Industrial processes rely on sensory data for decision-making processes, risk assessment, and performance evaluation. Extracting actionable insights from the collected data calls for an infrastructure that can ensure the dissemination of trustworthy data. For the physical data to be trustworthy, it needs to be cross-validated through multiple sensor sources with overlapping fields of view. Cross-validated data can then be stored on blockchain, to maintain its integrity and trustworthiness. Once trustworthy data is recorded on the blockchain, product lifecycle events can be fed into data-driven systems for process monitoring, diagnostics, and optimized control. In this regard, Digital Twins (DTs) can be leveraged in industry to draw intelligent conclusions from data by identifying the faults and recommending precautionary measures ahead of critical events.

Empowering DTs with blockchain in industrial use-cases targets key challenges of disparate data repositories, untrustworthy data dissemination, and the need for predictive maintenance. In this survey, while highlighting the key benefits of using blockchain-based DTs, we present a comprehensive review of the state-of-the-art research results for blockchain-based DTs. Based on the current research trends, we discuss in detail a framework for trustworthy blockchain-based DTs. Furthermore, we also discuss current and future research and deployment challenges along with essential measures that must be taken by the blockchain-based DTs.

CCS Concepts: • General and reference → Surveys and overviews; • Security and privacy → Distributed systems security.

Additional Key Words and Phrases: Artificial Intelligence (AI), Blockchain, Digital Twins (DTs), Internet of Things (IoT), Industry 4.0

1 INTRODUCTION

Traditional Industrial Control Systems (ICS) include operational technology (OT) such as supervisory control and data acquisition (SCADA) systems, programmable logic controllers (PLCs), and other field devices that are able to command and control physical processes within industrial environments [15]. In the course of Industry 4.0, this industrial infrastructure is increasingly integrated with general-purpose Information Technology (IT) systems by wireless connections with cost-effective miniaturized devices having sensing, computation, and communication capabilities to collect, process, analyze, and interpret data. Whereas integrating IT and OT systems provides promising solutions in a plethora of ubiquitous industrial ecosystems, it introduces novel attack vectors. Loopholes in the system infrastructure lure adversaries to launch different attacks; for instance, denial of participation, false data injection, data forging, and replay attacks, to name a few [81]. Such attacks can have catastrophic consequences for the high-assurance applications that are involved in crucial decision-making processes based on sensor data [59]. Thus, to provide protection against data forgery, potential countermeasures for data security highlight the need for rigorous scrutiny to thwart vulnerabilities, enforce verifiable capabilities, and ensure integrity.

Considering the involvement of multiple entangled participating entities in intricate industrial processes, the overarching question is: How to ensure the trustworthiness of data collated from disparate data repositories? In this regard, blockchain technology gained ground to address challenging issues in the industry with regard to product lifecycle data management and data security [79]. Utilizing blockchain allows industries to manage data on a shared distributed ledger to solve important glitches in traceability, and record events in a secure, immutable, and irrevocable way [14]. Relying on the trustworthy data from the blockchain and inputting the retrieved data to a data-driven system to draw intelligent information can certainly open ways for the industries that consider several factors for maximizing their revenues, such as risk prognosis, cost management, and quality assurance [80].

For predictive maintenance, one of the promising solutions is to create a digital fingerprint (or virtual replica) of the underlying product, process, or service. Such a replica can be used to analyze, predict, and optimize all operations before carrying out its real-world implementation. Following a closed-loop, the simulation data are fed back to the physical object to calibrate the operations and to enhance the system performance. Such a bi-directional mapping between physical space and virtual space is called Digital Twin (DT) [82]. As physical assets begin to operate, DTs collect and integrate data from multiple sources, such as sensor data from factory floor, historical production data acquired from product lifecycle data, and domain knowledge to generate comprehensive data in the form of models, simulations, replications, or behavioral analytics. During industrial processes, DTs run synchronously with their physical counterparts where the primary objective is to track and trace data inconsistencies between the physical and virtual objects. Data inconsistencies between the physical object and virtual object call for the adoption of better calibration and testing strategies that evolve DT models and physical counterparts to support problem-solving in manufacturing, more accurate estimation, prediction, and optimization of the industrial processes [85].

Combining DTs and blockchain can reshape the industry such that blockchain ensures secure data management and DTs use trustworthy data as input to extract actionable insights for predictive maintenance. For instance, in a manufacturing plant for asset management, on the one hand, upon utilizing a trust architecture (such as [13]) for sensor data cross-validation, trustworthy key threshold data from the sensors and actuators (affixed with equipment) can be stored and retrieved from the blockchain and can be used to detect trends (such as excessive vibration or heat) to avoid failures or operator injury. On the other hand, through DTs, maintenance and operations personnel can acquire more thorough and accurate insight into asset performance based on the analytics and cognitive data generated on the factory floor. Also, other regulators and suppliers of plant...
equipment can monitor the data logged at blockchain for preventive maintenance, conduct timely inspections to ensure equipment reliability in addition to record their work or analysis on the blockchain ledger [53].

1.1 Existing Surveys

To the best of our knowledge, no survey has been conducted that thoroughly investigates design and implementation issues in blockchain-based DTs. However, some of the recent work emphasized the integration of blockchains for DTs. Starting with the most relevant paper, in [91], the authors taxonomize DTs while providing insights into DTs levels, design phases, enabling technologies, and their potential in core applications. The authors explore the benefits of using blockchains for DTs and discuss DTs synergies and case studies for the automobile industry including Genie, Volvo, and Volkswagen. This study outline technical and social barriers and identify open issues to the adoption of blockchain in DTs, for instance, scalability, data privacy, limitations due to resource-constrained devices, and interoperability issues due to heterogeneous consensus models, transaction schemes, and smart contracts. Also, it outlines security features such as confidentiality and integrity to protect DTs design and operational information, however does not consider other security-related design details such as access control and quantum immunity. A more recent theoretical work [68] covers applications and benefits of DTs in different industry verticals including manufacturing, automotive, logistics, utilities, aircraft, and healthcare. The focal point of this work is to create blockchain-based DTs to facilitate digital identity and data tracking through blockchain traceability. Besides, it also highlights other features of blockchain including decentralization, safe and secure data transfer, data immutability, authentication of users and data sources in connection with DTs industrial use cases. Despite providing a succinct overview of the blockchain-based DTs, these works do not cover the existing literature on blockchain-based DTs approaches.

