentially on different quantum simulators, for the Ising Hamiltonian. We exploit this feature to evaluate a separate set of \( \{B^z_i; J^z_{ij}\} \) values, below, for each of the two diagonal blocks of the molecular Hamiltonian, while maintaining \( \{B^z_i; B^y_j\} \) to be identically zero.

A. Obtaining ion-trap parameters \( \{B^z_i; J^z_{ij}\} \) from the diagonal elements of the molecular Hamiltonian

The diagonal elements of the molecular Hamiltonian are directly invoked in the map of the unitary transformed grid basis \( (\tilde{\kappa}) \) to the permuted computational basis \( (\tilde{\lambda}) \). Each diagonal element of the molecular Hamiltonian in the transformed grid representation, \( \langle \tilde{\kappa}|\hat{H}^{Mol}|\tilde{\kappa} \rangle \), is equivalent to the corresponding element of the ion-trap Hamiltonian, \( \langle \tilde{\lambda}|\hat{H}_{IT}|\tilde{\lambda} \rangle \) in the permuted computational basis representation. See Eqs. (6) and (7). In doing so, the set of on-site and inter-site coupling parameters, \( \{B^z_i; J^z_{ij}\} \), of the ion-trap that occur along the diagonal of \( \hat{H}_{IT} \) can be evaluated. The mapping expression between the diagonal elements of the molecular Hamiltonian and the ion-trap Hamiltonian may be written as

\[
\langle \tilde{\kappa}|\hat{H}^{Mol}|\tilde{\kappa} \rangle \equiv \langle \tilde{\lambda}|\hat{H}_{IT}|\tilde{\lambda} \rangle = \sum_{j=1}^{N} (-1)^{\tilde{\lambda}_j} B^z_j + \sum_{j=1}^{N-1} \sum_{k>j}^{N} (-1)^{\tilde{\lambda}_j \oplus \tilde{\lambda}_k} J^z_{jk} \tag{10}
\]

where \( \oplus \) denotes the addition modulo 2, \( \tilde{\lambda}_j \) is the \( j \)th bit of the bit representation of \( \tilde{\lambda} \) with values 0 or 1 for up- or down-spin, respectively, as shown in Figures 2 and 3. Our goal here now is to be able to simulate the diagonal elements of \( \hat{H}^{Mol} \) that are influenced by the Born-Oppenheimer potential, by tuning the set of ion-trap parameters \( \{B^z_i; J^z_{ij}\} \) that determine the diagonal elements of \( \hat{H}_{IT} \).

To this effect, we treat all parameters in \( \{B^z_i; J^z_{ij}\} \) on an equal footing and write the mapping expression for the diagonal elements in each block as,

\[
\langle \tilde{\kappa}|\hat{H}^{Mol}|\tilde{\kappa} \rangle \equiv \langle \tilde{\lambda}|\hat{H}_{IT}|\tilde{\lambda} \rangle = \sum_{i=1}^{N(N+1)} T_{\lambda_i} D^z_i \tag{11}
\]

where \( \{\tilde{\lambda}\} \) correspond to either of the two sets of permuted computational basis states (see Figure 2) that independently span \( \{S^z_1 \cdots S^z_{2^n}|11 \cdots 1\} \) or \( \{S^z_1 \cdots S^z_{2^n-1}|11 \cdots 1\} \).\( D^z \) is a vector that represents in a consolidated fashion, the individual \( \{B^z_i; J^z_{ij}\} \) parameters and the \( T_{\lambda_i} \) represents a coefficient matrix for the phase preceding the corresponding \( D^z_i \) as seen from Eq. (10). The upper-limit for the index \( i \) in the above expression thus denotes the maximum number of independent parameters in \( \{B^z_i; J^z_{ij}\} \) that will be used to encode the diagonal part of \( \hat{H}^{Mol} \) for a given number of qubits. This aspect of matching the number of parameters is further discussed in Appendix C. Thus, the diagonal elements of the transformed Ising Hamiltonian, \( \langle \tilde{\lambda}|\hat{H}_{IT}|\tilde{\lambda} \rangle \) encode both the Born-Oppenheimer potential energy surface, \( V(\tilde{x}) \), and the Givens transformed elements of the nuclear kinetic energy that appear due to block diagonalization process, needed to make the two Hamiltonians have the same structure (see Eq. (6)). The columns of the transformation matrix on the right side of Eq. (11) with elements, \( T_{\lambda_i} = \pm 1 \), resemble a subset of columns that span a \( N-1 \) dimensional Hadamard matrix, which is a \( (N-1)^{th} \) order tensor product of the standard 2×2 Hadamard transform \( H \). Thus, the columns of \( T \) in Eq. (11) are orthogonal and the \( \{B^z_i; J^z_{ij}\} \) values may be computed as:

\[
D^z_i = \frac{1}{2^{N-1}} \sum_{\lambda} T_{\lambda_i} \langle \tilde{\lambda}|\hat{H}_{IT}|\tilde{\lambda} \rangle \tag{12}
\]

