Quantum Pseudorandomness and Classical Complexity

William Kretschmer∗

Abstract

We construct a quantum oracle relative to which $\text{BQP} = \text{QMA}$ but cryptographic pseudorandom quantum states and pseudorandom unitary transformations exist, a counterintuitive result in light of the fact that pseudorandom states can be “broken” by quantum Merlin-Arthur adversaries. We explain how this nuance arises as the result of a distinction between algorithms that operate on quantum and classical inputs. On the other hand, we show that some computational complexity assumption is needed to construct pseudorandom states, by proving that pseudorandom states do not exist if $\text{BQP} = \text{PP}$. We discuss implications of these results for cryptography, complexity theory, and quantum tomography.

1 Introduction

Pseudorandomness is a key concept in complexity theory and cryptography, capturing the notion of objects that appear random to computationally-bounded adversaries. Recent works have extended the theory of computational pseudorandomness to quantum objects, with a particular focus on quantum states and unitary transformations that resemble the Haar measure [JLS18, BS19, BFV20].

Ji, Liu, and Song [JLS18] define a pseudorandom state (PRS) ensemble as a keyed family of quantum states $\{|\phi_k\rangle\}_{k \in K}$ such that states from the ensemble can be generated in polynomial time, and such that no polynomial-time quantum adversary can distinguish polynomially many copies of a random $|\phi_k\rangle$ from polynomially many copies of a Haar-random state. They also define an ensemble of pseudorandom unitary transformations (PRUs) analogously as a set of efficiently implementable unitary transformations that are computationally indistinguishable from the Haar measure. These definitions can be viewed as quantum analogues of pseudorandom generators (PRGs) and pseudorandom functions (PRFs), respectively. The authors then present a construction of PRSs assuming the existence of quantum-secure one-way functions, and also give a candidate construction of PRUs that they conjecture is secure.

Several applications of PRSs and PRUs are known. PRSs and PRUs are potentially useful in quantum algorithms: in computational applications that require approximations to the Haar measure, PRSs and PRUs can be much more efficient than $t$-designs, which are information-theoretic approximations to the Haar measure that are analogous to $t$-wise independent functions.̈ Cryptographic applications are possible, with [JLS18] giving a construction of a private-key quantum money scheme based on PRSs. Recent work by Bouland, Fefferman, and Vazirani [BFV20] has also established a fundamental connection between PRSs and any possible resolution to the so-called “wormhole growth paradox” in the AdS/CFT correspondence.

∗University of Texas at Austin. Email: kretsch@cs.utexas.edu. Supported by an NDSEG Fellowship.

1$t$-designs are also sometimes called “pseudorandom” in the literature, e.g. [WBV08, BHH16a]. We emphasize that $t$-designs and PRSs/PRUs are fundamentally different notions and that they are generally incomparable: a $t$-design need not be a PRS/PRU ensemble, or vice-versa.
1.1 Main Results

Given the importance of PRSs and PRUs across quantum complexity theory, in this work we seek to better understand the theoretical basis for the existence of these primitives. We start with a very basic question: what hardness assumptions are necessary for the existence of PRSs,\(^2\) and which unlikely complexity collapses (such as \(P = \text{PSPACE}\) or \(BQP = \text{QMA}\)) would invalidate the security of PRSs? Viewed another way, we ask: what computational power suffices to distinguish PRSs from Haar-random states?

At first glance, it appears that an “obvious” upper bound on the power needed to break PRSs is QMA, the quantum analogue of \(\text{NP}\) consisting of problems decidable by a polynomial-time quantum Merlin-Arthur protocol (or even QCMA, where the witness is restricted to be classical). If Arthur holds many copies of a pure quantum state \(|\psi\rangle\) that can be prepared by some polynomial-size quantum circuit \(C\), then Merlin can send Arthur a classical description of \(C\), and Arthur can verify via the swap test that the output of \(C\) approximates \(|\psi\rangle\). By contrast, most Haar-random states cannot even be approximated by small quantum circuits. So, in some sense, PRSs can be “distinguished” from Haar-random by quantum Merlin-Arthur adversaries.

There is a subtle problem here, though: QMA is defined as a set of decision problems where the inputs are classical bit strings, whereas an adversary against a PRS ensemble inherently operates on a quantum input. As a result, it is unclear whether the hardness of breaking PRSs can be related to the hardness of QMA, or any other standard complexity class. Even if we had a proof that \(BQP = \text{QMA}\), this might not give rise to an efficient algorithm for breaking the security of PRSs.

One way to tackle this is to consider quantum adversaries that can query a classical oracle. If we can show that PRSs can be broken by a polynomial-time quantum algorithm with oracle access to some language \(\mathcal{L} \subseteq \{0,1\}^*\), we conclude that if PRSs exist, then \(\mathcal{L} \not\in \text{BQP}\). A priori, it is not immediately obvious whether oracle access to any language \(\mathcal{L}\) suffices for a polynomial-time quantum adversary to break PRSs. For our first result, we show that a \(\text{PP}\)-complete language works. Hence, if \(\text{BQP} = \text{PP}\), then PRSs do not exist.

**Theorem 1** (Informal version of Theorem 17). There exists a polynomial-time quantum algorithm augmented with a \(\text{PP}\) oracle that can distinguish PRSs from Haar-random states.

This raises the natural question of whether the \(\text{PP}\) oracle in the above theorem can be made weaker. For instance, can we break PRSs with a QCMA or QMA oracle, coinciding with our intuition that the task is solvable by a quantum Merlin-Arthur protocol? In our second result, we show that this intuition is perhaps misguided, as we construct a quantum oracle relative to which such a QMA reduction is impossible.

**Theorem 2** (Informal version of Theorem 20 and Theorem 23). There exists a quantum oracle \(\mathcal{O}\) such that:

1. \(\text{BQP}^{\mathcal{O}} = \text{QMA}^{\mathcal{O}}\), and
2. PRUs (and hence PRSs) exist relative to \(\mathcal{O}\).

Let us remark how bizarre this theorem appears from a cryptographer’s point of view. If \(\text{BQP} = \text{QMA}\), then no quantum-secure classical cryptographic primitives exist, because such primitives can be broken in \(\text{NP}\). So, our construction is a black-box separation between PRUs and all quantum-secure classical cryptography—a relativized world in which any computationally-secure cryptography must use quantum communication. **Theorem 2** thus provides a negative answer (in the quantum black box setting) to a question of Ji, Liu, and Song [JLS18] that asks if quantum-secure one-way functions are necessary for PRSs. One could even view our result as evidence that it might be possible to base the existence of PRSs and PRUs on weaker assumptions than those usually used for classical cryptography.

\(^2\)Note that PRUs imply PRSs, so we focus only on PRSs for this part.
1.2 Application: Hyperefficient Shadow Tomography

An immediate corollary of our results is a new impossibility result for shadow tomography. Aaronson [Aar18] defined the shadow tomography problem as the following estimation task: given copies of an $n$-qubit mixed state $\rho$ and a list of two-outcome measurements $O_1, \ldots, O_M$, estimate $\text{Tr}(O_i \rho)$ for each $i$ up to additive error $\epsilon$. Aaronson showed that, remarkably, this is possible using very few copies of $\rho$: just $\text{poly}(n, \log M, 1/\epsilon)$ copies suffice, which is polylogarithmic in both the dimension of $\rho$ and the number of quantities to be estimated.

Aaronson then asked in what cases shadow tomography can be made computationally efficient with respect to $n$ and $\log M$. Of course, just writing down the input to the problem would take $\Omega(4^n M)$ time if the measurements are given explicitly as Hermitian matrices, and listing the outputs would also take $\Omega(M)$ time. But perhaps one could hope for an algorithm that only operates implicitly on both the inputs and outputs. For example, suppose we stipulate the existence of a quantum algorithm that performs the measurement $O_i$ given input $i \in [M]$, and that this algorithm runs in time $\text{poly}(n, \log M)$. Consider a shadow tomography procedure that takes a description of such an algorithm as input, and that outputs a quantum circuit $C$ such that $|C(i) - \text{Tr}(O_i \rho)| \leq \epsilon$ for each $i \in [M]$.

Aaronson calls this a “hyperefficient” shadow tomography protocol if it additionally runs in time $\text{poly}(n, \log M, 1/\epsilon)$.

However, Aaronson and Kuperberg [AK07] showed a quantum oracle $U$ relative to which $\text{BQP}^{\text{poly}} \neq \text{BQP}^{\text{poly}}$, which implies that hyperefficient shadow tomography is impossible if the observables are merely given as a black box that implements the measurement. The proof of this oracle separation amounts to showing that if the oracle $U$ either (1) implements a reflection about a Haar-random $n$-qubit state, or (2) acts as the identity, then no poly($n$)-query algorithm can distinguish these two cases, even given a classical witness of size $\text{poly}(n)$.

One can consider stronger forms of query access to the observables. For instance, in the common scenario where each observable measures fidelity with a pure state, meaning it has the form $O_i = |\psi_i\rangle \langle \psi_i|$, then in addition to the ability to measure overlap with $|\psi_i\rangle$, one might also have the power to produce copies of $|\psi_i\rangle$. Note that the ability to prepare $|\psi_i\rangle$ is generally much more powerful than the ability to recognize $|\psi_i\rangle$, the latter of which is equivalent to oracle access to the reflection $1 - 2 |\psi_i\rangle \langle \psi_i|$. For example, Aaronson and Kuperberg’s oracle separation of QCMA and QMA [AK07] amounts to building an oracle relative to which certain quantum states can be recognized efficiently but cannot be approximately prepared by small quantum circuits. Other black-box separations of state preparation and state reflection are known, e.g. [BR20], so one might hope that this type of query access could be substantially more powerful for shadow tomography as well.

