We investigate the occurrence of n-fold exceptional points (EPs) in non-Hermitian systems, and show that they are stable in $n - 1$ dimensions in the presence of anti-unitary symmetries that are local in parameter space, such as e.g. parity-time (PT) or charge-conjugation parity (CP) symmetries. This implies in particular that 3-fold and 4-fold symmetry-protected EPs are stable respectively in 2 and 3 dimensions. The stability of such multifold exceptional points (i.e. beyond the usual 2-fold EPs) is expressed in terms of the homotopy properties of a resultant vector that we introduce. Our framework also allows us to rephrase the previously proposed $\mathbb{Z}_2$ index of PT and CP symmetric gapped phases beyond the realm of two-band models. We apply this general formalism to a frictional shallow water model that is found to exhibit 3-fold exceptional points associated with topological numbers $\pm 1$. For this model, we also show different non-Hermitian topological transitions associated with these exceptional points, such as their merging and a transition to a regime where propagation is forbidden, but can counter-intuitively be recovered when friction is increased furthermore.

Since the discovery of graphene, Dirac points have been revealed to be an ubiquitous property of various two dimensional (2D) materials. The existence of such 2-fold degeneracies is enforced by symmetries [1] [2], and their stability can be expressed with winding numbers of the phase of the wave functions [3] [5]. Similarly, non-hermitian Hamiltonians may exhibit degeneracy points of their complex eigenvalues, called exceptional points (EPs). The quest for EPs, their topological properties and their physical implications, stimulated tremendous logical properties and their physical implications, stimulated tremendous interest in the past few years [6–15]. At an EP, the number of degenerated eigenvalues (the algebraic multiplicity $\mu$) is generically larger than the number of eigenvectors (the geometric multiplicity) leaving the Hamiltonian non-diagonalizable. Quite remarkably, 2-fold EPs (EP2s) do not require any symmetry to be stable in 2D, and this stability can be expressed in terms of a winding number [8] associated to their complex eigenvalues [16]. This is however not the case for multi-fold exceptional points EPmfs. Those were indeed shown to be unstable in 2D [16], although stable in higher dimensions $D = 2\mu − 2$ dimension [6] [17], so that EPmfs beyond $\mu = 2$ have remained overlooked. Still, a few examples of multifold EPs were surprisingly reported recently [18–20], including in PT-symmetric systems [21]. This asks the crucial question of the conditions of existence of multifold EPs, in particular in dimensions $D < 3$, their robustness and the role of symmetries.

Here we answer this question by showing that $\mu$-fold EPs have a codimension $\mu − 1$ provided certain anti-unitary symmetries are satisfied, meaning that they appear as isolated points in $\mu − 1$ dimensions. The relevant symmetries consist in PT symmetry, CP symmetry and their generalizations, called pseudo-Hermiticity (pSH) and pseudo-chirality (pSc), that classify non-Hermitian EPs [13][22]. It follows that 3-fold and 4-fold EPs are stable in 2D and 3D respectively when such symmetries apply. Then, we propose a topological characterization for symmetry-protected EPmfs through the homotopy properties of a resultant vector that we introduce. Finally, we illustrate our theory by discussing a frictional fluid model that exhibits several EP3s with opposite windings. These EPs constitute a threshold beyond which the propagation of all the eigenmodes vanishes in a certain range of wavelength, but can counter-intuitively be recovered when increasing friction furthermore.

To investigate $n$-fold EPs, we focus on $n \times n$ matrices without loss of generality, because $n$-fold degeneracies are described by a $n \times n$ effective Hamiltonians $H(\lambda)$, with $\lambda \in \mathbb{R}^D$. The degeneracies of the eigenvalues $E(\lambda)$ are generically EPs, since arbitrary non-Hermitian matrices require fine tuning to be diagonalizable at the degeneracy point [23]. Therefore, looking for $n$-fold EPs essentially amounts to searching for the conditions such that the characteristic polynomial $P_1(\lambda) \equiv \det(H(\lambda) - E) = a_0(\lambda)E^n + a_{n-1}(\lambda)E^{n-1} + \cdots + a_1(\lambda)E + a_0(\lambda)$ has $n$-fold multiple roots and $n = \mu$.

At an EP of energy $E_0$, $P_1(\lambda)$ and its $\mu - 1$ successive derivatives $P_1^{(j)}(\lambda) \equiv \partial^j P_1/\partial E^j$ must vanish at $E = E_0$. This property is encoded in the zeros of the so-called resultant $R_{P_1,P_0}(\lambda)$. The resultant of two polynomials $P_1(\lambda)$ and $P_2(\lambda)$ is an elementary concept in algebra [24]. It reads $R_{P_1,P_2} \equiv \det S_{P_1,P_2}$ where $S_{P_1,P_2}$ is the Sylvester matrix of $P_1$ and $P_2$. Importantly, this quantity vanishes if and only if the two polynomials $P_1$ and $P_2$ have a common root. Actually, we demonstrate (see [23]) that a polynomial $P(\lambda)$ of degree $\mu$ has an $\mu$-fold multiple root if and only if the resultants of its successive derivatives $R_{P^{(j)},P_0} \equiv 0$ vanish. Put formally,

$$\mu \times \mu$$-non-Hermitian matrices have a resultant vector $R_{P^{(j)},P_0}(\lambda_0) = 0$ for $j = 1 \ldots \mu - 1$. 