Owing to the equivalence of \( \langle \tilde{x}|\hat{H}^{Mol}|\tilde{x} \rangle \) and \( \langle \tilde{\lambda}|\hat{H}_{IT}|\tilde{\lambda} \rangle \), as seen in Eq. (8), we use the precomputed diagonal elements of the unitary transformed molecular Hamiltonian in Eq.(12) to obtain the on-site parameters of the ion-trap. As per Eq. (10), \( \langle \tilde{\lambda}|\hat{H}_{IT}|\tilde{\lambda} \rangle \) may be replaced by \( \langle \tilde{x}|\hat{H}^{Mol}|\tilde{x} \rangle \) in Eq. (12) leading to,

\[
D^z_i = \frac{1}{2^{N-1}} \sum_{i=\tilde{\lambda}} T_{\lambda_i} \langle \tilde{\lambda}|\hat{H}^{Mol}|\tilde{\lambda} \rangle \tag{13}
\]

where we tersely assume the summation over \( \{\tilde{\lambda}\} \) to also correspond to the summation over \( \{\tilde{x}\} \) as allowed by the correspondence in Eq. (9). The transformation matrix in Eq. (13), that is \( T^{T} \), is illustrated in Figure 5 (b and c) for the \( 2^4 \)-dimensional sub-blocks of a 5-qubit Ising and for the \( 2^2 \)-dimensional sub-blocks of a 3-qubit Ising Hamiltonian in Figure 5 (a). The dimension, \( 2^{N-1} \times \frac{N(N+1)}{2} \) of the \( T \) matrix is apparent from this figure. The latter dimension of the \( T \) matrix that depends on the number of independent \( D^z_i \) values is at most \( \frac{N(N+1)}{2} \), and is found to be 3 for the 3-qubit system and 15 for the
5-qubit system. More general expressions comparing the number of Ising Hamiltonian control parameters to the number of independent matrix elements in the molecular Hamiltonian, are given in Appendix C. While the figure is only presented for 3-qubit and 5-qubit systems, the transformation is completely general.

At this stage, as noted in Appendix C, Eqs. (C1) and (C2), and by comparison with the upper limit of the summation in Eq. (11), where clearly \( \frac{N(N+1)}{2} < 2^{N-1} \) for \( N > 4 \), it is clear that the number of \( \{ B_1^z; J_2^z \} \) ion-trap handles are fewer than the number of diagonal elements in the molecular Hamiltonian for large number of qubits. However, it may be possible to pre-rotate the molecular Hamiltonian basis (similar to the Givens rotation based unitary transform in Section (III A)) so as to compress the amount of information along the diagonal and these aspects will be considered in a future publication.

1. Error bounds on mapping \( \langle \hat{x} | \hat{H}^{mol} | \hat{x} \rangle \leftrightarrow \langle \lambda | \hat{H}_{TT} | \lambda \rangle \) for larger number of qubits

Arising from the above discussion, the error, \( \epsilon \), associated with such a partial Hadamard transform of the diagonal elements of the molecular Hamiltonian, can be obtained from the orthogonal complement of the transformation matrix in the corresponding Hadamard matrix. This can be expressed in a closed form as,

\[
\epsilon = \frac{1}{2^{N-1}} \sqrt{\left( \hat{H}^{mol}_{\text{Diag}} \right)^T \mathbf{T} \hat{H}^{mol}_{\text{Diag}}} \]

(14)

where \( \hat{H}^{mol}_{\text{Diag}} \) contains the diagonal elements of \( \hat{H}^{mol} \), that is \( \langle \hat{x} | \hat{H}^{mol} | \hat{x} \rangle \) in the equations above and \( \mathbf{T} \) is a projector on to the orthogonal complement of transformation matrix \( \mathbf{T} \) as obtained from the Hadamard matrix.

\[
\mathbf{T} = 2^{N-1} \mathbf{I}^{(N-1)} \mathbf{H}^{(N-1)} - \mathbf{T} \mathbf{T}^T
\]

(15)
Thus, in cases where the diagonal part of the molecular Hamiltonian are exactly captured within the subspace represented by Eq. (13), may be exactly modeled using the ion-trap simulator/computer. In all these cases the orthogonal complement in Eq. (14) is identically zero. An illustration of the transformation matrices that are used to compute \( \{ B^*_i; J^*_{ij} \} \) and the errors corresponding to the simulation of the diagonal elements, for the particular case of three qubits, is provided in Appendix B.