Nevertheless, our results imply that black-box hyperefficient shadow tomography is impossible even in this setting where we have state preparation access to the observables. This follows from the simple observation that hyperefficient shadow tomography of this form would suffice to break PRS ensembles with a QCMA oracle.

**Theorem 3.** If a hyperefficient shadow tomography procedure exists that works for any list of observables of the form $|\psi_1\rangle \langle \psi_1|, \ldots, |\psi_M\rangle \langle \psi_M|$ given state preparation access to $|\psi_1\rangle, \ldots, |\psi_M\rangle$, then all PRS ensembles can be broken by polynomial-time quantum adversaries with oracle access to QCMA.

**Proof sketch.** For a given PRS ensemble $\{|\phi_k\rangle\}_{k \in \mathcal{K}}$, we have state preparation access to the observable list $\{|\varphi_k\rangle \langle \varphi_k|\}_{k \in \mathcal{K}}$ by way of the generating algorithm of the PRS. Hence, we can

\footnote{Note the slight abuse of notation here, as the shadow tomography procedure can err with some small probability, and $C$ itself might be a probabilistic quantum circuit. For simplicity, we assume that the shadow tomography procedure always succeeds and that $C$ is deterministic in this exposition.}
run hyperefficient shadow tomography using this observable list on copies of some unknown state \(|\psi\rangle\). Suppose that this produces a quantum circuit \(C\) such that \(|C(k) - \text{Tr}(\varphi_k \langle \varphi_k | \psi \rangle \langle | \psi |)| \leq \frac{1}{10}\) for each \(k \in K\). Observe that the problem of deciding whether there exists some \(k\) such that \(C(k) \geq \frac{1}{10}\) is in QCMA. If \(|\psi\rangle\) is pseudorandom, then such a \(k\) always exists (whichever \(k\) satisfies \(|\psi\rangle = |\varphi_k\rangle\), whereas if \(|\psi\rangle\) is Haar-random, such a \(k\) exists with negligible probability over the choice of \(|\psi\rangle\). Hence, these two ensembles can be distinguished by feeding \(C\) into this QCMA language. \(\blacksquare\)

The above theorem also relativizes, in the sense that if the shadow tomography procedure only accesses the state preparation algorithm via a black box \(O\), then hyperefficient shadow tomography lets us break PRSs in polynomial time with oracle access to \(O\) and QCMA\(^O\). Since Theorem 2 gives an oracle relative to which BQP\(^O\) = QCMA\(^O\) = QMA\(^O\) and PRSs exist, we conclude that hyperefficient shadow tomography is impossible with only black-box state preparation access to the observables.

1.3 Our Techniques

The starting point for the proof of Theorem 1, which gives an upper bound of PP on the power needed to break pseudorandom states, is a theorem of Huang, Kueng, and Preskill [HKP20] that gives a simple procedure for shadow tomography.

**Theorem 4 ([HKP20]).** Fix \(M\) different observables \(O_1, O_2, \ldots, O_M\) and an unknown \(n\)-qubit mixed state \(\rho\). Then there exists a quantum algorithm that performs \(T = O(\log(M/\delta))\), \(\max_i \text{Tr}(O_i^2)\) single-copy measurements in random Clifford bases of \(\rho\), and uses the measurement results to estimate the quantities \(\text{Tr}(O_1 \rho), \text{Tr}(O_2 \rho), \ldots, \text{Tr}(O_M \rho)\), such that with probability at least \(1 - \delta\), all of the \(M\) quantities are correct up to additive error \(\varepsilon\).

If \(\{|\varphi_k\rangle\}_{k \in K}\) is a family of PRSs, then by choosing \(O_k = |\varphi_k\rangle \langle \varphi_k|\) for each \(k \in K\) to be the list of observables, we can use the above algorithm to determine whether \(\rho\) is close to one of the states in the PRS ensemble. A Haar-random state will be far from all of the pseudorandom states with overwhelming probability. Hence, Theorem 4 implies the existence of an algorithm that distinguishes the pseudorandom and Haar-random ensembles, by performing a polynomial number of random Clifford measurements and analyzing the results. The key observation is that the Clifford measurements can be performed efficiently, even though the resulting analysis (which operates on purely classical information) might be computationally expensive.

Next, one could try to argue that the computationally difficult steps in the above algorithm can be made efficient with a PP oracle. However, we take a different approach. We adopt a Bayesian perspective: suppose that with 50% probability we are given copies of a Haar-random state, and otherwise with 50% probability we are given copies of a randomly chosen state from the pseudorandom ensemble. We wish to distinguish these two cases using only the results of the random Clifford measurements as observed data. One way to do this is via the Bayes decision rule: we compute the posterior probability of being Haar-random or pseudorandom given the measurements, and then guess the more likely result. In fact, the Bayes decision rule is well-known to be the optimal decision rule in general, in the sense that any decision rule errs at least as often as the Bayes decision rule (see e.g. [Ber13, Chapter 4.4.1]). Hence, because the algorithm of Huang, Kueng, and Preskill (Theorem 4) distinguishes the Haar-random and pseudorandom ensembles with good probability, the Bayes decision rule conditioned on the random Clifford measurements must work at least as well at the same distinguishing task.

Finally, we observe that using a quantum algorithm with postselection, we can approximate the relevant posterior probabilities needed for the Bayes decision rule. This allows us to appeal to the equivalence PostBQP = PP [Aar05] to simulate this postselection with a PP oracle.

Technically, one challenge is that the postselected quantum algorithm requires the ability to prepare copies of a Haar-random state, even though a polynomial-time quantum algorithm
cannot even approximately prepare most Haar-random states. The solution is to replace the Haar ensemble by an approximate quantum design, which we argue does not substantially change the success probability of the algorithm.

For our second result (Theorem 2), the oracle construction we use is simple to describe. The oracle \( \mathcal{O} \) consists of two parts: a quantum oracle \( \mathcal{U} = \{ \mathcal{U}_n \}_{n \in \mathbb{N}} \), where each \( \mathcal{U}_n \) consists of \( 2^n \) different Haar-random \( n \)-qubit unitary matrices, and a classical oracle \( \mathcal{P} \) that is an arbitrary \( \text{PSPACE} \)-complete language. We prove that Theorem 2 holds with probability 1 over the choice of \( \mathcal{U} \).

Showing that PRUs exist relative to \( (\mathcal{U}, \mathcal{P}) \) is reasonably straightforward. The proof uses the BBBV theorem (i.e., the optimality of Grover’s algorithm) [BBBV97], and is analogous to showing that one-way functions or pseudorandom generators exist relative to a random classical oracle, as was shown by Impagliazzo and Rudich [IR89]. We only rigorously prove security against adversaries with classical advice, though we believe that the recently introduced framework of Chung, Guo, Liu, and Qian [CGLQ20] should yield a security proof against adversaries with quantum advice.

Slightly more technically involved is proving that \( \text{BQP}^{\mathcal{U}, \mathcal{P}} = \text{QMA}^{\mathcal{U}, \mathcal{P}} \). To do so, we argue that a QMA verifier is not substantially more powerful than a BQP machine at learning nontrivial properties of \( \mathcal{U} \). More precisely, we argue that if a QMA verifier \( \mathcal{V} \) makes \( T \) queries to \( \mathcal{U}_n \) for some \( n \in \mathbb{N} \), then either (1) \( n = O(\log T) \) is sufficiently small that poly\((T)\) queries to \( \mathcal{U}_n \) actually suffice to learn \( \mathcal{U}_n \) to inverse-polynomial precision, or else (2) \( n = \omega(\log t) \) is sufficiently large that with high probability, the maximum acceptance probability of \( \mathcal{V} \) (over the choice of Merlin’s witness) is close to the average maximum acceptance probability of \( \mathcal{V} \) when \( \mathcal{U}_n \) is replaced by a random set of matrices sampled from the Haar measure. We prove this as a consequence of the extremely strong concentration of measure properties exhibited by the Haar measure [Mec19].

This allows a \( \text{BQP}^{\mathcal{U}, \mathcal{P}} \) machine to approximate the maximum acceptance probability of \( \mathcal{V}^{\mathcal{U}, \mathcal{P}} \) as follows. In case (1), the \( \text{BQP}^{\mathcal{U}, \mathcal{P}} \) machine first queries \( \mathcal{U}_n \) enough times to learn a unitary transformation \( \hat{\mathcal{U}}_n \) that is close to \( \mathcal{U}_n \), and then hard codes \( \hat{\mathcal{U}}_n \) into a new QMA\(^P\) verifier \( \hat{\mathcal{V}} \) that simulates \( \mathcal{V} \) by replacing queries to \( \mathcal{U}_n \) with calls to \( \hat{\mathcal{U}}_n \). In case (2), the \( \text{BQP}^{\mathcal{U}, \mathcal{P}} \) machine similarly constructs a new QMA\(^P\) verifier \( \tilde{\mathcal{V}} \), instead simulating \( \mathcal{V} \) by replacing queries to \( \mathcal{U}_n \) with unitaries chosen from an approximate polynomial design.\(^4\) In both cases, \( \tilde{\mathcal{V}} \) defines a QMA\(^P\) problem. Because \( \mathcal{P} \) is \( \text{PSPACE} \)-complete, \( \text{BQP}^P = \text{QMA}^P = \text{PSPACE} \), and therefore this problem can be decided with a single query to \( \mathcal{P} \).

The astute reader may notice that this proof works for more general choices of \( \mathcal{P} \): it shows that for any oracle \( \mathcal{P} \), if \( \text{BQP}^P = \text{QMA}^P \), then \( \text{BQP}^{\mathcal{U}, \mathcal{P}} = \text{QMA}^{\mathcal{U}, \mathcal{P}} \) with probability 1 over the choice of \( \mathcal{U} \). An interesting consequence is the special case when \( \mathcal{P} \) is trivial.