In [28], the authors explore the interoperability and integrability of blockchains and DTs for asset life cycle management. They proposed a model of the blockchain-based DT framework based on surveys of existing literature and questionnaire to industry professionals and mapping of technological use cases for DTs, IoT, blockchains, and smart contracts. This work also outlines integration constraints of blockchain-based DTs with possible solutions. For instance, focus on separable blockchains for easy troubleshooting and combating errors arising during scaling networks and collaboration of the different system areas. Nevertheless, the paper does not survey works on blockchain-based DTs in particular. Similarly, a blockchain-oriented work [48] focuses more on the role of blockchain in manufacturing with fewer insights into DTs, whereas a DT-oriented study [71] merely touches blockchain technology as a key to solve trust in information issues.

By narrowing down our survey to blockchain-based DTs featuring industrial use cases and focusing on more high-level issues, we present a holistic approach towards blockchains for DTs while presenting design components, fusion with enabling technologies, benefits, and challenges. Furthermore, we also cover existing works based on proposed design and development strategies through a survey of blockchain-based DTs.

1.2 Scope of This Survey

In this survey, we present a thoroughly comprehensive, and systematic review of state-of-the-art results for blockchain-based DTs. We also focus on blockchain-based DTs design and implementation issues in detail and provide possible solutions to address such issues. Additionally, we investigate technical, logistical, and social issues that arise due to the integration of blockchain with DTs and must be addressed by stakeholders. We summarize the main contributions of this paper below:

- We present an in-depth comprehensive and systematic review of the state-of-the-art blockchain-based DTs approaches covering design and implementation issues in terms of blockchain, DTs, and security.
- Based on the limitations of the current works, we propose a framework for trustworthy blockchain-based DTs.
In addition to ongoing standardization efforts, we provide an in-depth review of various research challenges such as technical, logistical, and social challenges. In contrast to existing surveys, we also map such requirements from both blockchain and DTs perspectives, provide pragmatic approaches for the adoption of blockchain-based DTs, and highlight the open-ended challenges that need to be addressed by the industry and research community.

The rest of the paper is organized as follows: Section 2 covers a quick high-level overview of DTs, blockchain, and the major benefits of using blockchain for DTs. Considering blockchain, DTs, and security as the key factors, we present the design and implementation details of existing research in Section 3. Section 4 discusses the role of enabling technologies in blockchain-based DTs. Section 5 describes the technical, logistical, and social challenges and requirements of blockchain-based DTs. Finally, Section 6 concludes the paper.

2 BACKGROUND

This section outlines the necessary background information for this survey. We first provide the main design components and applications of DTs in the industry followed by a discussion on blockchain and its role in ensuring secure data management in the industry.

2.1 Digital Twins

The concept of DT was first introduced by Micheal Grieves in 2003 during his course on Product Lifecycle Management (PLM). In 2012, the National Aeronautics and Space Administration (NASA) formalized the definition of DTs as an integrated multi-physics, multi-scale, probabilistic simulation mirroring the physical system based on models, sensors, history data, etc. [27] in the field of the aerospace industry. In 2014, Grieves' white paper [29] proposed a preliminary form of a three-dimensional (3D) DT model that includes a physical space containing a physical entity, a virtual space containing a virtual entity, and a connection to allow synchronization of data between both spaces (as shown in Fig. 1). In continuation of the role of DTs in the aviation industry, DTs lead to the notion of Airframe Digital Twin (ADT) for predicting the life of aircraft structure and maintenance needs [88]. In parallel, continuous advances in DT enabling technologies, for instance, IoT, big data processing techniques, cloud computing, and Artificial Intelligence (AI) further motivate the adoption of DTs beyond the aerospace industry and thus are promoted in numerous applications including manufacturing, supply chain, smart cities, industrial IoT, servitization, healthcare, etc. According to Gartner's survey report, 13% of enterprises are already using DTs, whereas 62% are in the process of deploying DTs [26].

Based on the Grieves’ 3D DT model, Tao et al. proposed a five-dimensional (5D) model that includes: physical space, virtual space, connection, DT data, and service (as shown in Fig. 2) [86]. The physical part supports the virtual part through assets data while the virtual part controls the physical part through simulation and decision-making. Service supports the management of both spaces during operation, evolution, and optimization. DT data repository acts as a primary source for knowledge creation and connection bridges all parts of the DT model.

The data-driven DTs focus on the areas of product design, production, manufacturing, operational control, Prognostic Health Management (PHM), etc. in the industrial domain [84]. For instance, DTs enable more accurate
predictions, rational decisions, and informed plans by reinforcing the collaboration between design and manufacturing phases. PHM plays a significant role in the lifecycle monitoring of equipment conditions where a DT of the equipment supported by data is used to depict the erratic behavior of the physical object, perform fault diagnosis, and provide design rules for maintenance [25]. Similarly, dispatching optimization and operational control are among other promising application areas of DTs [84]. Industry leaders including International Business Machines Corporation (IBM), Siemens, General Electric (GE), Microsoft Azure, Airbus, Systems, Applications and Products in Data Processing (SAPSE) have deployed DTs in various industrial application areas.

2.2 Blockchain

The emerging technology of blockchain has attracted immense attention from academics and practitioners in diverse disciplines including finance, law, and computer science due to its promising secure distributed framework that facilitates sharing and synchronization of information across all participating entities [65]. In the blockchain, transactions among nodes serve as the basic communication primitives that are recorded as append-only time-stamped logs in a shared digital ledger. To establish a secure trusted network among untrusted nodes, a consensus mechanism is employed that involves solving a resource-demanding hard-to-solve and easy-to-verify cryptographic puzzle. Following the consensus algorithm, transactions are collated to form a block which is then appended to the ledger. To enforce immutability in blockchain structure, each block contains the hash of the previous block, thereby can readily detect tampering to a block and hence transactions.

The rapid adoption of blockchain has largely been spurred by the success of Bitcoin (the first prototype of cryptocurrency) [58] and successfully replaced economic transaction systems in many organizations. Other alternatives (Ethereum and Ripple) continue to mature, thus proving to be a highly disruptive force in finance and e-commerce sectors [31]. Later on, numerous non-monetary application scenarios are identified as potential candidates of blockchain-based solutions, for instance, intellectual property, proof of location, voting, healthcare, to name a few. Recently, blockchain-based solutions in combination with IoT are gaining ground to revamp heterogeneous business models (such as Business to Business (B2B) and Business to Consumer (B2C)) in a variety of industrial sectors, including supply chain and manufacturing plant asset management [53].
2.3 Major Benefits of Using Blockchain-based Digital Twins in Industry