$$R_{P^{(j)},P_0}(\lambda_0)$$ is in general a complex-valued function of $\lambda$. The equivalence [1] thus yields $2(\mu - 1)$ constraints to be satisfied, which gives the codimension of an EP$\mu$ in the absence of symmetry, in agreement with [6] [17]. Note that the usual EP2s are defined by $R_{P,P} (\lambda_0) = 0$, where $R_{P,P}(\lambda)$ is proportional to the discriminant $\Delta$ of the characteristic polynomial. Since $\Delta$ is in general a complex function of $\lambda$, the stability of
EP2s can be expressed by the winding of \( \arg(R_{P,P}(\lambda)) \) along a close circuit around \( \lambda_0 \) in a 2D parameter space \([16]\).

As we discuss now, anti-unitary symmetries that are local in parameter space, have important consequences. First, they decrease the codimension of the EPs. Second, they make critical points of \( \infty \) filtration be assigned to multifold EPs. But we shall see that another natural homotopy property can be satisfied. The reality of the resultants naturally generates a resultant vector \( \mathcal{R} \) of components \( R_{\mu,P,0} \), that maps the \( \lambda \)-space of parameters to \( \mathbb{R}^{\mu - 1} \). When the dimension of the \( \lambda \)-space is \( \mu - 1 \), the homotopy properties of the map \( \lambda \to \mathcal{R}/|\mathcal{R}| \) can be used to characterize the EP\( \mu \).

In fact, a similar construction can be done from different resultants, so that another resultant vector, \( \mathcal{R} \), can be introduced. Indeed, the existence of an EP\( \mu \) imposes resultants between other derivatives of \( P(E) \) to vanish as well, and in particular

\[
R_{P,P,j}(\lambda_0) = 0 \quad \text{with } j = 1 \ldots \mu - 1.
\]

Actually, such a constraint, to be compared with \([1]\), is also a necessary and sufficient condition for an EP\( \mu \) to exist, at least for \( \mu = 2, 3 \) and 4 \([23]\). It turns out that those resultants are either real or purely imaginary. It is thus natural to define the resultant vector \( \mathcal{R} \) from its components

\[
\mathcal{R}_j \equiv \begin{cases} R_{P,P,0} & \text{PT and psH} \\ \left(-1\right)^{(n-j)} R_{P,P,j} & \text{CP and psCh} \end{cases}
\]

that depend on the symmetries, and where the coefficient \((-1)^{(n-j)} \) guarantees the reality of \( \mathcal{R}_j \).

The two resultant vectors we have introduced have the same first component \( \mathcal{R}_1 \), which is proportional to the discriminant \( \Delta \) of the characteristic polynomial \( P_1(E) \) of degree \( n \) as \( R_{P,P}(\Delta) = (-1)^{(n-1)/2} a_n(\Delta) \Delta(\lambda) \). The vanishing of the discriminant at a given \( \lambda_0 \) indicates the existence of at least two roots of \( P_\lambda(E) \). In the presence of a symmetry \([3]\), the discriminant is also a real quantity, since both \( R_{P,P} \) and \( a_n \) are always real. Its sign (or equivalently that of \( \mathcal{R}_1 \)) is therefore well defined and turns out to encode crucial properties about the complex eigenenergies \( E_j \). For instance, it is well known that for a polynomial of degree \( n = 2 \), \( \Delta > 0 \) comes along with distinct real roots, while \( \Delta < 0 \) indicates a pair of complex conjugated roots. These two behaviours are separated by a critical point \( \Delta = 0 \) where the gap separating complex energy bands closes. More generally, a change in the number of complex conjugated roots is a property of the sign of the discriminant that generalizes beyond \( n = 2 \) \([23]\). One can thus use sign(\( \Delta \)) as a \( \mathbb{Z}_2 \) index to distinguish two different regimes for non-Hermitian Hamiltonians of arbitrary size that satisfy one of the symmetries \([2]\). The cases \( n = 2 \) and \( n = 3 \) are presented in table \([4]\). Such an index encompasses the previously proposed topological invariants given by \( \text{sgn(det}H) \) [resp. \( \text{sgn}(\text{det}iH) \)] for \( 2 \times 2 \) PT [resp. CP] symmetric Hamiltonians \([25,27]\).

It is worth pointing out that a change of sign(\( \Delta \)) reveals that the symmetry \([2]\) under consideration is \textit{spontaneously} broken. Let us recall this notion in PT-symmetric systems \([28]\). Consider \( H|\psi \rangle = E|\psi \rangle \), then \( U_{PT}^{-1}|\psi \rangle \) is also an eigenstate of \( H \) with eigenvalue \( E^* \), where \( k \) is the complex conjugation operator. If \( U_{PT}^{-1}|\psi \rangle \) is proportional to \( |\psi \rangle \), then \( |\psi \rangle \) is an eigenstate of the PT operator, and the eigenenergies are real. In the other case, \( |\psi \rangle \) is not an eigenstate of \( U_{PT}^{-1} \) and the eigenenergies come by pairs \( (E,E^*) \). PT symmetry is then said to be \textit{spontaneously} broken : it still holds at the level of the Hamiltonian, but not at the level of the eigenstates. The same reasoning applies to CP-symmetric and pseudo-chiral...
Hamiltonians, where eigenenergies come by either by pairs \((E, -E^*)\) or are purely imaginary. In any case, the spontaneous symmetry breaking is accompanied with a change of sign of the discriminant that governs the complex nature and the pairing of the eigenvalues.