\textbf{Corollary 5.} If \( \text{BQP} = \text{QMA} \), then \( \text{BQP}^{\mathcal{U}} = \text{QMA}^{\mathcal{U}} \) with probability 1 over the choice of \( \mathcal{U} \).

In words, if \( \text{BQP} = \text{QMA} \) in the unrelativized world, then the complexity classes also coincide relative to a collection \( \mathcal{U} \) of Haar-random oracles. Or, viewed another way, separating BQP from QMA relative to \( \mathcal{U} \) requires separating them in the unrelativized world. This is in stark contrast to the case of random classical oracles, where we can prove unconditionally that for a uniformly random oracle \( \mathcal{O} \), \( \text{BQP}^\mathcal{O} \neq \text{QMA}^\mathcal{O} \) (and indeed, \( \text{NP}^\mathcal{O} \nsubseteq \text{BQP}^\mathcal{O} \)) with probability 1 over \( \mathcal{O} \) [BBBV97].

\subsection{1.4 Open Problems}

Can we prove a similar result to Theorem 2 using a classical oracle, for either PRUs or PRSs? Attempting to resolve this question seems to run into many of the same difficulties that arise

\(^4\)Technically, this requires choosing a random element of the polynomial design for each \( x \in \{0, 1\}^n \) by means of a random oracle, so we use Zhandry’s strategy [Zha12] to simulate \( T \) quantum queries to a random oracle using a \( 2T \)-wise independent function.
in constructing a classical oracle separation between QCMA and QMA, which also remains an open problem [AK07]. For one, as pointed out in [AK07], we do not even know whether every \( n \)-qubit unitary transformation can be approximately implemented in \( \text{poly}(n) \) time relative to some classical oracle. Even if one could resolve this, it is not clear whether the resulting PRUs or PRSs would be secure against adversaries with the power of QMA. For instance, we show in Appendix A that an existing construction of PRSs, whose security is provable in the random oracle model [BS19], can be broken with an NP oracle.

What else can be said about the hardness of learning quantum states and unitary transformations, either in the worst case or on average? A related question is to explore the hardness of problems involving quantum meta-complexity: that is, problems that themselves encode computational complexity or difficulty. Consider, for example, a version of the minimum circuit size problem (MCSP) for quantum states: given copies of a pure quantum state \( |\psi\rangle \), determine the size of the smallest quantum circuit that approximately outputs \( |\psi\rangle \). If PRSs exist, then this task should be hard, but placing an upper bound on the complexity of this task might be difficult in light of our results. We view this problem as particularly intriguing because it does not appear to have an obvious classical analogue, and also because of its relevance to the wormhole growth paradox and Susskind’s Complexity=Volume conjecture in AdS/CFT [BFV20, Sus16b, Sus16a]. A number of recent breakthroughs in complexity theory have involved ideas from meta-complexity (see surveys by Allender [All17, All20]), and it would be interesting to see which of these techniques could be ported to the quantum setting.

What other complexity-theoretic evidence can be given for the existence of PRSs and PRUs? Can we give candidate constructions of PRSs or PRUs that do not rely on the assumption BQP \( \neq \text{QMA} \)? To give a specific example, an interesting question is whether polynomial-size quantum circuits with random local gates form PRUs. Random circuits are known to information-theoretically approximate the Haar measure in the sense that they form approximate unitary designs [BHH16b], and it seems conceivable that they could also be computationally pseudorandom.

## 2 Preliminaries

### 2.1 Notation

Throughout, \([n]\) denotes the set of integers \( \{1,2,\ldots,n\} \), and \([n,m]\) denotes the set of integers \( \{n,n+1,n+2,\ldots,m\} \). If \( x \in \{0,1\}^n \) is a binary string, then \(|x|\) denotes the length of \( x \). For \( X \) a finite set, we let \(|X|\) denote the size of \( X \). If \( X \) is a probability distribution, then we use \( x \leftarrow X \) to denote a random variable \( x \) sampled according to \( X \). When \( X \) is a finite set, we also use \( x \leftarrow X \) to indicate a random variable \( x \) drawn uniformly from \( X \). A function \( f(n) \) is negligible if for every constant \( c > 0 \), \( f(n) \leq \frac{1}{n^c} \) for all sufficiently large \( n \). We use \( \text{negl}(n) \) to denote an arbitrary negligible function, and \( \text{poly}(n) \) to denote an arbitrary polynomially-bounded function.

We use \( ||M||_F = \sqrt{\text{Tr}(M^\dagger M)} \) to denote the Frobenius norm of a matrix \( M \). We denote by \( ||A||_o \) the diamond norm of a superoperator \( A \) acting on density matrices (see [AKN98] for a definition). For a unitary matrix \( U \), we use \( U \cdot U^\dagger \) to denote the superoperator that maps a density matrix \( \rho \) to \( U \rho U^\dagger \).

We use \( \mathbb{S}(N) \) to denote the set of \( N \)-dimensional pure quantum states, and \( \mathbb{U}(N) \) to denote the group of \( N \times N \) unitary matrices. When \( N = 2^n \), we identify these with \( n \)-qubit states and unitary transformations, respectively. We use \( \sigma_N \) to denote the Haar measure on \( \mathbb{S}(N) \), and we let \( \mu_N \) denote the Haar measure over \( \mathbb{U}(N) \). We write \( \mathbb{U}(N)^M \) for the space of \( MN \times MN \) block-diagonal unitary matrices, where each block has size \( N \times N \), and we also identify \( \mathbb{U}(N)^M \) with \( M \)-tuples of \( N \times N \) unitary matrices. We use \( \mu^M_N \) to denote the product measure \( \mu^M_N(U_1,U_2,\ldots,U_M) = \mu_N(U_1) \cdot \mu_N(U_2) \cdots \mu_N(U_M) \) on \( \mathbb{U}(N)^M \).
We use superscript notation for algorithms that query oracles (see Section 2.3 for an explanation of the query model). For instance, \( \mathcal{A}^U(x, |\psi\rangle) \) denotes a quantum algorithm \( \mathcal{A} \) that queries an oracle \( U \) and receives a classical input \( x \) and a quantum input \( |\psi\rangle \).

2.2 Quantum Information

We require the following well-known fact, which bounds the distance in the diamond norm between two unitary superoperators in terms of the Frobenius norm of the difference of the two matrices. We provide a proof for completeness.

Lemma 6. Let \( U, V \in \mathbb{U}(N) \). Then \( ||U \cdot U^\dagger - V \cdot V^\dagger||_\diamond \leq 2||U - V||_F \).

Proof. Let \( \{\lambda_i : i \in [N]\} \) denote the eigenvalues of \( UV^\dagger \). Then we have:

\[
||U - V||_F^2 = \text{Tr}((U - V)(U - V)^\dagger) \\
= \text{Tr}(2I - UV^\dagger - VU^\dagger) \\
= 2N - \sum_{i=1}^{N}(\lambda_i + \lambda_i^*) \\
= \sum_{i=1}^{N}(2 - 2\text{Re}(\lambda_i)) \\
\geq \max_i(2 - 2\text{Re}(\lambda_i)),
\]

where \( \text{Re}(\lambda_i) \) denotes the real part of \( \lambda_i \). The last line holds because the eigenvalues of a unitary matrix have absolute value 1. Aharonov, Kitaev, and Nisan [AKN98] show that \( ||U \cdot U^\dagger - V \cdot V^\dagger||_\diamond = 2\sqrt{1 - d^2} \), where \( d \) is the distance in the complex plane between 0 and the polygon whose vertices are \( \lambda_1, \ldots, \lambda_N \). From this we may conclude:

\[
||U \cdot U^\dagger - V \cdot V^\dagger||_\diamond \leq \max_i 2\sqrt{1 - \max\{\text{Re}(\lambda_i), 0\}^2} \\
\leq \max_i 2\sqrt{2 - 2\text{Re}(\lambda_i)} \\
\leq 2||U - V||_F,
\]

where the first inequality uses the fact that either all of the eigenvalues have positive real components and therefore \( d \geq \min_i \text{Re}(\lambda_i) \), or else \( d \geq 0 \); the second inequality substitutes \( 1 - \max\{x, 0\}^2 \leq 2 - 2x \) which holds for all \( x \in \mathbb{R} \); and the third inequality substitutes (1). \( \blacksquare \)

We use the notion of an \( \varepsilon \)-approximate quantum (state) \( t \)-design, which is a distribution over quantum states that information-theoretically approximates the Haar measure over states.

Definition 7 (Approximate quantum design [AE07]). A probability distribution \( S \) over \( \mathbb{S}(N) \) is an \( \varepsilon \)-approximate quantum \( t \)-design if:

\[
(1 - \varepsilon) \mathbb{E}_{|\psi\rangle \sim \sigma_N} |\psi\rangle \langle \psi|^\otimes t \leq \mathbb{E}_{|\psi\rangle \sim S} |\psi\rangle \langle \psi|^\otimes t \leq (1 + \varepsilon) \mathbb{E}_{|\psi\rangle \sim \sigma_N} |\psi\rangle \langle \psi|^\otimes t
\]

and:

\[
\mathbb{E}_{|\psi\rangle \sim S} |\psi\rangle \langle \psi| = \mathbb{E}_{|\psi\rangle \sim \sigma_N} |\psi\rangle \langle \psi|.
\]

Similarly, we require \( \varepsilon \)-approximate unitary \( t \)-designs, which are approximations to the Haar measure over unitary matrices. The definition of \( \varepsilon \)-approximate unitary \( t \)-designs is more technical, so we point to [BHH16b, Definition 2] for a formal definition. While there are several definitions of approximate \( t \)-designs used in the literature, for this work it is crucial that we
use multiplicative approximate designs for both states and unitaries, meaning that the designs approximate the first $t$ moments of the Haar measure to within a multiplicative $1 \pm \varepsilon$ error (as opposed to additive error).