V. PERFORMANCE OF THE MAPPING PROTOCOL FOR A SYMMETRIC HYDROGEN BONDED SYSTEM

We examine the map by simulating the quantum dynamics of the molecular system and the ion-trap dynamics, on classical hardware, independently. In doing so we study the time-evolution of the initial wavepacket states prepared in the respective permuted basis representations for the molecular and Ising model Hamiltonians. As stated, the parameters in the Ising Hamiltonian are determined, and thus controlled, by the pre-computed matrix elements of the molecular Hamiltonian. The specific intra-molecular proton transfer problem considered here is that in the protonated 1,8-bis(dimethylamino) naphthalene (DMANH\(^+\)) system shown in Figure 6(a). The DMAN molecule has an extremely large proton affinity of 242 kcal/mol [65], with DMANH\(^+\) \( \text{pK}_a \) value in the range 12.1–12.3 [66]. As a result, the system is one of the most frequently investigated proton sponges. The NHN\(^+\) hydrogen bond in proton sponges is attractive from the point of view of both the nature of the short potentially symmetric hydrogen-bond bridges [67–70], their infrared spectroscopic behavior and their propensity to occur in common nitrogen activation catalysts [71, 72]. Thus, the DMANH\(^+\) system has been frequently studied as a model for short, low-barrier hydrogen bonds that have a role in certain enzyme-catalyzed reactions. In solution, the shared proton delocalization in DMANH\(^+\) is controlled by a low-barrier symmetric double-well potential, with barrier height being influenced by solvent and temperature [73, 74]. In fact, the environment, variables such as solvent and temperature, influence the donor-acceptor distance fluctuations thus having a critical role on the quantum mechanical nature of the shared proton. The effect of these donor-acceptor variables is seen in Figure 6(b) where we present the shared-proton one-dimensional symmetric potentials (red-curves on right side of Figure 6(b)) for a range of donor-acceptor distances (left vertical axis in Figure 6(b)) with significant classical Boltzmann populations (black horizontally placed histograms in Figure 6(b)) at room temperature. Clearly, the barrier heights separating the minima in the red-curves as well as respective minimum energy positions are sensitive to donor-acceptor fluctuations and influence the spectroscopic properties of such hydrogen-bonded systems [75, 76]. To emphasize this, in Figure 6(b), the light gray vertical lines are positioned to approximately coincide with the minimum energy values.

FIG. 6. Figure (a): The molecular geometry for DMANH\(^+\) with the shared proton potential surface shown in red. The quantum mechanical nature of the shared proton allows it to be simultaneously present in both wells, and here we use Eq. (1) to simulate the behavior of this shared proton through out mapping protocol in Eq. (8). Figure (b): The change in double well potential (and barrier height) can be seen as a function of donor-acceptor (N–N) distance. The bar-heights show the classical Boltzmann population for each N–N distance.
for the red potential energy surface at an NN distance of 2.83 Å. As the NN-distance gets smaller, the minimum energy points get closer to each other and changes the nature of the confinement potential in the shared hydrogen nucleus. Here, the effect of all of these aspects are studied by mapping the quantum nuclear dynamics problem on multiple potential surfaces, obtained from different donor-acceptor (NN) distances, to ion-trap quantum simulators.

In the following subsections, we present the methods used to classically pre-compute the nuclear Hamiltonian for each of the donor-acceptor distances shown in Figure 6(b), and simulate the quantum nuclear dynamics on these potentials using the Ising model based ion-trap simulators. We treat the shared proton stretch dimension within the Born-Oppenheimer limit. The nuclear Hamiltonian is determined by the ground electronic state potential energy surface.

A. Pre-computing the molecular Hamiltonian (\(H_{\text{Mol}}^{\text{3dol}}\) in Eq. (2)) on classical hardware

In order to compute the potential energy surface for the intra-molecular proton transfer in the molecular system DMANH\(^+\) (Figures 1a and 6(a)), we locate a symmetric stationary point with the shared proton at the center of the donor-acceptor axis. For the case of DMANH\(^+\), this stationary point turns out to be a transition state with one imaginary frequency that is obtained from the eigenstates of the electronic structure Hessian matrix, with the vibrational mode corresponding to the intra-molecular proton transfer direction. At this geometry, the shared proton is symmetrically located between the donor and acceptor nitrogen atoms. These calculations are performed using standard electronic structure methods. The level of electronic structure theory used is density functional theory with hybrid functional, B3LYP, and an atom-centered Gaussian basis set containing polarization and diffuse functions on all atoms, that is, 6-311++G(d,p). Future work will also include mapping of this Hamiltonian pre-computation step onto quantum hardware. A reduced dimensional potential energy surface calculation for one-dimensional proton motional energy points get closer to each other and changes the nature of the confinement potential in the shared hydrogen nucleus. Here, the effect of all of these aspects are studied by mapping the quantum nuclear dynamics problem on multiple potential surfaces, obtained from different donor-acceptor (NN) distances, to ion-trap quantum simulators.