As DTs offer assets and products analysis even before their actual manufacture, they also help in reducing the maintenance cost by tracking the lifecycle of an asset in past and present to take decisive actions for the future. Although DTs enable the realization of futuristic services and applications in a transparent and efficient way, these benefits of DT are based on an assumption about data trust, integrity, and security. Nevertheless, in real-life scenarios, data breaches could occur due to a number of reasons, both malicious and otherwise. Therefore, to fully harness the features of DT, the data used by the DT should be trustworthy and secure. It is also worth noting that Digital Twin Instance (DTI) is a singular entity that mirrors the physical asset and/or activity, whereas Digital Twin Aggregate (DTA) is the combination of DTIs (preferably similar DTIs) to mimic the bigger picture of the physical world. [68] rightly pointed out that the breach in DTA will have far worst consequences than a breach in DTI because a breach in DTI will affect one instance (of a product) whereas a breach in DTA might expose the whole product line. Therefore, it is essential to circumvent the issues related to data breaches as well as data integrity and trust. Wust et al. [90] critically analyzed the need for blockchain in different sectors and designed a framework that helps to assess whether or not the blockchain is needed for a particular use-case. The main elements of the assessments are the number of readers/writers of the data, presence of a trusted third party, identification of readers/writers, and nature of verifiability of the exchanged data. According to the model of Wust et al. [90], a permissioned blockchain can be the right candidate for DT to cope with these issues because of, but not limited to, the cryptographic primitives of blockchain guarantee data immutability and the consensus mechanism of the blockchain (where different stakeholders of the data come to a common consensus while managing the data) provides transparency and accountability. Therefore, in the case of the digital twins in the industry, different stakeholders can share the data and the transactions of the data sharing can be stored on the blockchain. In light of the above arguments, a permissioned blockchain has innate potential to integrate with DT for data trust and security in the industry. In the following, we discuss the key benefits of using blockchain-based DTs. The benefits are summarized in Fig. 3.
2.3.1 Distributed Infrastructure. To establish a distributed data storage, a tamper-proof and immutable blockchain can be leveraged to procure distributed data across multiple participating entities. To do so, not only the DTs’ data but data from other sources (such as data generated within the production facility or during the supply chain trade events), provenance data, etc. flowing across multiple tiers or entities are stored and accessed through blockchain ledger [79].

2.3.2 Secure Digital Twins Data. The immutable nature of blockchain keeps the history of DTs transactions, thus providing integrity of DTs [66]. The use of pseudonyms, such as public keys for representing node identities, for blockchain transactions can support the coexistence of transparency and privacy. Nodes can maintain multiple pseudonyms to remain anonymous, to enable confidential data flows, and to cope with industrial espionage for competitive advantage.

2.3.3 Data Traceability in Digital Twins. Integrating DTs with blockchain solves the key issues, i.e., disparate data repositories and untrustworthy data dissemination. Additionally, provenance-enabled blockchain-based DTs can reason about the current state of a data object such as why, where, and how throughout the process chain [79]. The complete lineage of DTs ranging from their origin to the present can be accessed to identify the cause of deviations between the physical and digital space in addition to data assessment (such as data debugging, reconciliation, performance tuning, auditing, etc.).

2.3.4 Fine-grained Access Control. Depending on the architecture of blockchain, the data on the blockchain can usually be viewed by anyone (in the case of public blockchain). However, in the case of the enterprise industry, both reading the data and the changes and modifications to the data must be subject to access rights. This argument can be true for DT as well where the data can be viewed by the selected set of entities and the modifications must be done by only authorized entities. In other words, individuals with the correct access rights should be allowed to perform their authorized actions. In essence, blockchain inherently retains the history of modifications and thus can circumvent the problem of illegal data modification that may lead to other data-related problems. We also note that in the case of industrial applications, we assume the presence of a consortium blockchain (based on the underlying industry requirements). The integration of blockchain with DT and the cryptographic strength of the blockchain will enable fine-grained access control in DTs.

2.3.5 Combating the Problem of Counterfeits. Skilled counterfeiting is one of the daunting challenges in the industry. Technology is a double-edged sword where on one hand, it enables the realization of new products. On the other hand, it also gives an edge to fraudsters to create counterfeit products that are near-replicas of the original products. This scenario does not only affect the investment of the industry stakeholders but also badly affects the brand value and reputation of the products. To overcome this challenge, the combination of blockchain and DT can ensure that counterfeit products are identified by providing product authenticity. More precisely, the transparency will come from the blockchain (for instance creating digital certificates on the blockchain) whereas the digitization of the products and assets will be guaranteed by the DT. Several start-ups are currently providing such services, for instance, LuxTag ¹ provides the digital notarization and ownership of products through blockchain that will aid in achieving the mitigation of counterfeits. Therefore, the integration of DT and blockchain will play a pivotal role in ensuring the Return on Investment (RoI) for the industry by removing the problem of counterfeits. Additionally, blockchain-based solutions for DTs can provide verifiable digital certificates to solve important glitches regarding the legitimacy of DTs by identifying counterfeiters attempting to imitate or distribute fake replicas of DTs [68].

3 BLOCKCHAIN-BASED DIGITAL TWINS: RESEARCH TRENDS

In this section, we review the existing works that focus on the design and implementation aspects of blockchain-based DTs. To discuss the existing works, we choose manifold criteria that cover different design aspects related to DTs, blockchain, and security. In addition to discussion on current solutions, we also emphasize challenges that are yet to be addressed. Furthermore, we provide a detailed discussion on a trustworthy blockchain-based DT that tries to address some of the outstanding challenges in the existing works. Fig. 4 shows the research trends of exploring the integration of blockchain with DTs by the research community. It can be clearly seen from Fig. 4 that there is an increased interest in the integration of blockchain with DT. Table 1 comprehensively summarizes relevant recent works on blockchain-based DTs. This table shows three main interesting design considerations for DT, blockchain, and security from the blockchain-based DT literature. Firstly, it covers DT-related design details including DT definition, component composability and integration, lifecycle phases, and implementation aspects. Secondly, it outlines blockchain-related design details including the type of blockchain in the proposed solution, implementation aspects, off-line data storage mechanism, traceability, and trustworthy data sources. Thirdly, it highlights the security-related design details including encryption, access control, and quantum resilience. In the following, we discuss each of them in detail.

3.1 Design Solutions for Digital Twins

The majority of existing works consider DTs as a representation of any asset, product, machine, or manufacturing events. However, the existing works do not cover the integration and interoperability of multiple components or sub-components to provide an aggregated view of the complex physical system. As a result, the lack of correlation among different elementary DTs leads to the failure of abstract views of larger phenomena. In the following, we discuss the design solutions for DTs from different perspectives such as design lifecycle, fusion and interoperability, security and safety, and synchronization and consistency. These are the cornerstones of DT design and we discuss both the existing works in these directions and the outstanding challenges.