Efficient constructions of approximate unitary $t$-designs over qubits are known, as below.

**Lemma 8.** Fix $\varepsilon > 0$. For each $n, t \in \mathbb{N}$, there exists $m(n) \leq \text{poly}(n)$ and a poly$(n,t)$-time classical algorithm $S$ that takes as input a random string $x \leftarrow \{0,1\}^m$ and outputs a description of a quantum circuit on $n$ qubits such that the circuits sampled from $S$ form an $\varepsilon$-approximate unitary $t$-design over $\mathbb{U}(2^n)$.

**Proof sketch.** Fix an arbitrary universal quantum gate set $G$ with algebraic entries that is closed under taking inverses (e.g. $G = \{\text{CNOT}, H, T, T\} \}$). Brandão, Harrow, and Horodecki [BHH16b, Corollary 7] show that $n$-qubit quantum circuits consisting of poly$(n,t)$ random gates sampled from $G$, applied to random pairs of qubits, form $\varepsilon$-approximate unitary $t$-designs. So, $S$ just has to sample from this distribution, which can be done with poly$(n,t)$ bits of randomness. ■

Note that this also implies an efficient construction of $\varepsilon$-approximate quantum (state) $t$-designs, as if $S$ is an $\varepsilon$-approximate unitary $t$-design over $\mathbb{U}(N)$ then $S |\psi\rangle$ is an $\varepsilon$-approximate quantum $t$-design for any fixed $|\psi\rangle$ (e.g. $|0^n\rangle$).

Essentially the only property we need of approximate $t$-designs is that they can be used in place of the Haar measure in any quantum algorithm that uses $t$ copies of a Haar-random state (or $t$ queries to a Haar-random unitary), and the measurement probabilities of the algorithm will change by only a small multiplicative factor.

**Fact 9.** Let $S$ be an $\varepsilon$-approximate quantum $t$-design over $S(N)$, and let $A$ be an arbitrary quantum measurement. Then:

$$(1 - \varepsilon) \Pr_{|\psi\rangle \leftarrow \sigma_N} [A(\langle \psi \rangle^{\otimes t}) = 1] \leq \Pr_{|\psi\rangle \leftarrow S} [A(\langle \psi \rangle^{\otimes t}) = 1] \leq (1 + \varepsilon) \Pr_{|\psi\rangle \leftarrow \sigma_N} [A(\langle \psi \rangle^{\otimes t}) = 1].$$

**Fact 10 ([BHH16b]).** Let $S$ be an $\varepsilon$-approximate unitary $t$-design over $\mathbb{U}(N)$, and let $A^U$ be an arbitrary quantum algorithm that makes $t$ queries to some $U \in \mathbb{U}(N)$. Then:

$$(1 - \varepsilon) \Pr_{U \leftarrow \mu_N} [A^U = 1] \leq \Pr_{U \leftarrow S} [A^U = 1] \leq (1 + \varepsilon) \Pr_{U \leftarrow \mu_N} [A = 1].$$

We require the following concentration inequality on the Haar measure, which is stated in terms of Lipschitz continuous functions. For a metric space $M$ with metric $d$, a function $f : M \rightarrow \mathbb{R}$ is $L$-Lipschitz if for all $x, y \in M$, $|f(x) - f(y)| \leq L \cdot d(x, y)$.

**Theorem 11 ([Mec19, Theorem 5.17]).** Given $N_1, \ldots, N_k \in \mathbb{N}$, let $X = \mathbb{U}(N_1) \oplus \cdots \oplus \mathbb{U}(N_k)$ be the space of block-diagonal unitary matrices with blocks of size $N_1, \ldots, N_k$. Let $\mu = \mu_{N_1} \times \cdots \times \mu_{N_k}$ be the product of Haar measures on $X$. Suppose that $f : X \rightarrow \mathbb{R}$ is $L$-Lipschitz in the Frobenius norm. Then for every $t > 0$:

$$\Pr_{U \leftarrow \mu} \left[ f(U) \geq \mathbb{E}_{V \leftarrow \mu} [f(V)] + t \right] \leq \exp \left( -\frac{(N - 2)L^2}{24L^2} \right),$$

where $N = \min\{N_1, \ldots, N_k\}$.

### 2.3 Complexity Theory

We assume familiarity with standard complexity classes such as BQP and PP. For completeness, we define some complexity classes and related terms, starting with QMA.

**Definition 12.** A promise problem $\mathcal{L} = (\mathcal{L}_{\text{yes}}, \mathcal{L}_{\text{no}})$ is in QMA if there exists a polynomial-time quantum algorithm $V(x, |\psi\rangle)$ called a QMA verifier and a polynomial $p$ such that:

$\Pr_{U \leftarrow \mu} \left[ V(U, |\psi\rangle) = 1 \right] = 1$ for all $x \in \mathcal{L}_{\text{yes}}$, and

$\Pr_{U \leftarrow \mu} \left[ V(U, |\psi\rangle) = 0 \right] \leq 1/2$ for all $x \in \mathcal{L}_{\text{no}},$ and

$\Pr_{U \leftarrow \mu, x \leftarrow \{0,1\}} \left[ V(U, |\psi\rangle) = 0 \right] \leq 1/2$ for all $|\psi\rangle \in \mathbb{U}(2^n)$.
1. (Completeness) If \( x \in \mathcal{L}_{\text{yes}} \), then there exists a state \(|\psi\rangle\) (called a witness or proof) on \( p(|x|) \) qubits such that \( \Pr[\mathcal{V}(x,|\psi\rangle) = 1] \geq \frac{2}{3} \).

2. (Soundness) If \( x \in \mathcal{L}_{\text{no}} \), then for every state \(|\psi\rangle\) on \( p(|x|) \) qubits, \( \Pr[\mathcal{V}(x,|\psi\rangle) = 1] \leq \frac{1}{3} \).

Aaronson [Aar05] defined PostBQP as follows, and showed that PostBQP = PP.

**Definition 13.** A promise problem \( \mathcal{L} = (\mathcal{L}_{\text{yes}}, \mathcal{L}_{\text{no}}) \) is in PostBQP if there exists a polynomial-time quantum algorithm \( \mathcal{A}(x) \) that outputs a trit \( \{0,1,*\} \) such that:

1. If \( x \in \mathcal{L}_{\text{yes}} \cup \mathcal{L}_{\text{no}} \), then \( \Pr[\mathcal{A}(x) \in \{0,1\}] > 0 \). When \( \mathcal{A}(x) \in \{0,1\} \), we say that postselection succeeds.

2. If \( x \in \mathcal{L}_{\text{yes}} \), then \( \Pr[\mathcal{A}(x) = 1 | \mathcal{A}(x) \in \{0,1\}] \geq \frac{2}{3} \). In other words, conditioned on postselection succeeding, \( \mathcal{A} \) outputs 1 with at least \( \frac{2}{3} \) probability.

3. If \( x \in \mathcal{L}_{\text{no}} \), then \( \Pr[\mathcal{A}(x) = 1 | \mathcal{A}(x) \in \{0,1\}] \leq \frac{1}{3} \). In other words, conditioned on postselection succeeding, \( \mathcal{A} \) outputs 1 with at most \( \frac{1}{3} \) probability.

Technically, the definition of PostBQP is sensitive to the choice of universal gate set used to specify quantum algorithms, as was observed by Kuperberg [Kup15]. However, for most “reasonable” gate sets, such as unitary gates with algebraic entries [Kup15], the choice of gate set is irrelevant. We assume such a gate set, e.g., \{\text{CNOT}, H, T\}.

We consider versions of BQP, QMA, and PostBQP augmented with quantum oracles, where the algorithm (or in the case of QMA, the verifier) can apply unitary transformations from an infinite sequence \( \mathcal{U} = \{U_n\}_{n \in \mathbb{N}} \). We denote the respective complexity classes by \( \text{BQP}^\mathcal{U}, \text{QMA}^\mathcal{U} \), and \( \text{PostBQP}^\mathcal{U} \). We assume the algorithm incurs a cost of \( n \) to query \( U_n \) so that a polynomial-time algorithm on input \( x \) can query \( U_n \) for any \( n \leq \text{poly}(|x|) \). In this model, a query to \( U_n \) consists of a single application of either \( U_n, U_n^\dagger \), or controlled versions of \( U_n \) or \( U_n^\dagger \).

The quantum oracle model includes classical oracles as a special case. For a language \( \mathcal{L} \), a query to \( \mathcal{L} \) is implemented via the unitary transformation \( \mathcal{U} \) that acts as \( \mathcal{U}|x\rangle|b\rangle = |x\rangle|b \oplus \mathcal{L}(x)\rangle \).

### 2.4 Cryptography

A family of functions \( \{f_k\}_{k \in \mathcal{K}} \) where \( f_k : \{0,1\}^n \rightarrow \{0,1\}^m \) is called \( t \)-wise independent if for every distinct \( x_1, x_2, \ldots, x_t \in \{0,1\}^n \) and every (not necessarily distinct) \( y_1, y_2, \ldots, y_t \in \{0,1\}^m \):

\[
\Pr_{k \leftarrow \mathcal{K}}[f_k(x_i) = y_i \forall i \in [t]] = 2^{-mt}.
\]

Efficient constructions of \( t \)-wise independent functions are known, in the sense that one can sample a random \( f_k \) from the \( t \)-wise independent function family and make queries to \( f_k \) in \( \text{poly}(t,n,m) \) time [Zha12]. Our primary use of \( t \)-wise independent functions is in simulating random oracles: \( 2t \)-wise independent functions can be used in place of a uniformly random function \( \{0,1\}^n \rightarrow \{0,1\}^m \) in any quantum algorithm that makes at most \( t \) queries to the random function; see Zhandry [Zha12, Theorem 6.1] for more details.