The integer \(i\) depicts the projection of a propagated state onto the \(i\)th permuted spin basis state and the corresponding Givens transformed grid basis state for the ion-trap (dashed) and the molecular system with \(d_{DA} = 2.53\) Å (solid), respectively. Note that all propagation are conducted on classical platforms. The agreement of the quantum dynamics in both systems is exact to within numerical round-off (10\(^{-15}\)). The two rows in the figure legend represent the two sets spanned by odd and even spin raising operators, \(\{S^+\}\) acting on the \(\downarrow\) spin state (dashed) and their corresponding Givens transformed grid basis states (solid) according to Eq. (9). An extended set of \(d_{DA}\) are considered in Figure (9), and results for a longer term dynamics for the most stable structure (\(d_{DA} = 2.53\) Å) is provided in Figure (8).

B. Quantum simulation of proton-transfer dynamics

Given the block structure of both molecular and Ising Hamiltonians in the permuted and Givens transformed basis representations, the initial wavepacket for the ion-trap system is chosen as a coherent linear combination of the spin basis states: \(\left\{ \frac{\left| \uparrow\uparrow\uparrow \right\rangle + \left| \downarrow\downarrow\downarrow \right\rangle}{\sqrt{2}} \right\} \) on a three qubit system. Given the block structure of the Ising Hamiltonian, the \((B^x_i, B^y_i)\) turned off, the components of this initial state, \(\left| \uparrow\uparrow\uparrow \right\rangle\) and \(\left| \down\down\down \right\rangle\), are not coupled. Additionally, these states will not couple such as might be the case in the presence of \(B^x_i = iB^y_i\) in the off-diagonal blocks: for example, pathways such as \(\left| \down\down\down \right\rangle \xrightarrow{B^x_i-iB^y_i} \left| \up\up\up \right\rangle, \left| \up\up\up \right\rangle \xrightarrow{J^x_{12}-J^y_{23}} \left| \down\down\down \right\rangle\) will remain unpopulated. Hence, in essence, \(\left| \up\up\up \right\rangle\) gets propagated as per the unitary evolution corresponding to the top diagonal block of the Ising Hamiltonian and \(\left| \down\down\down \right\rangle\) as per the bottom-block. This critical feature allows us to treat the two separated blocks as arising from two different ion-traps with two
The spin-lattice and molecular wavepackets are then independently propagated for each potential obtained for different donor-acceptor separations, and compared to gauge accuracy of the quantum simulation.

Given the recursive form of the matrix representation of the Ising Hamiltonian in Eq. (1), as discussed in Appendix A (see Eq. (A3)), the ion-trap hardware initial wavepacket state is directly propagated by the choice of \( \{B^i_0; J^0_0\} \) for arbitrary time-segments. In this publication we do not seek experimental validation using a real ion-trap simulator, but emulate the time-evolution of the ion-trap system according to the Hamiltonian in Eq. (1) on classical hardware, by using the eigenstates of the Ising Hamiltonian in Appendix A. The time-dependent probabilities resulting from the projection of the resultant time-dependent wavepacket on the computational basis, at each interval of time, is shown using dashed lines in Figures 7 and 8 for a donor-acceptor distance value of 2.53Å and for the full set of donor-acceptor distance values in Figure 9. (The donor-acceptor distance value of 2.53Å corresponds to the most stable structure, but as seen from Figure 9, there are several other geometries that are also populated (at 300K) even from a purely classical Boltzmann estimation.) Similarly, we determine the time-evolution of the initial wavepacket for the molecular system by using the eigenstates of the transformed Hamiltonian in Eq. (5), and the resulting probabilities from the projection of the time-dependent wavepacket on the Givens transformed grid basis, \( \{\tilde{x}\} \) are shown using solid lines in figures 7, 8, and 9. The probabilities match exactly, apart from numerical round-off error (10^{-15}), for the quantum simulation of the dynamics of the two systems. Clearly, this is also true for much longer time intervals as can be seen in Figure 8. Given the exact match between the spin-lattice dynamics and the quantum chemical dynamics, the features present in ion-trap dynamics must also exist in the chemical dynamics problem. Thus through the isomorphism constructed above, our algorithm allows the ability to probe any entanglement that may be present in chemical systems.