3.1.1 Digital Twin Lifecycle. The lifecycle phases of DT (as shown in Fig. 5) start from design to dismissal, in addition to the potentially involved lifecycle parities (i.e., owner, manufacturers, distributors, and maintainers) [6]. Firstly, the asset prototype is designed and is evolved based on historical data, static data, and simulation data during the design phase. Then the physical asset is tailored based on the asset prototype and other technical requirements during the development phase. Secondly, following a synergic and continuous interaction between
the prototype and the asset, the asset further evolves and optimizes its functionalities during operational and maintenance phase while the prototype grows and self-adapts to the asset during its existence. Finally, due to obsolescence or other reasons, the asset along with its DTs is demolished during the dismissal phase.

The existing works have usually focused on tackling early ([41, 49]), medium ([2]), or both of these phases ([16, 30, 33, 51, 94]) of the DTs lifecycle. While developing a prototypical blockchain-based DT solution called EtherTwin, Putz et al. [66] mentioned the dismissal phase during the DT lifecycle; however, they do not discuss the details such as how the object is disassembled and the stored historical data of the DT product are backed-up and made available to other objects or domain experts to optimize the production of future devices.

3.1.2 Data Fusion and Interoperability. Regarding the implementation details of DTs, fusion and interoperability of data from multimodal and heterogeneous sensors is one of the significant prerequisites. This involves cleaning invalid, duplicate, or missing data, converting heterogeneous data formats into a unified data structure, and then fusion of such data to generate a consistent interpretation of a certain object. As depicted from Table 1, none of the existing works consider the process of data fusion from technical perspective. Similarly, interoperability is partially addressed by [16, 94]. For example, a hardware infrastructure proposed by Zhang et al. [94], introduced adopters for parsing the data collected from systems with different communication protocols. Additionally, it includes edge gateway nodes to pre-process the perceived data through filtration and aggregation. Similarly, Dietz et al. [16] discussed the integration of data in multiple formats to support data variety. They categorized the data as semi-structured data to model physical asset (static properties of the device) by using AutomationML (AML) format, structured data (sensor data), and unstructured data (human-readable documents). However, the above-mentioned theoretical solutions lack implementation details to demonstrate their feasibility in practice. Interoperability and data fusion provides a more comprehensive, consistent and accurate representation compared with the single perspective of data. However, the existing works still lack due attention to the relation of data fusion with the DT functionality.

3.1.3 Safety and Security (S&S). Some other implementation aspects including Safety and Security (S&S) threats, malicious or accidental, must be integrated to detect misconfigurations and to mitigate the outcomes of malfunctioning components and malicious activities in a production system. For example, safety rules may define upper- and lower-speed thresholds on a motor [23]. Inability to impose such rules leads to devastating results on the system in the form of cyberattacks or Advanced Persistent Threats (APT), for instance, Stuxnet worm [45] and Triton [54]. Despite being a critical construction parameter of “security by design”, S&S rules are overlooked by existing works. To the best of our knowledge, only one of the existing works by Dietz et al. [16], suggested adopting S&S works by referring to interesting work by Eckhart and Ekelhart [23]. In this work, the authors
consider monitoring of S&S rules and demonstrated the detection of the notorious Man-in-The-Middle attack (MiTM) attack by targeting the manipulation of a motor’s speed. Moreover, to further explore this parameter, future directions such as modeling language for S&S rules, investigating device templates with security rules, behavior learning, and analysis in conjunction with anomaly detection are also highlighted. Introducing S&S mechanisms at the DT design phase can help to lower security and incident-response costs thereby making later lifecycle phases less prone to errors and incidents [15]. Whereas, S&S rules must be stored and retrieved from the ledger to ensure their reliability. This further strengthens the rationale for integrating blockchain with DTs.

3.1.4 Synchronization and Consistency. Another key factor of DT-related design is the synchronization and consistency of data between the physical and digital spaces. Both of these factors are highly associated with the volume and velocity of data generation and data storage. DT data can be categorized as descriptive (or static) data and behavioral (or dynamic) data. The latter changes infrequently with time along the lifecycle of the real-world counterpart whereas the former evolves frequently with each lifecycle phase resulting in different versions and a dynamic information structure [73]. In the existing works, the issue of supporting data volume and velocity is partially considered. For example, Huang et al. [33] suggested storing sensor data based on preset time intervals. However, they did not consider the fundamental requirement of real-time data synchronization. On the other hand, Dietz et al. [16] discussed a more feasible solution to store the hash reference to the data stream on the ledger while storing data off-chain. Although this solution addresses the data storage issues, the details subjected to performance metrics are still missing. Similarly, Putz et al. [66] suggested the off-chain data storage pattern to meet the data volume and latency requirements and suggested sharing only non-nominal or aggregated sensor data to reduce the data volume.

Leng et al. [49] suggested a multi-view synchronization-based DT model that uses blockchain as an indexing server to record the transactions that are critical for the life-cycle quality control and product anti-counterfeiting. They also use traditional databases for the fast retrieval of history transactions. Considering the existing solutions, the crux of the problem is that the dynamic data produced by the deployed sensors and actuators providing real-time updates about the asset’s actual state usually amass in intervals ranging from minutes to milliseconds. However, sensor data streams’ velocity and volume exceed the performance characteristics of mainstream blockchain frameworks. Furthermore, deciding which data to store on-chain and which to off-chain, also needs due attention.

To address data synchronization challenges, the blockchain-based DTs solutions must exhibit high throughput and low sharing latency to efficiently sync data between physical and virtual space in addition to improving data collection and using it intelligently to manage big data challenges.

3.1.5 Data Granularity. Data is considered as the fuel for ensuring precise decision-making while at the same time quality of the data matters at par with quantity for decision-making. Therefore, the amount of collected data holds as an important design parameter. The granularity level (fine- and coarse-grained) of collected data which in turn also depends on the optimal number and placing of sensors [83], is still missing in the existing works. Further gaps that are required to be addressed include what types of data to sample, which sensors to use and where to install them [44].

3.2 Design Solutions for Blockchain

In the following, we discuss blockchain-related design solutions (for instance, selection of blockchain, implementation aspects, on-off chain storage, traceability, and trustworthy data sources) proposed by the existing works and associated challenges.

3.2.1 Blockchain Type. Depending on the underlying application requirements, current blockchain solutions mostly adopt mainstream sequential chain-structured public or private blockchains, such as Ethereum (ETH) or
Hyperledger (HLF). For instance, [2, 30, 66] use ETH while [49, 94] use HLF as the underlying framework for DTs. The selection of apropos blockchain is of significant importance to avoid futuristic challenges. Suhail et al. [80] investigated that, among the current solutions, the adoption of chain-structured blockchain has overlooked the scalability snag that may arise due to the growing number of participating entities. Therefore, the solutions that are expected to solve scalability issue, such as DAG-structured blockchains (IOTA [63], NANO [47], Byteball [12]), lightweight chain-structured blockchains (LSB [22], PoET [36]), or alternative structures (Tree-Chain [19]), must be considered.