We use the following definitions of pseudorandom quantum states (PRSs) and pseudorandom unitaries (PRUs), which were introduced by Ji, Liu, and Song [JLS18].

**Definition 14** (Pseudorandom quantum states [JLS18]). Let \( \kappa \in \mathbb{N} \) be the security parameter. Let \( D \) be the dimension of a quantum system and let \( \mathcal{K} \) be the key set, both parameterized by \( \kappa \). A keyed family of quantum states \( \{|\varphi_k\rangle\}_{k \in \mathcal{K}} \subset \mathbb{S}(D) \) is pseudorandom if the following two conditions hold:

1. (Efficient generation) There is a polynomial-time quantum algorithm \( G \) that generates \(|\varphi_k\rangle\) on input \( k \), meaning \( G(k) = |\varphi_k\rangle \).
(2) (Computationally indistinguishable) For any polynomial-time quantum algorithm $A$ and $T = \text{poly}(\kappa)$:

$$\left| \Pr_{k \leftarrow \mathcal{K}} \left[ A(\varphi)^{\otimes T} = 1 \right] - \Pr_{\psi \leftarrow \sigma_D} \left[ A(\psi)^{\otimes T} = 1 \right] \right| = \text{negl}(\kappa).$$

**Definition 15** (Pseudorandom unitary transformations [JLS18]). Let $\kappa \in \mathbb{N}$ be the security parameter. Let $D$ be the dimension of a quantum system and let $\mathcal{K}$ be the key set, both parameterized by $\kappa$. A keyed family of unitary transformations $\{U_k\}_{k \in \mathcal{K}} \subset \mathbb{U}(D)$ is pseudorandom if the following two conditions hold:

(1) (Efficient computation) There is a polynomial-time quantum algorithm $G$ that implements $U_k$ on input $k$, meaning that for any $|\psi\rangle \in \mathcal{S}(D)$, $G(k, |\psi\rangle) = U_k |\psi\rangle$.

(2) (Computationally indistinguishable) For any polynomial-time quantum algorithm $A^U$ that queries $U \in \mathbb{U}(D)$:

$$\left| \Pr_{k \leftarrow \mathcal{K}} \left[ A^U_k (1^\kappa) = 1 \right] - \Pr_{U \leftarrow \mu_D} \left[ A^U (1^\kappa) = 1 \right] \right| = \text{negl}(\kappa).$$

We generally take the key set $\mathcal{K} = \{0, 1\}^\kappa$ and choose $D = 2^n$ for some $n = \text{poly}(\kappa)$ in the above definitions. We sometimes call the negligible quantities in the above definitions the advantage of the quantum adversary $A$.

In this work, we consider security against non-uniform quantum algorithms with classical advice, which means that the adversary is allowed to be a different polynomial-time quantum algorithm for each setting of the security parameter $\kappa \in \mathbb{N}$. Without loss of generality, such an adversary can always be assumed to take the form of a uniform $\text{poly}(\kappa)$-time quantum algorithm $A(1^\kappa, x)$, where $x \in \{0, 1\}^{\text{poly}(\kappa)}$ is an advice string that depends only on $\kappa$.

# 3 Breaking Pseudorandomness with a Classical Oracle

In this section, we prove that a polynomial-time quantum algorithm with a PP oracle can distinguish a PRS from a Haar-random state. First, we need a lemma about the overlap between a fixed state $|\varphi\rangle$ and a Haar-random state $|\psi\rangle$.

**Lemma 16.** Let $|\varphi\rangle \in \mathcal{S}(N)$, and let $\epsilon > 0$. Then:

$$\Pr_{|\psi\rangle \leftarrow \sigma_N} \left[ |\langle \psi | \varphi \rangle|^2 \geq \epsilon \right] \leq e^{-\epsilon N}.$$

**Proof.** This follows from standard concentration inequalities, or even an explicit computation, using the fact that $|\langle \psi | \varphi \rangle|^2$ is roughly exponentially distributed for a random state $|\psi\rangle$. See e.g. [BHH16b, Equation (14)]

The formal statement of our result is below.

**Theorem 17.** For any PRS ensemble $\{|\varphi_k\rangle\}_{k \in \mathcal{K}}$ of $n$-qubit states with security parameter $\kappa$, there exists a PP language $\mathcal{L}$, a $\text{poly}(\kappa)$-time quantum algorithm $\mathcal{A}^\mathcal{L}$, and $T = \text{poly}(\kappa)$ such that the following holds. Let $X \leftarrow \{0, 1\}$ be a uniform random bit. Let $|\psi\rangle$ be sampled uniformly from the PRS ensemble if $X = 0$, and otherwise let $|\psi\rangle$ be sampled from the Haar measure $\sigma_{2^n}$ if $X = 1$. Then we have:

$$\Pr_{X,|\psi\rangle} \left[ \mathcal{A}^\mathcal{L}(|\psi\rangle^{\otimes T}) = X \right] \geq 0.995.$$
Proof. We first describe $\mathcal{A}$. For some $T$ to be chosen later, on input $|\psi\rangle^\otimes T$, $\mathcal{A}$ measures each copy of $|\psi\rangle$ in a different randomly chosen Clifford basis. Call the list of measurement bases $b = (b_1, b_2, \ldots, b_T)$ and the measurement results $c = (c_1, c_2, \ldots, c_T)$. $\mathcal{A}$ then feeds $(b, c)$ into a single query to $\mathcal{L}$, and outputs the result of the query. This takes polynomial time because there exists an $O(n^3)$-time algorithm to sample a random $n$-qubit Clifford unitary, and this algorithm also produces an implementation of the unitary with $O(n^2 / \log n)$ gates [KS14, AG04].

The PP language $\mathcal{L}$ we choose for the oracle is most easily described in terms of a PostBQP algorithm $\mathcal{B}(b, c)$ (i.e. a postselected polynomial-time quantum algorithm, as in Definition 13), by the equivalence PostBQP = PP [Aar05]. Let $S$ be a $\frac{1}{T}$-approximate $n$-qubit quantum $T$-design (Definition 7) such that a state can be drawn from $S$ in poly($\kappa$) time (because $n, T \leq \text{poly}(\kappa)$, the existence of such a design follows from Lemma 8). $\mathcal{B}$ begins by initializing the state:

$$\hat{\rho} = \frac{1}{2} |0\rangle \langle 0| \otimes \mathbb{E}_{k \leftarrow \mathcal{K}} \left[ |\varphi_k\rangle \langle \varphi_k|^\otimes T \right] + \frac{1}{2} |1\rangle \langle 1| \otimes \mathbb{E}_{|\psi\rangle \leftarrow S} \left[ |\psi\rangle \langle \psi|^\otimes T \right].$$

$\mathcal{B}$ measures all but the leftmost qubit of $\hat{\rho}$ in the basis given by $b$, and postselects on observing $c$ (i.e. $\mathcal{B}$ outputs * if the measurements are not equal to $c$). Finally, conditioned on postselection succeeding, $\mathcal{B}$ measures and outputs the result of the leftmost qubit that was not measured.

It remains to show that $\mathcal{A}$ distinguishes the pseudorandom and Haar-random state ensembles. For the purpose of this analysis, it will be convenient to view $\hat{\rho}$ as an approximation to the state:

$$\rho = \frac{1}{2} |0\rangle \langle 0| \otimes \mathbb{E}_{k \leftarrow \mathcal{K}} \left[ |\varphi_k\rangle \langle \varphi_k|^\otimes T \right] + \frac{1}{2} |1\rangle \langle 1| \otimes \mathbb{E}_{|\psi\rangle \leftarrow \sigma_{2^n}} \left[ |\psi\rangle \langle \psi|^\otimes T \right],$$

where the $\varepsilon$-approximate $T$-design $S$ is replaced by the Haar measure $\sigma_{2^n}$. Indeed, we will essentially argue the algorithm’s correctness if the state $\hat{\rho}$ is replaced by $\rho$, and then argue that this implies the correctness of the actual algorithm.

For each $k \in \mathcal{K}$, define $O_k = |\varphi_k\rangle \langle \varphi_k|$. Note that if $X = 0$ (i.e. $|\psi\rangle$ is pseudorandom), there always exists a $k$ such that $\text{Tr}(O_k |\psi\rangle \langle \psi|) = 1$, namely whichever $k$ satisfies $|\psi\rangle = |\varphi_k\rangle$. On the other hand, by Lemma 16 and a union bound, if $X = 1$ (i.e. $|\psi\rangle$ is Haar-random), $\text{Tr}(O_k |\psi\rangle \langle \psi|) < \frac{1}{T}$ for every $k \in \mathcal{K}$, except with probability at most $|\mathcal{K}| \cdot e^{-2n/3} \leq \text{neg}(\kappa)$ over $|\psi\rangle$.

If we choose $M = |\mathcal{K}|$, $\varepsilon = \frac{2}{3}$, and $\delta = 0.001 - |\mathcal{K}| \cdot e^{-2n/3}$, then by Theorem 4 there exists a quantum algorithm that takes as input the results $(b, c)$ of $T = O(\log |\mathcal{K}|) = O(\kappa)$ single-copy random Clifford measurements, uses the measurement results to estimate $\text{Tr}(O_k |\psi\rangle \langle \psi|)$ for each $k$ up to additive error $\frac{1}{3}$, and is correct with probability at least 0.999 + $|\mathcal{K}| \cdot e^{-2n/3}$. In particular, this algorithm can distinguish the pseudorandom ensemble from the Haar-random ensemble, by checking if there exists a $k$ such that the estimate for $\text{Tr}(O_k |\psi\rangle \langle \psi|)$ is at least $\frac{2}{3}$. Call this algorithm $\mathcal{C}$, so that $\text{Pr}[\mathcal{C}(b, c) = X] \geq 0.999$.