VI. CONCLUSIONS AND OUTLOOK

The successful simulation of quantum nuclear dynamics on quantum hardware promises a new paradigm for studying a broader class of coupled electron nuclear transfer problems. In this publication, we provide a general, but approximate mapping procedure between a quantum chemical dynamics problem, constructed on a single Born-Oppenheimer surface, and an ion-trap quantum simulator where the dynamics is dictated by a generalized form of the Ising model Hamiltonian. The key step involved in facilitating our map is the partitioning of the coupled qubit space into two zones using only odd
FIG. 9. Similar to Figure 7 but for multiple donor-acceptor distances \((d_{DA})\) between the nitrogen atoms for the molecule in Figure 1a. Boltzmann populations \((\rho_B)\) are computed at 300K relative to the population of the configuration used in Figure 7, that has a \(d_{DA}\) value of 2.53\(\text{Å}\). The correlated changes in the \(|0\rangle\) and \(|7\rangle\) projections, are clearly facilitated by components along other basis vectors, and these may have a critical role on the reactive process as a function of temperature. The fact that the ion-lattice dynamics displays the same dynamical trends provides an additional probe to complex chemical systems.

or even powers of the total spin raising operators that are used to generate such a coupled qubit space. Once the coupled qubit computational basis set is partitioned in such a way, the Ising model Hamiltonian reduces into a block form thus allowing the possibility to map all problems that may be written in a similar block form. In some sense, we have also taken here the necessary steps to detail the kinds of general problems that can be solved exactly on a quantum system whose dynamics is dictated by a generalized form of the Ising model.
Hamiltonian. In this particular paper, though, we consider a symmetric proton-transfer problem and then go on to show how such a problem can be mapped to an ion-trap system, and also show that the dynamics of the two systems is identical provided the parameters of the ion trap are chosen in concert with that of the molecular system obtained from classical pre-computation. We also provide error bounds for this approximate algorithm for arbitrary number of qubits.

General quantum nuclear dynamics problems, however, have unsymmetric potential energy surfaces and are generally performed in higher dimensions. This work will become critical in extending our mapping protocol to general potentials in higher dimensions, as will be considered in future publications. In addition, the next set of steps also include inspection of nuclear wavepacket basis set dependence on the accuracy of the proposed map. Using appropriate basis sets, it may be possible to reduce the number of independent descriptors within the molecular Hamiltonian, thus tailoring the accuracy of the map according to the constraints provided in this paper.

Appendix A: Recursive, block structure of the Ising Hamiltonian matrix

The Ising Hamiltonian matrix, $H_N$, for a spin-lattice containing $N$ spin sites that represents Eq. (1), when represented in the aforementioned computational basis set partitioned according to sets that independently span $\{S^{1+2n-1}|2^N-1\}$ and $\{S^{1+2n-1}|2^N-1\}$, may be recursively written in a blocked form as,

$$H_N = \begin{bmatrix} H_{N}^{D1} & B_N \\ B_N^{†} & H_{N}^{D2} \end{bmatrix} = \begin{bmatrix} H_{N-1}^{D1} + B_N^{xy} I_{2N-2} + J_N^{xy} & J_N^{1x,N} \\ J_N^{1y,N} & H_{N-1}^{D2} + B_N^{xy} I_{2N-2} + J_N^{xy} \end{bmatrix} \begin{bmatrix} B_{N-1} \\ B_{N-1}^{†} \end{bmatrix}$$

(A1)

where both the diagonal blocks $H_{N}^{D1}$ and $H_{N}^{D2}$, and the off-diagonal block $B_N$ are recursively defined above, and $I_{2N}$ denotes an identity matrix of size $2^N$. The $J_N^{xy,N}$ and $J_N^{x,y,N}$ matrices that appear in the recursive definition of the diagonal blocks, labeled with superscripts $D_1$ and $D_2$ respectively, contain intersite coupling of the $N^{th}$ spin site with the remaining $N-1$ sites. To arrive at the matrix elements belonging to $J_N^{xy,N}$ and $J_N^{x,y,N}$ above, a bitwise XOR operation is constructed between the corresponding computational bases, $|\tilde{\lambda}\rangle$ and $|\tilde{\lambda}'\rangle$ coupled by the them. The XOR operation provides the identity of the spin sites where these computational basis vectors differ, that is when the spin states are flipped across $|\tilde{\lambda}\rangle$ and $|\tilde{\lambda}'\rangle$. When the bases differ at two spin lattice site locations, i and j, the corresponding matrix element of $J_N^{xy,N}$ or $J_N^{x,y,N}$ is given by $J_{ij}^{xy} \pm J_{ij}^{x,y}$. The phase preceding the corresponding $J_N^{xy}$ values results from an XNOR operation on the $i, j$ lattice sites discovered through the XOR operation above.