3.2.2 Implementation. While most of the existing schemes proposed only a theoretical blockchain-based framework ([16, 41, 94]) neglecting the prototypical implementation. However, several works such as [30, 51] only partially accomplished prototype implementation. To date, only Putz et al. [66] carried out a thorough implementation. EtherTwin [66], an open-source prototype, is based on blockchain design patterns and DApp technologies with performance and cost measurements. Some other works such as [33, 51] do exist in the literature but do not provide any technical details about the blockchain type and other evaluation metrics. Similarly, Khan et al. [41] proposed a quantum-immune blockchain variant; however, it lacks technical and other supporting implementation details. On the other hand, in addition to other evaluation metrics, providing a user interface is another important aspect of implementation that is suggested by [16], however, in [66] they design and additionally implement it.

Overall, the existing works are not extensively evaluated to gain additional practical insights in the industry, and thus require focusing more on the prototype to identify potential adoption barriers and to provide avenues for future research. Moreover, validation of the prototype’s practical suitability by the industrial experts can further bridge the gap between industry and academia.

3.2.3 Data Storage. In terms of data storage, most of the existing works suggest using off-chain storage [2, 16, 30], however, do not properly implement it. For instance, Hasan et al. [30] suggested using InterPlanetary File System (IPFS) storage but the details on how IPFS is used, are still missing. In comparison to other works, Putz et al. [66] implemented off-chain storage based on swarm Distributed Hash Table (DHT). Following this approach, the off-chain data storage can meet the data volume and latency requirements where sensor feed is stored off-chain after registering sensor on-chain.

The idea of off-chain storage can help to solve the scalability issues in addition to reducing on-chain storage costs in the traditional blockchain. However, integrating off-chain storage solutions with blockchain-based DTs have several key challenges, e.g., there is no guarantee on the validity of the off-chain transactions, off-chain storage requires centralization, state consistency with on-chain storage in a real-time manner, and security issues [89].

3.2.4 Traceability. Though blockchain ensures traceability through its append-only nature, it requires the selection of key parameters to track and trace the entire chain throughout the process. Some of the existing works ([16, 30, 94]) discuss traceability but do not illustrate its working mechanism or actual implementation. To enforce traceability in the industrial system, provenance data based on (source, destination) pair and other key identifiers can be constructed (as suggested in [80]) while traversing through the process and can be stored on the blockchain to reconstruct the process chain on demand.

3.2.5 Trustworthy Sources. While stringent security solutions are inherited from the blockchain, ensuring the trustworthiness of data-generating sources and data in transit is, by far, not considered by most existing works. Maliciously or mistakenly, data adulteration may occur due to various reasons such as device tampering, data forging, or maliciously participating entity thereby causing the Garbage In Garbage Out (GIGO) problem [80]. Given that blockchain mechanisms do not guarantee the trustworthiness of data at the origin, [13] proposed a blockchain-based layered trust architecture for IoT for improving end-to-end trust. In this proposed framework, at the data layer, the data trust module quantifies the confidence in observational data based on (i) evidence
from neighboring data sources, (ii) reputation of data sources depending on their long-term behavior, and (iii) confidence level of the observation reported by data sources. To address such issues in blockchain-based DTs, Suhail et al. [79] suggested the following measures:

- To circumvent device tampering, the sensor nodes are required to register as authorized devices through their public keys and digital certificates in the blockchain. Such measures enable the gateways to collect data from authorized devices only by first confirming their authenticity from the blockchain. Furthermore, firmware updates are also carried out through blockchain to avoid malicious code injection or malware.
- To diagnose data forgery during data transition, potential solutions involve, i) reliance on provenance data to identify the faulty entity in the underlying chained processes and ii) leveraging twinned data to identify anomalies in the system that can be detected based on the digital-physical mapping.
- To identify a rogue participating entity through, i) issuing or revoking participation certificates by conducting a periodic on-site inspection of the units to ascertain that industrial processes are abiding by environment-friendly operations and ethical practices, and ii) deploying a monetary punishment mechanism [70] to reward honest entities while penalizing or revoking trader’s participation.

3.3 Design Solutions for Security

In this subsection, we discuss the existing works pertaining to security-related design issues including encryption, access control, and quantum resistance.

3.3.1 Encryption. Ensuring confidentiality through encryption is proposed by some of the works but is not described in detail or properly implemented. For example, Huang et al. [33] suggested encrypting the product lifecycle data; however, the implementation details of such encryption mechanisms are not provided which makes it hard to analyze. Similarly, Putz et al. [66] encrypt data before uploading it to the DHT using AES-256 whereas permissions are enforced by encrypting a symmetric key with the corresponding entity’s public key. It is also an established fact that the security of de-facto cryptographic primitives is at risk of being broken by quantum computers [11]. Therefore, to address this critical issue, one set of solutions is to use quantum-resistant public-key cryptography (also called Post-Quantum Cryptography (PQC)) as drop-in-replacements [10]. Based on mathematical problems other than factoring and discrete logarithms (used by the traditional cryptographic algorithms), such solutions are yet believed to be secure against quantum attacks. Another set of solutions is quantum cryptography, most notably, Quantum-Key Distribution (QKD), which is a method for establishing symmetric keys [56]. However, due to certain limitations (i.e., presence of quantum channel for sending bits), it is difficult to use such a solution as a plug-and-play replacement for the current security methods [57].

3.3.2 Access Control. The current literature on blockchain-based DTs has a few authentication and authorization mechanisms as the concomitant of access control. However, we could not find their implementation details. For instance, Dietz et al. [16] proposed a stored role-permission mapping to grant or deny access based on Role-Based Access Control (RBAC). Similarly, Putz et al. [66] implemented a hybrid access control model by combining RBAC and Attribute-Based Access Control (ABAC). The access control capability provides authentication and authorization to enable data sharing among the involved parties and therefore must be considered carefully.

3.3.3 Quantum Resilience. With the arrival of quantum computers, wrongdoers are able to forge digital signatures and sabotage transactions thereby putting blockchain security at risk [24]. To prepare for the quantum apocalypse, blockchain-enabled schemes that already support post-quantum techniques such as IOTA [63] (using WOTS), Quantum Resistant Ledger (QRL) [67] (using XMSS), and Corda (using BPQS: a single-chain variant of XMSS) should be considered for long term security [81]. Moreover, to further enhance security and enable blockchain to become faster and more efficient, requires quantum-linked features including quantum Internet, quantum-safe communication, and QKD for both communication and computational processing of blockchain data [24].
the existing works, Khan et al. [41] proposed a variant of blockchain called Twinchain which replaces Elliptic Curve Digital Signature (ECDSA) with quantum-safe Hash-Based Signature (HBS). However, the proposed quantum-resilient blockchain does not provide sufficient details about the chosen HBS. To this end, there are still outstanding challenges and research avenues that could be investigated by the research community.