We will not actually use $\mathcal{C}$, but only its existence. By the optimality of the Bayes decision rule [Ber13, Chapter 4.4.1], because $\mathcal{C}$ uses $(b, c)$ to identify a state $|\psi\rangle$ as either Haar-random or pseudorandom with probability 0.999, an algorithm that computes the maximum a posteriori estimate of $X$ also succeeds with probability at least 0.999. In symbols, let $p_i = \text{Pr}[X = i \mid b, c]$, which we view as a random variable (depending on $b$ and $c$) for each $i \in \{0, 1\}$. Then $\text{Pr} \left[ \text{arg max}_i p_i = X \right] \geq 0.999$.

Next, observe that $\text{Pr} \left[ \text{arg max}_i p_i = X \right] = \mathbb{E} \left[ \text{Pr} \left[ \text{arg max}_i p_i = X \mid b, c \right] \right] = \mathbb{E} \left[ \text{max}_i p_i \right]$, by the law of total expectation. Hence, by Markov’s inequality (and the fact that $\frac{1}{2} \leq \text{max}_i p_i \leq 1$), we know that $\text{Pr} \left[ \text{max}_i p_i \geq \frac{3}{4} \right] \geq 0.996$. In other words, the Bayes decision rule is usually confident in its predictions, so to speak.

\footnote{Note that any promise problem in PostBQP is also in PP [Aar05], and any promise problem in PP can be extended to a language in PP because PP is a syntactic class. Hence, we might as well take a language in PP instead of a promise problem.}
Notice that $p_i$ equals the probability (conditioned on postselection succeeding) that $B$ outputs $i$ if it starts with $\rho$ in place of $\hat{\rho}$. For $i \in \{0,1\}$, define $\hat{p}_i$ analogously as the postselected output probabilities of $B$ itself: $\hat{p}_i = \Pr [B(b,c) = i \mid B(b,c) \in \{0,1\}]$. To argue that $A$ is correct with 0.995 probability, it suffices to show that $\Pr \left[ \max_i \hat{p}_i \geq \frac{2}{3} \wedge \arg \max_i \hat{p}_i = X \right] \geq 0.995$, as in this case the PostBQP promise is satisfied and the output of $L$ agrees with $X$. We have that:

$$\Pr \left[ \max_i \hat{p}_i \geq \frac{2}{3} \wedge \arg \max_i \hat{p}_i = X \right] \geq \Pr \left[ \max_i p_i \geq \frac{3}{4} \wedge \arg \max_i p_i = X \right]$$

$$\geq 1 - \Pr \left[ \max_i p_i < \frac{3}{4} \right] - \Pr \left[ \arg \max_i p_i \neq X \right]$$

$$\geq 0.996 - \Pr \left[ \arg \max_i p_i \neq X \right]$$

$$\geq 0.995$$

Above, the first inequality follows from the assumption that $S$ is a $\frac{1}{17}$-approximate $T$-design, because the acceptance probability of a postselected quantum algorithm can be viewed as the ratio of two probabilities:

$$\hat{p}_i = \frac{\Pr [B(b,c) = i]}{\Pr [B(b,c) \in \{0,1\}]}.$$

Fact 9 implies that both the numerator and denominator change by at most a multiplicative factor of $1 \pm \frac{1}{17}$ when switching between $\rho$ and $\hat{\rho}$. So, if $p_i \geq \frac{3}{4}$, then $\hat{p}_i \geq \frac{3}{4} \cdot \frac{15}{16} = \frac{45}{64}$. The second inequality follows by a union bound, and the remaining inequalities were established above.

We remark that the above theorem also holds relative to all oracles, in the sense that if the state generation algorithm $G$ in the definition of the PRS (Definition 14) queries a classical or quantum oracle $U$, then the corresponding ensemble of states can be distinguished from Haar-random by a polynomial-time quantum algorithm with a PostBQP$^U$ oracle.

## 4 Pseudorandomness from a Quantum Oracle

In this section, we construct a quantum oracle $(\mathcal{U}, \mathcal{P})$ relative to which BQP = QMA and PRUs exist.

### 4.1 BQP = QMA Relative to $(\mathcal{U}, \mathcal{P})$

We start with a lemma showing that the acceptance probability of a quantum query algorithm, viewed as a function of the unitary transformation used in the query, is Lipschitz.

**Lemma 18.** Let $A^U$ be quantum algorithm that makes $T$ queries to $U \in \mathcal{U}(D)$, and define $f(U) = \Pr [A^U = 1]$. Then $f$ is $2T$-Lipschitz in the Frobenius norm.

**Proof.** Suppose that $\|U - V\|_F \leq d$. By Lemma 6, this implies that the distance between $U$ and $V$ in the diamond norm is at most $2d$. The sub-additivity of the diamond norm under composition implies that as superoperators, $\|A^U - A^V\|_o \leq 2Td$. By the definition of the diamond norm, it must be the case that $|f(U) - f(V)| \leq 2Td$. ■

The next lemma extends Lemma 18 to QMA verifiers: we should think of $V$ as a QMA verifier that receives a witness $|\psi\rangle$, in which case this lemma states that the maximum acceptance probability of $V$ is Lipschitz with respect to the queried unitary.
Lemma 19. Let \( \mathcal{V}(\psi) \) be quantum algorithm that makes \( T \) queries to \( U \in \mathbb{U}(D) \) and takes as input a quantum state \( \psi \) on some fixed (but arbitrary) number of qubits. Define \( f(U) = \max_{|\psi\rangle} \Pr[\mathcal{V}(\psi) = 1] \). Then \( f \) is \( 2T \)-Lipschitz in the Frobenius norm.

**Proof.** Note that \( f \) is well-defined because of the extreme value theorem. Define \( f_\psi : \mathbb{U}(D) \to \mathbb{R} \) by:

\[
  f_\psi(U) = \Pr[\mathcal{V}(\psi) = 1],
\]

so that \( f(U) = \max_{|\psi\rangle} f_\psi(U) \). Lemma 18 implies that \( f_\psi \) is \( 2T \)-Lipschitz for every \( |\psi\rangle \). Let \( U, V \in \mathbb{U}(D) \), and suppose that \( |\psi\rangle \) and \( |\varphi\rangle \) are such that \( f(U) = f_\psi(U) \) and \( f(V) = f_\varphi(V) \). Then:

\[
  |f(U) - f(V)| = |f_\psi(U) - f_\varphi(V)|
  = \max\{f_\psi(U) - f_\varphi(V), f_\varphi(V) - f_\psi(U)\}
  \leq \max\{f_\psi(U) - f_\varphi(V), f_\varphi(V) - f_\psi(U)\}
  \leq 2T||U - V||_F,
\]

where the third line uses the fact that \( f_\psi(V) \leq f_\varphi(V) \) and \( f_\varphi(U) \leq f_\psi(U) \), and the last line uses the fact that \( f_\psi \) and \( f_\varphi \) are \( 2T \)-Lipschitz.

We are now ready to prove the first main result of this section, that \( \text{BQP}^{L, P} = \text{QMA}^{L, P} \).

**Theorem 20.** Let \( \mathcal{U} = \{\mathcal{U}_n\}_{n \in \mathbb{N}} \) be a quantum oracle where each \( \mathcal{U}_n \) is chosen randomly from \( \mu_n^{2^n} \). Let \( \mathcal{P} \) be an arbitrary \( \text{PSPACE} \)-complete language. Then with probability 1 over \( \mathcal{U} \), \( \text{BQP}^{L, P} = \text{QMA}^{L, P} \).

**Proof.** First, some notation. We view each \( \mathcal{U}_n \) alternatively as either a unitary transformation on \( 2n \) qubits, or as a list of \( 2^n \) different \( n \)-qubit unitary transformations \( \mathcal{U}_n = \{\mathcal{U}_{nm}\}_{m \in \{0,1\}^n} \) indexed by \( n \)-bit strings.

Let \( \mathcal{L} \in \text{QMA}^{L, P} \), which means that there exists a polynomial-time \( \text{QMA}^{L, P} \) verifier \( \mathcal{V}^{L, P}(x, |\psi\rangle) \) with completeness \( \frac{2}{3} \) and soundness \( \frac{1}{3} \). Without loss of generality, we can amplify the completeness and soundness probabilities of \( \mathcal{V} \) to \( \frac{11}{12} \) and \( \frac{11}{12} \), respectively. Let \( p(n) \) be a polynomial upper bound on the running time of \( \mathcal{V} \) on inputs of length \( n \).

We now describe a \( \text{BQP}^{L, P} \) machine \( \mathcal{A}^{L, P}(x) \) such that, with probability 1 over \( \mathcal{U} \), \( \mathcal{A} \) computes \( \mathcal{L} \) on all but finitely many inputs \( x \in \{0,1\}^* \). Let \( d = \lceil \log_2 \left( 13824 \cdot |p(|x|)|^2 + 2 \right) \rceil \). For each \( n \in [d] \), \( \mathcal{A} \) performs process tomography on each \( \mathcal{U}_n \), producing estimates \( \tilde{\mathcal{U}}_n \) such that \( \| \tilde{\mathcal{U}}_n \cdot \mathcal{U}_n - \mathcal{U}_n \cdot \tilde{\mathcal{U}}_n \|_1 \leq \frac{1}{12|p(|x|)|} \) for every \( n \), with probability at least \( \frac{2}{3} \) over the randomness of \( \mathcal{A} \). Let \( S \) be the algorithm from Lemma 8 that samples from a \( \frac{1}{12} \)-approximate unitary \( p(|x|) \)-design on \( n \) qubits, given as input a random seed \( r \leftarrow \{0,1\}^{k_n} \) where \( k_n = \text{poly}(n, |x|) \).