Symmetry-protected multifold EPs are special points where the symmetry is spontaneously broken, since they also demand the vanishing of the other components \(\mathcal{R}_j = 0\). From a geometrical point of view \([13, 27, 28, 30]\), the solutions \(\lambda\) of each equation \(\mathcal{R}_j(\lambda) = 0\) define a “manifold” \(\mathcal{M}_j\) of dimension \(D - 1\) in parameter space of dimension \(D\) (i.e. codimension 1). Thus, the coordinates \(\lambda_0\) of EPs define a space that consists in their mutual \(\mu - 1\) intersections. For instance, in \(D = 2\) dimensions, \(\mathcal{M}_1\) and \(\mathcal{M}_2\) consist in curves in a plane, and their mutual intersections are points that correspond to EP3s. Importantly, such intersections are generically robust to perturbations. Let us illustrate this point on a concrete model, the rotating shallow water model with friction.

The linearized rotating shallow water model describes waves propagating in a thin layer of fluid in rotation. It is currently used to describe atmospheric and oceanic waves over large distances where the Coriolis force, encoded into a parameter \(f\), is relevant \([31]\). We consider a non-Hermitian version of this model that reads \(H\Psi = E\Psi\) with

\[
H = \begin{pmatrix} \delta u_x & \delta h \\ -\delta h & \delta u_y \end{pmatrix}, \quad \Psi = \begin{pmatrix} \delta u_x \\ \delta h \end{pmatrix}
\]

with \(\delta u_x\) and \(\delta u_y\) the small variations of the horizontal fluid velocity, \(\delta h\) a small variation of the fluid’s thickness, \(k_x\) and \(k_y\) the in-plane wave numbers, \(\gamma\) and \(\gamma_x\) the Rayleigh friction terms, and \(\gamma_N\) the Newtonian friction. The competition between the two friction terms plays for instance a crucial role in the phenomenon of super-rotation \([32]\). Actually, this minimal model equivalently describes active fluids where the thickness field \(h\) is formally replaced by a pressure field. \([33]\) In that context, it was shown that the \(\gamma\) terms can also be negative, thus allowing for gain \([34]\). We now show that the friction terms generate symmetry-protected EP3s.

Assuming isotropic friction \(\gamma_x = \gamma_y \equiv \gamma_R\), the model remains rotational symmetric and can thus be simplified by fixing a direction (say \(k_x = 0\)). Moreover, any choice of \(\gamma_R\) can be reabsorbed in \(\gamma_N\) up to a global shift of the spectrum, that does not affect the existence of degeneracies, as \(H = \gamma_R \mathbf{1} + \tilde{H}\) with

\[
\tilde{H} = \begin{pmatrix} 0 & f k_x \\ -i f & 0 \end{pmatrix}
\]

where \(\gamma = \gamma_N - \gamma_R\). This matrix satisfies CP-symmetry \([25]\) with \(U_{CP} = \text{diag}(1, 1, -1)\), and one thus expects EP3s of codimension 2, according to the relation \([4]\). Since the parameter space has a dimension \(D = 3\), with \(\lambda = \{k_x, f, \gamma\}\), the set of EP3s must consist in a manifold of codimension 2, that is a line. For this specific model, the equation of this line can be derived explicitly from \(\mathcal{R}_1(\lambda_0) = 0\) and \(\mathcal{R}_2(\lambda_0) = 0\), which yields \(\gamma_0 = \pm 2 \sqrt{3} f_0\) and \(k_0 = \pm 2 \sqrt{2} f_0\). Geometrically, this line of EP3s corresponds to the intersection of the two spaces \(\mathcal{M}_1\) and \(\mathcal{M}_2\), each of codimension 1. \(\mathcal{M}_1\) and \(\mathcal{M}_2\) are thus surfaces in 3D (figure 1(a)), and lines in 2D (Fig. 1(b) and (c)).

Remarkably, the space \(\mathcal{M}_1 \cap \mathcal{M}_2\) of EP3s correspond to a fold of \(\mathcal{M}_1\). Similar singular points to that shown in figure 1(b) and (c) were found in \([18, 19]\). This suggests a quite fundamental property of EP3s, that can be addressed within catastrophe theory which classifies the possible kinks of curves and thus establishes their topological stability \([35]\). Intuitively, such a singular shape can be traced back to the third order characteristic polynomial \(P_3(E) = 0\), since cubic curves are known as a basic example that displays such
a catastrophe when the three roots coincide. To characterize more precisely this singularity, we use the machinery of catastrophe theory and compute a list of invariants (called corank, codimension and determinacy) that classify the catastrophe. Following [35, 36], we find a corank of 1, a codimension of 1 and a determinacy of 3, which identifies EP3s as a fold of \( M_1 \). This is the simplest fundamental catastrophe in the classification of catastrophe theory.