Fig. 6. A trustworthy 7D DT model.

In the following, we discuss a seven-dimension (7D) DT framework (Fig. 6) based on the limitations of the existing works. We first provide a high-level layered structure of blockchain-based DTs (Fig. 7). Then we further discuss the main and supporting components and their functionalities in connection with DTs-, blockchain-, and security-related design issues outlined in Table 1.

3.4 Trustworthy Blockchain-based Digital Twins: A Unified Framework

Curating and mining information from the collected data calls for an infrastructure that can manifest the trustworthiness of data-generating sources, data in transit, and data at rest (storage) [79]. In this regard, Suhail et al. [79] recently addressed the requirements of trustworthy data management, data security, and predictive maintenance through a provenance-enabled blockchain-based DT framework. The main components of the proposed framework are presented in Fig. 7. At first, the participating entities such as sensors, machines, and humans register as authorized entities at the blockchain (step 1). Next, at the data layer, cyber-physical mapping is performed by monitoring, collecting, and processing designated parameters at the physical space that are mirrored at the virtual space (step 2a). The collected data along with provenance (i.e., a complete lineage of data along with a set of actions [93]) is sent to the storage layer (step 2b). At the twinned system, models are generated based on collected data, domain knowledge, and system historical data and are stored at the storage layer (step 3). The application layer continuously analyzes data to detect manufacturing disturbances (step 4) and calls for the scheduling services (step 5a) or model calibration services (step 5b), thereby completing the agile feedback loop. Additionally, physical security countermeasures can be exercised through monitoring devices such as surveillance cameras, power monitoring, fire alarms, etc. Thus, blockchain ensures secure data management and DTs use...
Blockchain-based Digital Twins: Research Trends, Issues, and Future Challenges

provenance-enabled trustworthy data as input to predict events and their associated causes by means of data analysis [79].

Fig. 7. Blockchain-based digital twin: A framework. (Adapted from [79])
In the following, we discuss the 7D blockchain-based DT model which enhances the functionalities of the 5D DT model (shown in Fig. 2) by introducing data integration and interoperability components (such as data fusion, data wrangler, and composability) and data synchronization. Also, it introduces blockchain (as an alternative to DT Data) to facilitate secure data management to all components. Table 2 presents a summary of the blockchain-based DT model by mapping them on the desirable properties of DTs. Furthermore, we map the high-level functionalities of the components in 7D blockchain-based DT model to the desirable characteristics outlined in Table 1.

3.4.1 Design of Digital Twin. In addition to the existing components of the 5D DT model (Fig. 2), Suhail et al.’s framework [79] introduces the following three components: (i) data wrangler, (ii) data synchronization, and (iii) data fusion. Data wrangler is responsible for cleaning erroneous (invalid or missing) data and converting different data formats into a unified format before inputting data to the physical and virtual spaces as mentioned in subsection 4.2.2. Data fusion is used to combine data from multiple sources to generate consistent interpretation for a certain object. For instance, before initiating the production process, the necessary details such as order information (e.g., material stock, production quantity, estimated cost), supply chain data (e.g., consignment information), simulation data (equipment historical data, prediction of equipment fault), thresholds and consistency checks (S&S rules), etc. are already available in the storage system for usage. Furthermore, to facilitate the creation of an abstract view of overall phenomena, DTs must support the correlation of different DTs associated with different physical sub-components. The framework uses composability that aggregates multiple DTs to integrate and interoperate multiple DTs or replicas.

To register any instantaneous change (based on requirements of applications) in the system status, DTs and their physical counterparts must be "constantly connected". To do so, data synchronization enforces self-adaptation by performing a continuous digital-physical mapping between the pre-defined system performance parameters retrieved from the storage, and real-time sensor data obtained from the manufacturing unit, to verify data consistency. To make DT reflecting the behavior and the status of the physical object, an effective and reliable communication suitable to the rate of changes are among other desirable properties to support entanglement between the physical space and the DT [55]. Depending on the data anomalies (defined in S&S rules) or uncertain data inconsistencies, the service component calls the corresponding scheduling services (in the physical space) or model calibration service (in the virtual space) to carry out the necessary measures. Based on the above-mentioned phases, the lifecycle of DT evolves from the early phase (design and development) to the medium phase (operation and maintenance). The existence of DT may occur before the creation of the product and it may continue to exist even after the end of product life. Usually, the dismissal of the object is followed by the dismantling of the DT.

3.4.2 Design of Blockchain. The storage layer provides secure distributed data storage through a lightweight, scalable, and quantum-immune blockchain. Data can be securely accessed to and from blockchain, for example, the application layer uses it for analysis and decision-making while DT uses it for generating and uploading updated virtual models. Also, the data synchronization can access the updated data directly from the ledger, to eliminate the qualms of untrustworthy data. Empowering DTs with blockchain solves the key issues, i.e., disparate data repositories, and untrustworthy data dissemination; however, to reason about the current source and state of a data object entails a complete lineage of processes chain. Therefore, to diagnose data forgery during data acquisition and transition and to support “track and trace solutions”, Suhail et al.’s framework relies on provenance data and twinned data to identify the cause of deviations between the physical-digital space in addition to data assessment.

Considering big data storage issues, we need to carefully consider what type of data needs to be stored on the blockchain. For instance, storing sensor data streams may not be an ideal situation due to data velocity and volume. The proposed framework relies on a data synchronization process that limits the frequent time-consuming access to the storage system, where the data flow of real-time sensor data and the less dynamic production and provenance data are explicitly separated.
3.4.3 Design of Security Features. Currently, most of the blockchain-based solutions heavily rely on de-facto cryptographic primitives. However, blockchains that are not quantum-resistant could pose long-tail data risk by potentially enabling attackers with high-powered quantum computers to monopolize the network by forging digital signatures and sabotage transactions [24]. Therefore, to prepare for the quantum world, blockchain schemes (e.g., [63]) that support post-quantum cryptography must be adopted [81]. Also, to allow multi-party use of DTs data, distributed data accessibility and auditability based on ownership, roles, and access levels are enforced.