The terms, $J_N^{x,N}$ and $J_N^{y,N}$, in Eq. (A1) are also defined in a similar fashion. Both $J_N^{x,N}$ and $J_N^{y,N}$ matrices are diagonal in form. Thus, the diagonal elements of $H_{N}^{D1}$ and $H_{N}^{D2}$ are incremented by a linear combination of all possible intersite couplings of the $N^{th}$ spin site with the remaining $N-1$ sites given by, $\sum_{i=1}^{N-1} (-1)^{i,\oplus \tilde{\lambda}N} J_{i,N}^{x,y}$.

As noted in the main paper, setting all the transverse local qubit magnetic fields, $B_N^{x}$ and $B_N^{y}$ to zero in Eq. (1), which may be recursively written as,
At this stage it is critical to realize that the two blocks in the equation above are completely decoupled and basis vector components that undergo unitary evolution due to the top block are never influenced by elements from the bottom block and vice versa. This is explicitly elaborated in Figure 10 for the case of two and three qubits. This presents us with an additional degree of flexibility for our quantum simulation. We exercise this flexibility here and map separately the top and bottom blocks of the equation above, to two different \( N \)-qubit ion trap systems controlled by parameters \( \{ B_i^\gamma; J_{ij}^\gamma \} \) and \( \{ \tilde{B}_i^\gamma; \tilde{J}_{ij}^\gamma \} \) respectively. It is important to note here, that while the underlying structure of each block in the Ising Hamiltonian matrix remains the same, two different sets of ion-trap control parameters are used to simulate the top and bottom blocks respectively, thus providing greater flexibility in simulating real systems. We, therefore, introduce a subtle change in denoting the corresponding Ising model Hamiltonian as \( \mathcal{H}_N \), and allow the diagonal blocks to be independently determined in the following manner:

\[
\mathcal{H}_N = \begin{bmatrix}
    (H_{N-1}^{D_1} + B_i^\gamma L_{N-2} + J_{i}^{\gamma \top}) & J_{xy,N}^{\gamma} & 0 & 0 \\
    J_{xy,N}^{\gamma \top} & (H_{N-1}^{D_2} - B_i^\gamma L_{N-2} + J_{i}^{\gamma \top}) & 0 & 0 \\
    0 & 0 & (H_{N-1}^{D_2} + B_i^\gamma L_{N-2} + J_{i}^{\gamma \top}) & J_{xy,N}^{\gamma \top} \\
    0 & 0 & J_{xy,N}^{\gamma} & (H_{N-1}^{D_1} - B_i^\gamma L_{N-2} + J_{i}^{\gamma \top})
\end{bmatrix}
\]  

where the top-block is controlled by parameters, \( \{ B_i^\gamma; J_{ij}^\gamma \} \), whereas the bottom block is controlled by a different set of ion-trap parameters, \( \{ \tilde{B}_i^\gamma; \tilde{J}_{ij}^\gamma \} \). The molecular Hamiltonian is mapped to the above form of the Ising model Hamiltonian matrix.

We now illustrate the above form of Ising Hamiltonian for the 2- and 3-qubit systems. But, we note that the aforementioned basis set partitioning and Hamiltonian structure is completely general and applies to all cases. Explicitly written, for the case of two-qubits, Eq. (A3) takes the form

\[
\mathcal{H}_2 = \begin{bmatrix}
    B_i^\gamma + B_i^\gamma + J_{i}^{\gamma \top} & J_{i}^{\gamma \top} - J_{i}^{\gamma \top} & J_{i}^{\gamma \top} + J_{i}^{\gamma \top} & 0 & 0 \\
    J_{i}^{\gamma \top} - J_{i}^{\gamma \top} & -B_i^\gamma - B_i^\gamma + J_{i}^{\gamma \top} & 0 & 0 \\
    0 & 0 & B_i^\gamma - B_i^\gamma - J_{i}^{\gamma \top} + J_{i}^{\gamma \top} & 0 \\
    0 & 0 & J_{i}^{\gamma \top} + J_{i}^{\gamma \top} & B_i^\gamma - B_i^\gamma - J_{i}^{\gamma \top}
\end{bmatrix}
\]  