Before characterizing in more details the robustness of the EP3, let us first comment on the original physical behaviours revealed in figure [1]. Indeed, \( M_1 \) indicates a change of sign of the discriminant, and thus, according to table [1] it denotes a transition between complex eigenvalues (\( \Delta > 0 \)) and purely imaginary eigenvalues (\( \Delta < 0 \)), which, in our case, all have the same sign which is fixed by \( \text{sgn}(\gamma) \). The eigenvalue spectrum of (8) is shown in figure [2]. It follows that the critical value \( \frac{\gamma}{f} = \frac{\gamma_0}{f} \) for an arbitrary \( f \) and its eigenfrequency is found to be \( E_0 = \frac{\gamma_0^2}{3} \). Beyond this point, the discriminant \( \Delta \) of the characteristic polynomial of \( \tilde{H} \) becomes negative over a finite domain of wavenumbers, where the three eigenmodes are fully damped.

One can characterize the stability of symmetry protected EPs further by using the topological properties of the resultant vector \( \mathbf{R} \in \mathbb{R}^{\mu-1} \) introduced above. For an EP3, it defines a map \( \mathbf{R}/|\mathbf{R}| : \mathbb{R}^2 \backslash \{ \mathbf{0} \} \rightarrow S^1 \) whose homotopy properties are encoded into the integer-valued winding number

\[
W_3 = \frac{1}{2\pi} \oint_{C_3} \frac{1}{|\mathbf{R}|^2} \left( \frac{\partial \mathbf{R}_2}{\partial \lambda_2} - \frac{\partial \mathbf{R}_1}{\partial \lambda_1} \right) \mathrm{d}\lambda_0 \tag{9}
\]

where the close circuit \( C_3 \) surrounds the EP3 and where an implicit sum is taken over \( \alpha = \{1,2\} \). It is worth noticing that, in lattice systems, \( M_1 \) and \( M_2 \) are necessarily closed loops in the 2D Brillouin zone, so that their intersections come by pairs with opposite \( W_3 \)'s, which can be seen by a straightforward extension of the doubling theorem by Nielsen and Ninomiya [37, 38] as recently generalized for non-Hermitian systems without symmetry [16].

The invariant \( W_3 \) is the winding number of the relative angle between \( \mathbf{R}_1 \) and \( \mathbf{R}_2 \). For the frictional shallow water model, its value is shown in figure [3](a). It turns out that in this model, EP3s come by pairs \( W_3 = \pm 1 \) at \( \kappa = \pm \kappa_0 \). This indicates that such pairs may possibly merge and annihilate each other if one moves them, similarly to Dirac and Weyl points in semimetals [19, 42]. Since the position of the EP3s is fixed in the isotropic case, a mechanism involving their motion necessarily breaks rotational symmetry. This can be achieved by considering now \( \gamma_x \neq \gamma_y \), as shown in figure [3](a) where one pair \((\gamma_y/f > 0)\) get closer while the other pair \((\gamma_y/f < 0)\) is pulled away. When increasing \( \gamma_x \) furthermore, the points of the pair at \( \gamma_y/f > 0 \) finally merge. Surprisingly enough, a new domain of non-propagating waves (\( \Delta < 0 \)) emerges for \( \gamma_y < 0 \) (see Fig. 3(b)). A similar analysis can be carried out from the other resultant vector \( \mathbf{R} \) introduced above, but its winding number is found to be zero for that model.

More generally, multifold (\( \mu > 3 \)) symmetry-protected EPs can be characterized by the homotopy properties of their resultant vectors \( \mathbf{R} \) (or \( \mathbf{R} \)). Let us fix \( d = 0 \), so that the EP is an isolated point \( \lambda_0 \in \mathbb{R}^{\mu-1} \), according to [4]. Then the resultant vector defines the map \( \mathbf{R}/|\mathbf{R}| : \mathbb{R}^2 \backslash \{ \mathbf{0} \} \rightarrow S^1 \) whose degree \( W_\mu \equiv \deg \mathbf{R} \in \mathbb{Z} \) is well-defined and reads [43]

\[
W_\mu = \sum_{\lambda_0} \text{sgn} \left( \frac{\partial \mathbf{R}_1}{\partial \lambda_\mu} \right) \bigg|_{\mathbf{R}(\lambda) = \mathbf{R}_0} \tag{10}
\]

where \( \mathbf{R}_0 \) is an arbitrary point where the Jacobian matrix \((\partial \mathbf{R}_j/\partial \lambda_\mu)\) does not vanish. This homotopy invariant is a topological property of multifold symmetry-protected EPs. The expression \( W_3 \) of the winding number \( W_3 \) for EP3s is the simplest example of such invariants.

Our analysis opens various novel perspectives in the control of topological properties of non-Hermitian systems. In
future works, it could be interesting to investigate symmetry-
protected EPs that should appear in three-dimensional pa-
rameter spaces, and whose topological charge \( W_4 \) takes the form of a wrapping number of the resultant vector

\[
W_4 = \frac{1}{4\pi} \oint_{S_3} \frac{\mathbf{R}}{|\mathbf{R}|} \left( \frac{\partial \mathbf{R}}{\partial \alpha} \times \frac{\partial \mathbf{R}}{\partial \beta} \right) \, d\alpha \wedge d\beta \quad (11)
\]

In particular, this suggests the existence of stable non-
Hermitian versions of 3D Dirac points in sharp contrast with
both Hermitian 3D Dirac points and non-Hermitian Weyl
points that were both found to be unstable.