Consider a \( \text{QMA}^{P} \) verifier \( \mathcal{V}^{P}(x, |\psi\rangle) \) that simulates \( \mathcal{V}^{L, P}(x, |\psi\rangle) \) by replacing queries to \( \mathcal{U} \) as follows. For each \( n \in [d+1, p(|x|)] \), \( \mathcal{V} \) samples a function \( f_n : \{0,1\}^n \to \{0,1\}^{k_n} \) from a \( 2p(|x|) \)-wise independent function family. Then, for \( n \in [d] \), queries to \( \tilde{\mathcal{U}}_n \) are replaced by queries to \( \tilde{\mathcal{U}}_n \). For \( n \in [d+1, p(|x|)] \) and \( m \in \{0,1\}^n \), queries to \( \tilde{\mathcal{U}}_m \) are replaced by queries to \( S(f_n(m)) \) (i.e., the \( m \)th unitary in \( \mathcal{U}_n \) is replaced by an element of the \( p(|x|) \)-design, selected by \( f_n(m) \)).

Consider the \( \text{QMA}^{P} \) promise problem \( \tilde{\mathcal{L}} \) corresponding to \( \mathcal{V} \) with completeness \( \frac{2}{3} \) and soundness \( \frac{1}{3} \). Since \( \text{QMA}^A \subseteq \text{PSPACE}^A \) for all classical oracles \( A \), \( \tilde{\mathcal{L}} \in \text{PSPACE}^P = \text{PSPACE} \), so \( \mathcal{A} \) can decide \( \tilde{\mathcal{L}}(x) \) with a single query to \( \mathcal{P} \). \( \mathcal{A} \) does this, and outputs \( \tilde{\mathcal{L}}(x) \).

We now argue that for any \( x \), with high probability over \( \mathcal{U} \), \( \Pr[\mathcal{A}^{L, P}(x) = \mathcal{L}(x)] \geq \frac{2}{3} \). It will be convenient to define several hybrid verifiers:

\[ ^6 \text{There are many ways to accomplish this. For instance, one can use the Choi-Jamiołkowski isomorphism and quantum state tomography [OW16] to estimate the Choi state of } \mathcal{U}_n \text{ to inverse polynomial (in } 2^n \text{) error in trace distance. The estimated unitary transformation } \mathcal{U}_n \text{ can then be compiled to a circuit using } 2^{O(n)} 1- \text{ and } 2\text{-qubit gates [VMS04]. Since } n \leq d = O(\log |x|), \text{this can be done in polynomial time.} \]
• $V_1 = \mathcal{V}$.

• $V_2$: For each $n \in [d + 1, p(|x|)]$, chooses a matrix $U_n \leftarrow \mu_{2^n}^2$. Simulates $V_1$, replacing queries to $U_n$ by $U_n$ for $n \in [d + 1, p(|x|)]$.

• $V_3$: For each $n \in [d + 1, p(|x|)]$, samples a function $g_n : \{0, 1\}^n \rightarrow \{0, 1\}^k$ uniformly at random. Simulates $V_2$, replacing queries to $U_{nm}$ by by queries to $\mathcal{S}(g_n(m))$ for $n \in [d + 1, p(|x|)]$ and $m \in \{0, 1\}^n$.

• $V_4$: For each $n \in [d + 1, p(|x|)]$, samples a function $f_n : \{0, 1\}^n \rightarrow \{0, 1\}^k$ from a 2$p(|x|)$-wise independent function family. Simulates $V_3$, replacing queries to $g_n$ by $f_n$.

• $V_5$: Simulates $V_4$, replacing queries to $\tilde{U}_n$ by queries to $\tilde{U}_n$ for $n \in [d]$. Note that $V_5$ and $\hat{V}$ are equivalent, and that of these hybrids, $V_5$ is the only one whose output depends on the randomness of $\mathcal{A}$ (by way of $\tilde{U}_n$).

For $i \in [5]$ and a fixed choice of $\mathcal{U}$, define:

$$\text{acc}(V_i) = \max_{\psi} \Pr[V_i(x, \psi) = 1],$$

which is well defined by the extreme value theorem. We now bound $|\text{acc}(V_i) - \text{acc}(V_{i-1})|$ for various $i$:

• By Lemma 19, because $\mathcal{V}$ makes at most $p(|x|)$ queries, we know that $\text{acc}(V_1)$, viewed as a function of $(\mathcal{U}_{d+1}, \mathcal{U}_{d+2}, \ldots, \mathcal{U}_{p(|x|)})$, is $2p(|x|)$-Lipschitz in the Frobenius norm. Hence, by Theorem 11 with $N = 13824|x|p(|x|)^2 + 2$, $L = 2p(|x|)$, and $t = \frac{1}{12}$, we have that:

$$\Pr_{\mathcal{U}} \left[ |\text{acc}(V_1) - \text{acc}(V_2)| \geq \frac{1}{12} \right] \leq 2 \exp \left( -\frac{(N - 2)t^2}{24L^2} \right) = 2 \exp \left( -\frac{13824|x|p(|x|)^2 \cdot \frac{1}{12}}{96p(|x|)^2} \right) = 2e^{-|x|}.$$

The factor of 2 appears because Theorem 11 applies to one-sided error, but the absolute value forces us to consider two-sided error.

• Fact 10 and the assumption that $\mathcal{S}$ samples from a $\frac{1}{12}$-approximate unitary $p(|x|)$-design implies that for any fixed $|\psi\rangle$, $|\Pr[V_2(x, |\psi\rangle) = 1] - \Pr[V_3(x, |\psi\rangle) = 1]| \leq \frac{1}{12}$. This in turn implies that $|\text{acc}(V_2) - \text{acc}(V_3)| \leq \frac{1}{12}$.

• Zhandry [Zha12, Theorem 6.1] shows that a quantum algorithm that makes $T$ queries to a random function can be exactly simulated by the same algorithm with $T$ queries to a $2T$-wise independent function, so $\text{acc}(V_5) = \text{acc}(V_4)$.

• Because $||\tilde{U}_n \cdot \tilde{U}_n^\dagger - \mathcal{U}_n \cdot \mathcal{U}_n^\dagger||_\infty \leq \frac{1}{12p(|x|)}$ for each $n \in [d]$ with probability at least $\frac{2}{3}$ over $\mathcal{A}$, from the definition of the diamond norm [AKN98] and because $\mathcal{V}$ makes at most $p(|x|)$ queries, it holds that $\Pr_{\mathcal{A}}[|\text{acc}(V_4) - \text{acc}(V_5)| \geq \frac{1}{12}] \leq \frac{1}{3}$.

Putting these bounds together, we have that, except with probability $2e^{-|x|}$ over $\mathcal{U}$:

$$\mathcal{L}(x) = 1 \implies \Pr_{\mathcal{A}} \left[ \max_{\psi} \Pr[\hat{V}(x, |\psi\rangle) = 1] \geq \frac{2}{3} \right] \geq \frac{2}{3},$$

$$\mathcal{L}(x) = 0 \implies \Pr_{\mathcal{A}} \left[ \max_{\psi} \Pr[\hat{V}(x, |\psi\rangle) = 1] \leq \frac{1}{3} \right] \geq \frac{2}{3}.$$
This is to say that $\mathcal{A}$ correctly decides $\mathcal{L}(x)$, expect with probability at most $2e^{-|x|}$ over $\mathcal{U}$. By the Borel-Cantelli Lemma, because $\sum_{i=1}^{\infty} 2^{-i} = \frac{1}{e} < \infty$, $\mathcal{A}$ correctly decides $\mathcal{L}(x)$ for all but finitely many $x \in \{0,1\}^*$, with probability 1 over $\mathcal{U}$. Hence, with probability 1 over $\mathcal{U}$, $\mathcal{A}$ can be modified into an algorithm $\mathcal{A}'$ that agrees with $\mathcal{L}$ on every $x \in \{0,1\}^*$, by simply hard-coding those $x$ on which $\mathcal{A}$ and $\mathcal{L}$ disagree.

Because there are only countably many QMA$^{U,P}$ machines, we can union bound over all $\mathcal{L} \in \text{QMA}^{U,P}$ to conclude that $\text{QMA}^{U,P} \subseteq \text{BQP}^{U,P}$ with probability 1 over $\mathcal{U}$. ■

4.2 PRUs Relative to $(\mathcal{U}, \mathcal{P})$

We proceed to the second part of the oracle construction, showing that PRUs exist relative to $(\mathcal{U}, \mathcal{P})$. We begin with a lemma establishing that the average advantage of a polynomial-time adversary is small against our PRU construction. Here, we should think of $\{U_k\}_{k \in [N]}$ as the PRU ensemble.

**Lemma 21.** Consider a quantum algorithm $\mathcal{A}^{O,U}$ that makes $T$ queries to $O \in \mathcal{U}(D)$ and $U = (U_1, \ldots, U_N) \in \mathcal{U}(D)^N$. For fixed $U$, define:

$$\text{adv}(A^U) := \Pr_{k \leftarrow [N]} [A^{U_k,U} = 1] - \Pr_{O \leftarrow \mu_D} [A^{O,U} = 1].$$

Then there exists a universal constant $c > 0$ such that:

$$\mathbb{E}_{U \leftarrow \mu_D^N} [\text{adv}(A^U)] \leq \frac{cT^2}{N}.$$

**Proof.** Our strategy is to reduce to the quantum query lower bound for unstructured search. Intuitively, if $\mathcal{A}$ could identify whether $O \in \{U_1, \ldots, U_N\}$ or not, then $\mathcal{A}$ could be modified into a quantum algorithm $\mathcal{B}$ that finds a single marked item from a list of size $N$. Then the BBBV theorem [BBBV97] forces $T$ to be $\Omega(\sqrt{N})$.