where again we have highlighted the distinction between ion-trap simulators that represent the top block, \( \{ B_i^\gamma; J_{ij}^\gamma \} \), and those that control the bottom block, \( \{ \tilde{B}_i^\gamma; \tilde{J}_{ij}^\gamma \} \).
FIG. 10. Complements Figure 3. At the base of each figure are the computational basis state kets. The interaction between any two states, $|\tilde{\lambda}_i\rangle$ and $|\tilde{\lambda}_j\rangle$ can be read off from the graph, by starting at the two states and following the lines to their intersection. The node at the intersection gives the interaction between the two. For example, $|2\rangle$ and $|7\rangle$ in Figure (c) have an off-diagonal matrix element of $[J_{13} - J'_{13}]$. The blank nodes are zero, and show the block diagonal form of the Ising Hamiltonian when $\{B^x_i; B^y_i\}$ are set to zero.

\[ \{ \tilde{B}^x_i; \tilde{J}^{xy}_{ij} \} \]. The three-qubit Hamiltonian is then recursively obtained from the two-qubit Hamiltonian as prescribed by Eq. (A3) and may be written in compact form as follows:

\[
\mathcal{H}_3 = \begin{bmatrix}
\mathcal{H}^{D1}_2 + B^z_2 I_2 & J^{1}_{1y,3} & 0 & 0 \\
J^{1}_{2y,3} & \mathcal{H}^{D2}_2 - B^z_2 I_2 & 0 & 0 \\
0 & 0 & \mathcal{H}^{D3}_2 + \tilde{J}^{xy}_{2,3} & \tilde{J}^{2}_{xy,3} \\
0 & 0 & \tilde{J}^{2}_{xy,3} & \tilde{H}^{D3}_1 - \tilde{B}^z_1 I_2 + \tilde{J}^{xy}_{1,3}
\end{bmatrix}
\]
Here, $H_2^{D1}$ and $H_2^{D2}$ refer to the top and bottom diagonal blocks of the two-qubit Ising Hamiltonian (Eq. (A4)) simulated using the ion-trap parameters $\{B^z_i; J^z_{ij}\}$ while $\tilde{H}_2^{D1}$ and $\tilde{H}_2^{D2}$ refer to the top and bottom blocks of a the two-qubit Ising Hamiltonian (Eq.A4) controlled by $\{\tilde{B}^z_i; \tilde{J}^z_{ij}\}$. While most of $H_2^{D1}$ and $H_2^{D2}$ is preserved and appear as diagonal blocks of the 2 qubit Hamiltonian, the $N^{th}$ qubit on-site term $B^z_i$, and appear as diagonal blocks of the 2 qubit Hamiltonian, the $N^{th}$ qubit on-site term $B^z_i$, and intersite coupling terms with all $N - 1$ qubits $J^z_{ij}$, $J^z_{ij}$ with appropriate phases are added to each diagonal element. The quantities, $J^z_{13}$, $J^z_{23}$ in the top block and $J^z_{13}$, $J^z_{23}$ in the bottom block capture the interaction of qubits 1 and 2 with qubit 3 in the form of the inter-site coupling terms for the two ion-traps respectively. Explicitly, the 3 qubit system Hamiltonian becomes:

$$H_3 = H_3^{D1} \oplus \tilde{H}_3^{D2} \quad (A6a)$$

where, for compactness we have written the ion-trap Hamiltonian as a direct sum of

$$H_3^{D1} = \begin{pmatrix}
B^z_1 + B^z_2 + B^z_3 & J^y_{12} - J^y_{13} & J^y_{12} - J^y_{13} & J^y_{23} - J^y_{23} \\
J^y_{12} - J^y_{13} & B^z_1 - B^z_2 - B^z_3 & B^z_1 - B^z_2 - B^z_3 & J^y_{23} - J^y_{23} \\
J^y_{12} - J^y_{13} & B^z_1 - B^z_2 - B^z_3 & B^z_1 - B^z_2 - B^z_3 & J^y_{23} - J^y_{23} \\
J^y_{12} - J^y_{13} & J^y_{12} - J^y_{13} & J^y_{12} - J^y_{13} & J^y_{23} - J^y_{23}
\end{pmatrix} \quad (A6b)$$