SM1 – Accidental diagonalization

By analyzing a 2×2 matrix, we illustrate that fine tuning is
necessary to make Hamiltonians diagonalizable.
Consider a one-dimensional \( PT \)-symmetric system whose non-Hermitian Hamiltonian is written as

\[
H(k) = \begin{pmatrix}
1 & k + \lambda \\
k - \lambda & 1
\end{pmatrix}
\]  
(12)

with \( \lambda \geq 0 \) and where \( k \) denotes the momentum. Diagonalizing this matrix yields the eigenvalues

\[
E_\pm(k) = 1 \pm \sqrt{k^2 - \lambda^2}
\]
(13)

and the eigenvectors

\[
\psi_\pm = \begin{pmatrix} k + \lambda \\ E_\pm(k) - 1 \end{pmatrix}.
\]
(14)

Those eigenvectors are clearly linearly independent, except when the two bands touch, which occurs at \( k = \lambda \). In that case, one has \( \psi_+ = \psi_- \), and the characteristic polynomial \( P(E) = E^2 - 2E - k^2 + \lambda^2 + 1 \) has a common root \( E = 1 \) with its derivative with respect to \( E, P'(E) = 2(E - 1) \). At this degeneracy point, fine tuning of \( \lambda \) is necessary in order to make \( H(k) \) diagonalizable. Indeed, \( H(k = \lambda) \) reads

\[
H(\lambda) = \begin{pmatrix}
1 & 2\lambda \\
0 & 1
\end{pmatrix}
\]
(15)

which has a single eigenvector, proportional to

\[
\begin{pmatrix} 1 \\ 0 \end{pmatrix}
\]
(16)

when \( \lambda > 0 \). Thus, the dimension of the associated eigenspace (i.e. the geometric multiplicity) is reduced to 1, while the algebraic multiplicity \( \mu = 2 \). This two-fold degeneracy point is therefore an exceptional point. The diagonalisation of \( H(k = \lambda) \) is then recovered if we tune \( \lambda = 0 \), and thus we simply have

\[
H(\lambda = 0) = \begin{pmatrix}
1 & 0 \\
0 & 1
\end{pmatrix},
\]
(17)

which is Hermitian, and which has two linearly independent eigenvectors

\[
\begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} 0 \\ 1 \end{pmatrix}
\]
(18)

so that the algebraic and geometric multiplicities accidentally coincide.

**SM2 – Proof that \( p \)-fold exceptional points imply \( R_{P^{(j-1)j},P^{(j-1)j}} = 0 \) and \( R_{P,P^{(j-1)j}} = 0 \) for \( j = 1 \ldots p - 1 \).**

Consider two polynomials

\[
A(X) = a_n X^n + a_{n-1} X^{n-1} + \cdots + a_1 X + a_0
\]
(19)

\[
B(X) = b_m X^m + b_{m-1} X^{m-1} + \cdots + b_1 X + b_0
\]
(20)

of roots \( \alpha_i \) and \( \beta_i \), respectively, with \( i = 1 \ldots n \) and \( j = 1 \ldots m \), and where \( a_n \) and \( b_m \) are assumed to be non-zero. Then, let us recall that, by definition, their resultant reads

\[
R_{A,B} = a_n b_m^n \prod_{i,j} (\alpha_i - \beta_j).
\]
(21)

It is clear from this expression that the resultant vanishes when the two polynomials \( A \) and \( B \) have at least a common root.

Consider now a polynomial \( P(X) \) of degree \( n \)

\[
P(X) = \prod_{i=1}^{n} (X - \alpha_i)
\]
(22)

If this polynomial has a \( p \)-fold multiple-root \( a = \alpha_1 = \alpha_2 = \cdots = \alpha_p \), i.e.

\[
P(X) = (X - a)^p \prod_{i=p+1}^{n} (X - \alpha_i)
\]
(23)

then any of its \( j = 1 \ldots p - 1 \) derivative \( P^{(j)}(X) \) factorizes by \( X - a \), and has therefore \( a \) a root. Interpreting now \( P \) has the characteristic polynomial of a non-Hermitian Hamiltonian \( H \), it follows that

\[
\text{\( H \) has a \( p \)-fold EP} \quad \Rightarrow \quad \text{\( R_{P^{(j-1)j},P^{(j-1)j}} = 0 \) for \( j = 1 \ldots p - 1 \).}
\]
(24)

**SM3 – Proof of equation (1) of the main text.**

Equation (1) of the main text is an equivalence. The “if” part of this equivalence follows from [24] by taking \( q = j - 1 \). Here we demonstrate the “only if” part, that is \( R_{P^{(j-1)j},P^{(j-1)j}} = 0 \) for \( j = 1 \ldots n - 1 \) implies an EP. We know that this statement is true for \( n = 2 \) (in that case the resultant is the discriminant).