More formally, we construct an algorithm $\mathcal{B}(x)$ that queries a string $x \in \{0,1\}^N$ as follows. $\mathcal{B}$ draws a unitary $V = (V_0, V_1, \ldots, V_N) \in \mathcal{U}(D)^{N+1}$ from $\mu_D^{N+1}$. Then, $\mathcal{B}$ runs $\mathcal{A}$, replacing queries to $O$ by queries to $V_0$, and replacing queries to $U_k \in U$ by $V_0$ if $x_k = 1$ and by $V_k$ if $x_k = 0$.

Let $e_k \in \{0,1\}^N$ be the string with 1 in the $k$th position and 0s everywhere else. We have that:

$$\mathbb{E}_{U \leftarrow \mu_D^N} [\text{adv}(A^U)] = \mathbb{E}_{U \leftarrow \mu_D^N} \left[ \Pr_{k \leftarrow [N]} [A^{U_k,U} = 1] \right] - \mathbb{E}_{U \leftarrow \mu_D^N} \left[ \Pr_{O \leftarrow \mu_D} [A^{O,U} = 1] \right]$$

$$= \Pr_{k \leftarrow [N]} [B(e_k) = 1] - \Pr [B(0^N) = 1]$$

$$\leq \frac{cT^2}{N}.$$

Above, the first line applies linearity of expectation, the second line holds by definition of $\mathcal{B}$, and the third line holds for some universal $c$ by the BBBV theorem [BBBV97]. ■

The next lemma uses Lemma 21 to show that the advantage of $\mathcal{A}$ is small with extremely high probability, which follows from the strong concentration properties of the Haar measure (Theorem 11).

**Lemma 22.** Consider a quantum algorithm $\mathcal{A}^{O,U}$ that makes $T$ queries to $O \in \mathcal{U}(D)$ and $U = (U_1, \ldots, U_N) \in \mathcal{U}(D)^N$. Let $\text{adv}(A^U)$ be defined as in Lemma 22. Then there exists a universal constant $c > 0$ such that for any $p$,

$$\Pr_{U \leftarrow \mu_D^N} [\text{adv}(A^U) \geq p] \leq 2 \exp \left( -\frac{(D-2)(p-cT^2/N)^2}{384T^2} \right).$$

15
Proof. By Lemma 18, $\text{adv}(A^U)$ is $4T$-Lipschitz as a function of $U$, because $\text{adv}(A^U)$ can be expressed as the difference between the acceptance probabilities of two algorithms that each make $T$ queries to $U$. Combining Lemma 21 and Theorem 11, we obtain:

$$\Pr_{U \leftarrow \mu^N_D}[\text{adv}(A^U) \geq p] \leq \exp\left(-\frac{(D - 2) (p - \epsilon T^2/N)^2}{384T^2}\right).$$

Similar reasoning yields the same upper bound on $\Pr_{U \leftarrow \mu^N_D}[\text{adv}(A^U) \leq -p]$, so we get the final bound (with an additional factor of 2) by a union bound.

Completing the security proof of the PRU construction amounts to combining Lemma 22 with a union bound over all possible polynomial-time adversaries.

**Theorem 23.** Let $U = \{U_n\}_{n \in \mathbb{N}}$ be a quantum oracle where each $U_n$ is chosen randomly from $\mu^{2^n}_2$. Let $P$ be an arbitrary PSPACE-complete language. Then with probability 1 over $U$, there exists a family of PRUs relative to $(U, P)$.

**Proof.** Fix an input length $n \in \mathbb{N}$. We take the key set $K = [2^n]$ and take the PRU family to be $\{U_k\}_{k \in K}$, where $U_n = (U_1, U_2, \ldots, U_{2^n}) \in \mathbb{U}(2^n)^{2^n}$. In words, the family consists of the $2^n$ different Haar-random $n$-qubit unitaries specified by $U_n$.

Without loss of generality, assume the adversary is a uniform polynomial-time quantum algorithm $A^{O,\mathcal{U},P}(1^n, x)$, where $x \in \{0, 1\}^{\text{poly}(n)}$ is the advice and $O \in \mathbb{U}(2^n)$ is the oracle that the adversary seeks to distinguish as pseudorandom or Haar-random.

By Lemma 22 with $N = D = 2^n$ and $T = \text{poly}(n)$, for any fixed $x \in \{0, 1\}^{\text{poly}(n)}$, $A^{O,\mathcal{U},P}(1^n, x)$ achieves non-negligible advantage with extremely low probability over $U$. This is to say that for any $p = \frac{1}{\text{poly}(n)}$:

$$\Pr_{U_n \leftarrow \mu^{2^n}_2}[\Pr_{k \leftarrow [2^n]}[A^{U_k,\mathcal{U},P}(1^n, x) = 1] - \Pr_{O \leftarrow \mu^{2^n}_2}[A^{O,\mathcal{U},P}(1^n, x) = 1] \geq p] \leq \exp\left(-\frac{2^n}{\text{poly}(n)}\right).$$

By a union bound over all $x \in \{0, 1\}^{\text{poly}(n)}$, $A^{O,\mathcal{U},P}(1^n, x)$ achieves advantage larger than $p$ for any $x \in \{0, 1\}^{\text{poly}(n)}$ with probability at most $2^{\text{poly}(n)} \cdot \exp\left(-\frac{2^n}{\text{poly}(n)}\right) \leq \text{negl}(n)$. Hence, by the Borel-Cantelli lemma, $A$ achieves negligible advantage for all but finitely many input lengths $n \in \mathbb{N}$ with probability 1 over $U$, as $\sum_{n=1}^{\infty} \text{negl}(n) < \infty$. This is to say that $\{U_k\}_{k \in K}$ defines a PRU ensemble.

We expect that using the techniques of Chung, Guo, Liu, and Qian [CGLQ20], one can extend Theorem 23 to a security proof against adversaries with quantum advice. Some version of [CGLQ20, Theorem 5.14] likely suffices. The idea is that breaking the PRU should remain hard even if $A$ could query an explicit description of $O$ and explicit descriptions of $U_k$ for $k \in [2^n]$, which is a strictly more powerful model. But then this corresponds to the security game defined in [CGLQ20, Definition 5.12], except that the range of the random oracle is $U(D)$ rather than the finite set $[M]$.

**Acknowledgements**

Thanks to Scott Aaronson for suggestions on the writing, Adam Bouland for insightful discussions, and Qipeng Liu for clarifying some questions about [CGLQ20].
References

In this section, we sketch a proof that a PRS construction proposed by Ji, Liu, and Song [JLS18] and shown secure by Brakerski and Shmueli [BS19] can be broken efficiently with an NP oracle. The PRS family is based on pseudorandom functions (PRFs). Let \( \{f_k\}_{k \in K} \) be a PRF family of functions \( f_k : \{0,1\}^n \rightarrow \{0,1\} \) keyed by \( K \). The corresponding PRS family is the set of states \( \{|\varphi_k\rangle\}_k \) given by:

\[
|\varphi_k\rangle = \frac{1}{2^{n/2}} \sum_{x \in \{0,1\}^n} (-1)^{f_k(x)} |x\rangle.
\]

For simplicity, suppose that each \( f_k \) is balanced, meaning that \( |f_k^{-1}(0)| = |f_k^{-1}(1)| = 2^{n-1} \). Consider the quantum circuit below:

```
|0\rangle \rightarrow H
|\psi\rangle \rightarrow H^{\otimes n} \oplus H^{\otimes n}
|0^{\otimes n}\rangle \rightarrow H^{\otimes n}
```

Observe that if \( |\psi\rangle = |\varphi_k\rangle \), then this circuit produces the state \( |0\rangle |\varphi_k\rangle^{\otimes n} + |+\rangle^{\otimes n} |\varphi_k\rangle \) from a single copy of \( |\varphi_k\rangle \). Notice that if we measure the resulting state in the computational basis, then we observe \( |0\rangle |x\rangle |y\rangle \) with nonzero probability for \( x, y \in \{0,1\}^n \) if and only if \( f_k(x) = f_k(y) \). This is because the amplitude on this basis state is given by:

\[
\langle x | \langle y | |\varphi_k\rangle |+\rangle^{\otimes n} + |+\rangle^{\otimes n} |\varphi_k\rangle \sqrt{2} = \frac{(-1)^{f_k(x)} + (-1)^{f_k(y)}}{2^n \sqrt{2}}.
\]

Furthermore, this shows that we in fact sample a uniformly random pair \( (x, y) \) such that \( f_k(x) = f_k(y) \).
Suppose that given a state $|\psi\rangle$ which is either pseudorandom or Haar-random, we repeat this procedure $\text{poly}(n)$ times to obtain a list of pairs $\{(x_i, y_i)\}$. It is an NP problem to decide whether there exists a $k$ such that $f_k(x_i) = f_k(y_i)$ for all $i$. If $|\psi\rangle = |\varphi_k\rangle$ for some $k$ then this NP language always returns true, while if $|\psi\rangle$ is Haar-random, this NP language returns true with negligible probability, so long as we take sufficiently many samples $(x_i, y_i)$.

In the case where $f_k$ is not perfectly balanced, we simply observe that the above procedure still works with good probability so long as $f_k$ is close to a balanced function. But PRFs must be close to balanced functions, in the sense that for most $k \in \mathcal{K}$, it must be possible to change a $\negl(n)$ fraction of the outputs of $f_k$ to turn it into a balanced function. Otherwise, the PRF family could be distinguished efficiently from random functions, which are $\negl(n)$-close to balanced with high probability.