4 INTEGRATING BLOCKCHAIN-BASED DIGITAL TWINS WITH AI: WAY FORWARD

Among other factors, the efficiency of processes and services is the driving demand of the industry. The current technological innovations have helped the industrial verticals in creating services and applications that aim at automation, customer satisfaction, Quality of Service (QoS), business enhancement, and Return on Investment (RoI). The balance of these factors is not easy because, for instance, for an increased QoS and customer satisfaction, huge investments might be needed whereas it might not be orthogonal with the RoI. Furthermore, a change in paradigm in the form of digitization has set a new path for the industry. For instance, communication and computation technologies have been extensively leveraged to automate industrial processes. Such automation results in a huge amount of data that is the pinnacle for decision in industrial processes.

According to Larsson et al. [46], digitalization has been incremental for the past couple of decades wherein the decade 2000-2010, the main focus of digitalization was on mobility and scalability, whereas the last decade has seen exponential growth in the development of AI. Larsson et al. argue that AI is the most significant stage of digitalization and it will play a decisive role in the growth of the industry. Moreover, it is also as important to assess the value that the current innovations through technologies, bring to the industry. Owing to the hype and interest in the enabling technologies (including blockchain and AI), it is important to weigh the need and the role of AI in the industry, in the context of DTs and blockchain. For instance, blockchain and AI can provide intelligent and trusted DTs as shown in Fig. 8. To this end, in this section, we provide a way forward for AI-driven blockchain-based DTs. We start with the rationale for AI in DTs and blockchain and then discuss the salient benefits of AI in both DT and blockchain. Then we look into the role of AI in blockchain-based DTs in a holistic way and the outstanding challenges that need to be addressed.

![Integrating AI and blockchain for intelligent and trusted DTs.](image_url)
4.1 Why Do We Need AI in Digital Twins?

DTs give us a mirrored world, the one in which we have a large scale of simulated, monitored, and streamlined real-time data obtained from different (IoT) devices. A mirrored world on which industry 4.0 relies, needs to be built on comprehensive, compatible, and trusted data. One of the main challenges of the DTs is how to handle/process large-scale data in real-time processing and how to provide integrity and trustworthiness of data collected from the physical world that are then shared with the digital world. In the existing literature, AI has been actively used to enrich DT with intelligence and make the decision-making process more optimized, accurate, and reliable. In the following, we shed light on a couple of domains where the benefits of AI are harnessed.

Rathore et al. [72] discussed the need of integrating AI into the digital twins technology in large part for the challenges of big data analytics. Big data are defined as large scale data, with high volume, velocity, heterogeneous variety (3Vs), value, veracity, and variability. For instance, the process of analyzing big data and converting it to valuable information, using state-of-the-art mathematical, statistical, probabilistic, or artificial intelligence models prompts us to the arena of new challenges. The main challenges and constraints are capturing, storing, managing, processing, analyzing, and visualizing the diverse variety of data. Similarly, Klein et al. [42] examined the leverage of the AI algorithms to the development of the DTs for the new generation digital multi-missions radars. The main idea is to develop full software-defined radars that are reinforced with scalable front-end, adaptive digital beamforming, diverse beam shapes etc. They also underlined the role of AI algorithms (optimization, learning) in the development of cognitive functions for DTs. It is important to note that AI fosters the capabilities of DTs as self-adaptation, environment and contextual situation understanding, inducing the DTs radars to become able to optimize their resources in a collaborative way. In [42], the authors also described a new model of the Radar Digital Twin, RadOpt (Radar Optimization) framework, that is based on miscellany of optimizing modes, including optimized scanning radar modes through beam synthesis, waveform generation and scan pattern optimization. The amalgamation of radar Digital Twin and AI is resulting in a framework that is a flexible tool, compatible with various extensions.

Örs et al. [96] discussed a generic framework for operational DT in chemical process engineering, pointing out the role of AI in operational DT, and proposed a novel generic framework for AI-based operational digital twin (ODT) in chemical process engineering. The main benefit of the use of AI in the ODT is facilitating forecast models for the exogenous variables. In a nutshell, using predicted values instead of real-time information, is beneficial in plant economics and might help in cost-benefit efficiency in industry. From the preceding discussion, we note that AI can be the right choice for DTs to make the predictions streamlined, data analytics more intelligent. Furthermore, AI synthesises the data from DT in more human understandable and consumable way. We also note that AI identifies the patterns and enriches the information obtained from DT that would otherwise not be possible with traditional data analytics.

4.2 Benefits of AI in Blockchain-based Digital Twins

Industry automation with futuristic technologies will play a pivotal role in the realization of the smart industry and Industry 4.0. The adoption of the Industrial Internet of Things (IIoT) and related technologies is a step forward for the smart industry. The common denominator in the smart industry is the volume, velocity, veracity, and variety of data generated by different components installed in the industrial setup. Since “data is the fuel” for predictions and decisions, empowering it with AI techniques will not only improve the production, but will also improve the quality, identify weak points, identify threats, faults, and so on. In the following, we discuss some of the benefits brought by AI in blockchain-based DTs.

4.2.1 AI-based anomaly detection solutions for DTs. The complex, heterogeneous, and interconnected nature of smart Cyber-Physical Systems (CPS) is prone to errors and attacks due to the integration of multiple un-trusted participating entities. As the interdependence of the underlying environment increases, predicting the effects of
apparently innocent actions or events could become infinitely more challenging. Whereas ignoring such small variations in the system behavior may collapse the whole system or may incur drastic effect on the long-term behavior of the system analogous to the “butterfly effect” where a small change in a complex system might cause large effects on the overall system.

Based on the “learn and prevent” mechanism, a blockchain-based DT governed by an intelligent AI-based system can detect the presence of malicious or mistaken disruptions in the system and can invoke the appropriate defense mechanisms automatically. Even if the damage is unavoidable, the AI-based solution, at the very least, isolates the attacked physical (sub) component thereby keeping the rest of the infrastructure safe from further damage attack. Thus, it is prudent to employ ML models in DTs data synchronization and model calibration services to ensure that stand-alone components have the ability to realize when it is being fed incorrect or malicious external data, detect the occurrence of an attack, and carry out a safe mission in the face of the attack. Though blockchain can aid in securely storing and tracing device logs from multiple sites in geographically distributed locations; however, a security breach is still possible from any dishonest middleman and insider. More precisely, communication glitches, device failure, or compromise may still result in erroneous data that might result in anomalies.