We then proceed by induction. Let us assume that the implication

\[
R_{P^{(j-1)j},P^{(j-1)j}} = 0 \quad \text{for} \quad j = 1 \ldots n - 1 \quad \Rightarrow \quad P \text{ has a multiple root of order } n
\]
(25)

is true for polynomials \( P \) of degree \( n \), and let us assume that

\[
R_{P^{(j-1)j},P^{(j-1)j}} = 0 \quad \text{for} \quad j = 1 \ldots n
\]
(26)

for polynomials \( P \) of degree \( n + 1 \). We then rewrite those equations as

\[
R_{P,P} = 0
\]
(27)

\[
R_{P^{(j-1)j}(P^{(j-1)j})} = 0 \quad \text{for} \quad j = 1 \ldots n - 1
\]
(28)

Since \( P' \) is of degree \( n \), the implication (25) is true, and therefore

\[
P' = A(X - a)^n
\]
(29)

where \( A \) is a constant, so that

\[
P = \frac{A}{n + 1} (X - a)^{n+1} + B
\]
(30)
with $B$ another constant. Next, since $R_{P,P'} = 0$, then $\alpha$ must be a root of $P$, and thus $B = 0$. It follows that $P$ as a multiple root of order $n + 1$, which completes the proof.

This, together with the result of the previous paragraph, demonstrates the equivalence (1) of the main text.

**SM4 – Proof of the equivalence between the existence of an EP$\mu$ and equation (5) of the main text for $\mu = 3$ and $\mu = 4$**

Equation (24) implies that if an EP$\mu$ exists, then $R_{P,P^0} = 0$ with $j = 1, \ldots, \mu - 1$ (by taking $q = 0$). We show now that the converse is also true (at least) for 3-fold and 4-fold EPs, as discussed in the main text. We can restrict the discussion to cases where the order of the EP is that of the polynomial, that is, $\mu = n$.

**Proof that $R_{P,P^j} = 0$ with $j = 1, 2$ implies an EP3**

The characteristic polynomial reads (up to a global non-zero factor that we shall ignore)

$$P(X) = (X - \alpha_1)(X - \alpha_2)(X - \alpha_3)$$

(31)

and its derivatives are

$$P'(X) = (X - \alpha_1)(X - \alpha_2) + (X - \alpha_2)(X - \alpha_3) +$$

$$+ (X - \alpha_3)(X - \alpha_1)$$

(32)

$$P''(X) = 2[(X - \alpha_1) + (X - \alpha_2) + (X - \alpha_3)]$$

(33)

We then assume that

$$R_{P,P'} = 0$$

(34)

$$R_{P,P''} = 0$$

(35)

Let us show that the three roots $\alpha_i$ are therefore equal. This can be performed with basic algebra.

First, (34) implies that a root of $P'$, that we shall denote by $X_1$, satisfies $X_1 = \alpha_1$ or $X_1 = \alpha_2$ or $X_1 = \alpha_3$. Let us fix $X_1 = \alpha_1$ without loss of generality. Inserting $X_1 = \alpha_1$ into (32) yields

$$(\alpha_1 - \alpha_2)(\alpha_1 - \alpha_3) = 0$$

(36)

which imposes $\alpha_1 = \alpha_2$ or $\alpha_1 = \alpha_3$. We shall consider those two possibilities, but first, let us translate the condition (35), which means that a root $X_2$ of $P''$ must be either $\alpha_1$ or $\alpha_2$ or $\alpha_3$.

Let us assume first that $X_2$ is a priori different than $X_1$, and take thus $X_2 = \alpha_2$ without loss of generality. It then follows from (35) that

$$2\alpha_2 - \alpha_1 - \alpha_3 = 0$$

(37)

Then, if we assume from (36) that $\alpha_1 = \alpha_2$, then it follows from the equation above that $\alpha_2 = \alpha_3$. Thus $X_2$ and $X_1$ must be the same root, and $\alpha_1 = \alpha_2 = \alpha_3$. If we assume instead from (36) that $\alpha_1 = \alpha_3$, then it follows again that $\alpha_2 = \alpha_3$, and the same conclusion applies. Therefore $X_1$ cannot be different from $X_2$.

Let us assume now that $X_2 = X_1$, that is $X_2 = \alpha_1$. In that case, it follows from (34) that

$$2\alpha_1 - \alpha_2 - \alpha_3 = 0$$

(38)

Again, if we assume now from (36) that $\alpha_1 = \alpha_3$, this equation yields $\alpha_2 = \alpha_3$. And if we assume instead from (36) that $\alpha_1 = \alpha_3$, one also get $\alpha_2 = \alpha_3$.

So, in any case, $\alpha_1 = \alpha_2 = \alpha_3$, that is, the polynomial $P$ has a triple root if (34) and (35) are satisfied. Since we shown previously that if $P$ has a triple root then $R_{P,P'} = R_{P,P''} = 0$, this proves the equivalence between these two statements.

**SM5 – Proof that $R_{P,P^j} = 0$ with $j = 1, 2, 3$ implies an EP4**

The demonstration of the equivalence for $n = 4$ follows the same line as that for $n = 3$, but is a bit longer. We have

$$P(X) = (X - \alpha_1)(X - \alpha_2)(X - \alpha_3)(X - \alpha_4)$$

(39)

$$P'(X) = (X - \alpha_1)(X - \alpha_2)(X - \alpha_3) + (X - \alpha_1)(X - \alpha_4)(X - \alpha_4) +$$

$$+ (X - \alpha_2)(X - \alpha_3)(X - \alpha_4) + (X - \alpha_2)(X - \alpha_3)(X - \alpha_4)$$

(40)

$$P''(X) = 2[(X - \alpha_1)(X - \alpha_2) + (X - \alpha_1)(X - \alpha_3) +$$

$$+ (X - \alpha_2)(X - \alpha_3) + (X - \alpha_3)(X - \alpha_4) + (X - \alpha_3)(X - \alpha_4)]$$