$$\tilde{H}_3^{D2} = \begin{pmatrix}
\tilde{B}^z_1 + \tilde{B}^z_2 + \tilde{B}^z_3 & \tilde{J}^y_{12} + \tilde{J}^y_{13} & \tilde{J}^y_{12} + \tilde{J}^y_{13} & \tilde{J}^y_{23} + \tilde{J}^y_{23} \\
\tilde{J}^y_{12} + \tilde{J}^y_{13} & -\tilde{B}^z_1 - \tilde{B}^z_2 - \tilde{B}^z_3 & -\tilde{B}^z_1 - \tilde{B}^z_2 - \tilde{B}^z_3 & \tilde{J}^y_{23} + \tilde{J}^y_{23} \\
\tilde{J}^y_{12} + \tilde{J}^y_{13} & -\tilde{B}^z_1 - \tilde{B}^z_2 - \tilde{B}^z_3 & -\tilde{B}^z_1 - \tilde{B}^z_2 - \tilde{B}^z_3 & \tilde{J}^y_{23} + \tilde{J}^y_{23} \\
\tilde{J}^y_{12} + \tilde{J}^y_{13} & \tilde{J}^y_{12} + \tilde{J}^y_{13} & \tilde{J}^y_{12} + \tilde{J}^y_{13} & \tilde{J}^y_{23} + \tilde{J}^y_{23}
\end{pmatrix} \quad (A6c)$$

We further clarify that the top-block, $H_3^{D1}$, is controlled by parameters $\{B^z_i; J^z_{ij}\}$ whereas the bottom block, $\tilde{H}_3^{D1}$, is controlled by $\{\tilde{B}^z_i; \tilde{J}^z_{ij}\}$.

Appendix B: Transformation matrix for obtaining the ion-trap parameters $\{B^z_i; J^z_{ij}\}$ and related error for a three qubit system.

For the 3-qubit case illustrated here, the orthogonal component of the transformation matrix $[T]^T$, can be obtained by comparing, the tensor product of two Hadamard matrices,

$$H_2 = \frac{1}{2} \begin{pmatrix}
1 & 1 & 1 & 1 \\
1 & -1 & 1 & -1 \\
1 & 1 & -1 & -1 \\
1 & -1 & -1 & 1
\end{pmatrix}$$

(B1)

and

$$[T]^T = \begin{pmatrix}
1 & -1 & -1 & -1 \\
1 & -1 & 1 & -1 \\
1 & 1 & -1 & -1 \\
1 & 1 & 1 & -1
\end{pmatrix}$$

(B2)

to arrive at the first row vector of Eq. (B1). This row is the zero-frequency component or the average of the diagonal elements of the molecular Hamiltonian and, therefore, simply results in a uniform shift of the diagonal elements. This results in a constant shift between the eigenvalues of the molecular Hamiltonian and the Ising Hamiltonian, which results in no change in the dynamics, as is clear from Figures 7, 8 and 9.

Appendix C: Number of degrees of control in the Ising Hamiltonian, Eq. (1)

For a given number of qubits, $N$, the number of ion-trap handles in Eq. (1) that control various sectors of the Hamiltonian matrix scale as

$$\{N + N(N-1)/2\} + \{N(N-1)\} + \{2N\} \rightarrow O(N^2),$$

(C1)

Here (a) the first quantity, $\{N + N(N-1)/2\}$, refers to the parameters, $\{B^z_i; J^z_{ij}\}$, that control the diagonal elements of the matrix, (b) the second quantity on the left, $\{N(N-1)\}$, refers to the parameters, $\{J^z_{ij} \pm J^z_{ij}\}$, that control the coupling between the basis vectors inside each block, and (c) finally $\{2N\}$ refers to the parameters, $\{B^z_i \pm B^z_i\}$, that control the coupling across the sets of basis vectors created by using the odd and even
raising operators described above. This characterization not only elucidates the degrees of freedom of the Ising model Hamiltonian in Eq. (1), but also provides the sectored availability of these control parameters.

At this stage there are two cases that become interesting insofar as mapping to realistic systems is concerned. In the first case, the structure of the Ising Hamiltonian is used as is, including the \( \{ B_i^x \pm \pm B_j^y \} \) terms, and the number of degrees of freedom is as given above and must match the same for the problem at hand to produce an accurate map. For the second case, if the \( \{ B_i^x \pm \pm B_j^y \} \) handles are eliminated, the system reduces to two separate blocks, that may be propagated independently, perhaps even on two different sets of ion-trap architectures arranged in parallel, or Trotterized on one single ion-trap architecture. It is this second case that we consider in this paper as it allows the ability to have different Ising model parameters for the two diagonal blocks, and in this case the number of ion-trap handles become:

\[
2 \{ N + N(N-1)/2 + N(N-1) \}.
\]

which is, in fact, greater than the number of Ising model handles available in an \( (N-1) \)-qubit system when \( N < 17 \). The above discussion also implies that for Hamiltonians containing \( 2^N \) independent terms, only approximate computation is possible. In this sense, the current paper takes a first step towards providing the necessary accuracy bounds. (Precise error bounds are provided in Section IV A.)