(41)

$$P'''(X) = 6(X - \alpha_1 + X - \alpha_2 + X - \alpha_3 + X - \alpha_4)$$

(42)

We then assume that

$$R_{P,P'} = 0$$

(43)

$$R_{P,P''} = 0$$

(44)

$$R_{P,P'''} = 0$$

(45)

and we want to show that the four roots $\alpha_i$ are necessarily equal. The equations (43) imply that each $P^{(j)}(X)$ shares a common root $X_j$ with $P(X)$, which are a priori different from each others. We can then choose $X_j = \alpha_j$ without loss of generality, which implies

$$(\alpha_1 - \alpha_2)(\alpha_1 - \alpha_3)(\alpha_1 - \alpha_4) = 0$$

(46)

$$(\alpha_2 - \alpha_1)(\alpha_1 - \alpha_3) + (\alpha_2 - \alpha_1)(\alpha_2 - \alpha_4) +$$

$$+ (\alpha_2 - \alpha_3)(\alpha_2 - \alpha_4) = 0$$

(47)

$$3\alpha_3 = \alpha_1 + \alpha_2 + \alpha_4$$

(48)

Equation (46) is satisfied when $\alpha_1 = \alpha_2$, or $\alpha_1 = \alpha_3$ or $\alpha_1 = \alpha_4$. Let us consider first the case where $\alpha_1 = \alpha_2$. Then, according to (47), it follows that

$$(\alpha_2 - \alpha_3)(\alpha_2 - \alpha_4) = 0$$

(49)

which means that at least two of the roots $X_j$ must be equal. We thus have two subcases to consider. If on the one hand...
α₂ = α₃, then equation (45) implies α₃ = α₄, and thus
the four roots αⱼ are equal, because α₁ = α₂. If on the other hand
α₂ = α₄, then equation (48) again implies that α₃ = α₄ and
one reaches the same conclusion about the equalities between
the roots.

From equation (45), we could instead assume that α₁ = α₃. In
that case, equation (47) implies
\[(α₂ - α₁)(3α₂ - α₁ - 2α₄) = 0.\] (50)

One then has to examine to possibilities. If α₂ = α₃, then
equation (48) readily implies that α₃ = α₄, and thus all the
roots are equal. If we assume instead that α₁ = 3α₂ - 2α₄, then
(48) yields α₂ = α₄, and the four roots are thus equal.

This demonstrates that if the three resultants in (43) vanish,
then P has a multiple root α₁ = α₂ = α₃ = α₄ of multiplicity
4.

As a conclusion, we have demonstrated the following

- **SM6 – Proof of the reality of the resultants Rₚₚ,ₚ₀ in the
  presence of a local anti-unitary symmetry**

When PT-symmetry (3a) or pseudo-Hermiticity (3b) is satis-
fied, the coefficients α₁ are real, and therefore the resultants
are real as well.

In contrast, CP-symmetry (3c) implies α₁ = (-1)ⁿ⁺ʲαⁿ⁺ʲ. This
means that a polynomial of degree n, has coefficients aᵢ ∈ ℝ,
aᵢ₁ ∈ ℍ, aᵢ₂ ∈ ℍ and so on. Let us then perform the change
of variable E → -iE, so that

- P⁽ⁿ⁾⁻¹(-iX) ∈ ℍ if n - j even
- iP⁽ⁿ⁾⁻¹(-iX) ∈ ℍ if n - j odd
- iP⁽ⁿ⁻¹⁾⁻¹(-iX) ∈ ℍ if n - j even
- P⁽ⁿ⁻¹⁾⁻¹(-iX) ∈ ℍ if n - j odd

Thus, one can consider the resultant Rₚₚ,ₚ₀ that is real, because
of (52). We then apply the formula (54) for ξ₁ = 1 and ξ₂ = -i
from which we deduce that Rₚₚ,ₚ₀ is real.

We have demonstrated that the resultants Rₚₚ,ₚ₀ are always real
when CP symmetry (and thus pseudo-chirality) is satisfied. Those resultants are therefore always real when
either of the four symmetries discussed in the main text is sat-
sified.

**SM7 – Proof of Eq. 6 of the main text.**

To proof Eq. (6), let us substitute Eq. (3c) or (3d) in equation (4).
It yields α₁ = (-1)ⁿ⁺ʲαⁿ⁺ʲ. The conditions for Rₚₚ,ₚ₀ to be real thus depend on the parity of n and j. To derive them,
it is useful to introduce the polynomial P(±) ≡ P(-iE). This
polynomial has real coefficients if n is even and imaginary
coefficients if n is odd. Let us discuss each of these two cases
separately.

- If n is even, then the resultants Rₚₚ,ₚ₀ are real for every j.

  They are also related to the resultants of the original
  polynomial P(E) through a formula that we recall:
  the resultant Rₚₚ,ₚ₀ of two polynomials P₁(X) and
  P₂(X) of degree d₁ and d₂, and that Rₚₚ,ₚ₀ of these same polynomials expressed in the variable
  X, are related by Rₚₚ,ₚ₀ = Aᵣᵈᵈₐₙ₋₁(λX). Applying
  this formula in our case simply yields Rₚₚ,ₚ₀ = (-i)ⁿ⁺ʲRₚₚ,ₚ₀. It follows that Rₚₚ,ₚ₀ ∈ ℍ for n even.

- If n is odd, then the polynomial iP has real coefficients, and
  its resultant is therefore real too. Due to the mul-
  tiplication by i, one has now the relation Rₚₚ,ₚ₀ = i²ⁿ⁻¹(-i)ⁿ⁺ʲRₚₚ,ₚ₀. Since n is assumed to be odd, then
  Rₚₚ,ₚ₀ ∈ ℍ for j even and Rₚₚ,ₚ₀ ∈ ℍ for j odd.

Thus, to summarize, Rₚₚ,ₚ₀ is either purely imaginary when n
is odd and j is even, or is real otherwise. The resultant vector
R of real components can then be defined as in equation (6)
of the main text.

**SM8 – Classification of eigenvalues of symmetric non-Hermitian
Hamiltonians according to the sign of the discriminant.**

A classification of the eigenvalues of non-Hermitian Hamiltonians
that satisfy a local anti-unitary symmetry given by Eq. (3)
can be established according the sign of the discriminant
Δ of their characteristic polynomial. This follows from the
fact that polynomials of degree n having real coefficients, and
thus a real discriminant, satisfy the properties given in Table
II for n ≥ 4. The cases n = 2 and n = 3 are shown in table 1
of the main text. A change of sign of the discriminant is thus
associated with a change of the number of complex conjugate
pairs of roots. This result directly implies to the eigenvalues
of PT-symmetric and pseudo-Hermitian Hamiltonians, since
their characteristic polynomial has real coefficients, and the change of the number of complex conjugate pairs of eigenvalues is interpreted as a spontaneously symmetry breaking.

For CP-symmetric and pseudo-chiral Hamiltonians, the coefficients $a_j$ of the characteristic polynomials satisfy $a_j = (-1)^{j/2} a_j^*$ (for $j = 0, 1 \ldots n$), and are thus not real in general. However, for a given $n$, those coefficients are either real or purely imaginary, depending on the parity of $j$. A change of variable $E \rightarrow -iE$ thus yields the polynomial equation $\tilde{P}(E) = 0$ that has only real coefficients.

Let us detail the case $n = 3$ with CP-symmetry as it is discussed in the main text. In that case, the even coefficients of the characteristic polynomial are imaginary and one can write $P(E) = a_3 E^3 + i a_2 E^2 + a_1 E + i a_0$ where $a_j = i a_j$ for $j$ even, with $a_j \in \mathbb{R}$. The change of variable $E \rightarrow -iE$ then yields $\tilde{P}(E) = 0$ with $\tilde{P}(E) = a_3 E^3 - a_2 E^2 - a_1 E + i a_0$ which has real coefficients. Also, note that the discriminant is transformed as $\Delta \rightarrow -\Delta$ under this change of transformation. This justifies Table 1 for CP-symmetric and pseudo-chiral systems.

TABLE II: Pairing of roots for polynomials of degree $n \geq 4$ with real coefficients.

The rotating shallow water model describes the dynamics of a thin layer of an incompressible fluid. Here, "thin" means that the vertical velocity of the fluid is neglected and that the horizontal velocity is constant in the vertical direction, i.e. $u(x, y, t) = (u_x(x, y, t), u_y(x, y, t))$. It is for instance routinely used to describe atmospheric and oceanic waves over planetary distances, as the thickness of those fluids can be disregarded when looking at the large scale dynamics \cite{31}. Also, the fluid’s thickness $h(x, y, t)$ is allowed to vary. The shallow water model then follows from the Euler equations

\begin{align}
\partial_t h + \nabla.(h u) &= 0 \\
\partial_t u + (u \nabla)u &= -g \nabla h
\end{align}

in that thin layer limit (with $g$ the standard gravity). Owing to mass and momentum conservation, the velocity field $u(x, y, t)$ couples to the variation of thickness $h(x, y, t)$ of the fluid layer. The shallow water model is thus a two dimensional model that involves three fields. When the fluid is rotating, a Coriolis term $f$ that is proportional to the angular velocity and couples the two velocity components, must be added to the momentum conservation \cite{31}.

A linearization around a state of rest (zero velocity and constant thickness $H$, i.e. $u \sim \delta u$ and $h \sim H + \delta h$) leads to the Shrödinger-like Hermitian eigenvalue problem $H \Psi = E \Psi$ after a Fourier decomposition on the basis $e^{i(E-k_x x-k_y y)}$, and where $\Psi$ is the three-vector of Fourier components of $(\delta u_x, \delta u_y, \delta h)$ with

\[
H = \begin{pmatrix}
0 & k_x & k_y \\
-k_x & 0 & k_z \\
k_y & -k_z & 0
\end{pmatrix}.
\]

In the main text, diagonal frictional terms, are added, to break Hermiticity while conserving CP symmetry.

\includegraphics[width=0.5\textwidth]{shallow_water_model.png}
\caption{Sketch of the fluid described in the shallow water approximation. The thickness $H$ is assumed to be small compared to its length $L$, such that the fluid’s velocity is constant in the vertical direction.}
\end{figure}

\textbf{SM9 – More details on the shallow water model}

In the main text, we apply our theory on the concrete example of the shallow water model in the presence of friction and rotation.