In this regard, AI-based techniques can be used to monitor the behavior of participating entities and predict anomalies. For instance, Castellani et al. [8] used weak supervised learning in DTs for anomaly detection in the industry settings. The training data is generated using DTs whereas labeled anomalous data is generated from the hardware components in the industry. More precisely, the authors used Siamese AutoEncoders (SAE), specially tailored for weak supervised learning with synthetic data to detect anomalies in the real data. A few other AI-based techniques have been leveraged in the literature for anomaly detection with an acceptable detection rate. For instance, Jadidi et al. [39] used multi-source deep learning (DL) model that uses Long Short Term Memory (LSTM) network to analyze the data received from multiple sources and learn anomalies in the data. This two-level DL model is used in the ICS which is the pinnacle of DTs.

To conclude, the afore-mentioned data breaches cause catastrophic consequences for industrial processes and call for dynamic and intelligent mechanisms to mitigate these challenges. In this regard, implementing intelligence-driven solutions (such as data analytics and threat intelligence) in S&S specifications can help to identify vulnerabilities, faulty models, threat actors, existing and potential attack vectors, thereby minimize the threat landscape and improving the cyber-security industry. Threat intelligence is recently used to identify data breaches, and cyber threats in huge enterprises by gathering and analyzing disjoint data from a number of sources and extract useful information about possible breaches by looking at the threat landscape of the enterprise [38]. It is worth mentioning that threat intelligence is not only about detecting an attack on a digital asset, but it covers the broader perspective of ‘who’, ‘why’, ‘when’, ‘how’, and the ‘magnitude of damage’ about the data breaches and attacks. Ibrahim et al. [38] discussed the challenges related to threat intelligence in different environments as the same threat intelligence framework might be different in different setups. They also discuss the key role of AI and ML in threat intelligence.

4.2.2 Improving Data Quality. In addition to predictions, AI helps in improving the data quality by implementing intelligent automated methods to fill in the missing data and to clean the data (such as data denoising, data de-duplication). For instance, AI-enabled data curation at the data wrangler method can help in achieving data completeness and data accuracy which ultimately improves the data analytics and optimization through the twinned system. Similarly, through algorithms such as neural network, Kalman filter, and bayesian inference, data collected from multiple heterogeneous sources can be fused to generate consistent and comprehensive interpretations of the object [85].

To this end, Generative Adversarial Networks (GANs) can be used to improve the data quality by imputing missing data. Yoon et al. [92] used GANs for data imputation where 3 kinds of missing data, i.e., data is completely
missing and does not depend on any of the observed parameters, data is missing but it depends on observed parameters, and the data that is missing depends both on observed and unobserved parameters. Yoon et al.’s technique impute the complete missing data using GANs. This data imputation mechanism is of paramount importance in DTs where it will drastically increase the quality of the data for analysis. Similarly, Tripathi et al. [87] use GANs for denoising images and producing good quality images. Although this work is in the image domain; nevertheless, with proper tweaking, GANs can be capable of denoising any kind of data which in turn improves the data quality.

4.2.3 AI-aided Predictive Maintenance in DTs. In DT, creating future scenarios in the absence of direct observation data is very challenging. In this regard, the predictive capability of LSTM can play a phenomenal role in creating future scenarios with DTs particularly when direct observation data is unavailable. For projections, predictions, or conducting sensitive analysis in a system through DTs, supervised learning algorithms can be used. However, in the absence of sufficient labeled data for training, unsupervised algorithms like hierarchical clustering, k-means methods, deep belief networks, autoencoders, and self-organizing maps have better utility [71]. It is also worthy to note that data is not always available, and therefore based on the context, data-independent models are needed. In such data-deprived situations, reinforcement learning can be used.

4.3 How AI Will Set a Course for Blockchain-based Digital Twins

Technology is increasingly employed for successfully tackling problems outside its original intended purpose, and some of those problems involve the necessity for secure processing, communication, and exchange of data. Nonetheless, a few limitations of blockchain technology including complexity, high transaction cost, network size (scalability), and the vulnerability of the smart contracts which are the core of the blockchain, need to be addressed before it can be efficiently and fruitfully applied to complement other technologies such as DTs [69, 76]. In that context, studies advocating for the integration of AI techniques with blockchain technology have emerged. In the following, we abstractly discuss some of the related work in this direction.

Kshetri et al. [43] discussed a few areas in which AI can empower blockchain technology. These areas include enabling faster and more effective processing of blockchain systems, automated handling of smart contracts through data validation and automatic condition update for optimized functionality, enabling automated real-time identification of cyber threats, and continued learning about attackers’ behavior. They also focused on enhancing the effectiveness and the quality of the application services that leverage blockchain. Similarly, Singh et al. [76] also discussed the areas in which AI can greatly benefit blockchain. They categorized the limitations of blockchain into several categories including energy consumption, scalability, efficiency, security and privacy, and hardware-dependence. Furthermore, Raja et al. [69] argued that the integration of AI and blockchain will result in advantages among which improving data security plays a crucial role.

Consequently, integrating AI and blockchain technologies can favorably affect many areas that focus on improving human lives including IoT, smart cities and industries, personalized healthcare, and other fields [75]. For instance, in DT technology which involves data exchange between the physical things/systems and their exact digital virtual representations, safeguarding digital data which usually involves crucial information such as the attributes of the physical objects, their future states, and data about the interaction with other objects, is of paramount importance for the success of this paradigm. A security breach of single or multiple DT instances can, in an industrial use case, for instance, endanger a product or a whole collection of products and processes [68]. AI-empowered blockchain technology can be employed to effectively mitigate these vulnerabilities, ensure data integrity and secure data exchange through strong user authentication, and hence, strengthen the digital twin paradigm.

Considering how important it is to provide trust, transparency, and security in DT, the properties of blockchain make it an excellent choice for a solution with a huge potential to ensure these critical attributes in DTs; however,
there are still a number of open issues that need to be tackled before blockchain can be successfully integrated with digital twin technology [91]. Data integrity can be naturally achieved with blockchain-based storage as it provides a manner of keeping the information in a decentralized way without being vulnerable to a single point of failure and control, and by allowing new information to be added without the possibility of corruption or deletion of the exiting information. This characteristic of blockchain facilitates authentication and identification, preventing the injection of counterfeits and execution of fraud. This is especially significant if we consider DTs as digital certificates of their corresponding physical objects. Such tamper-proof reinforcement can undoubtedly redefine the DT technology and take it to a whole new level to be utilized in many fields including industry, healthcare, logistics, and utilities [68].

Nevertheless, as discussed by Yaqoob et al. [91], there are several challenges that hinder the effective adoption of blockchain for DTs including scalability with a focus on transaction speed, data privacy in the face of a public nature of transactions that could risk the disclosure of identification information, interoperability of various parameters, high energy consumption, given a complex nature of problem-solving involved, and integration with legacy systems that could induce high implementation costs or even risk violation or loss of data. These issues need to be addressed before blockchain technology can be efficiently adopted and integrated with digital twin technology. AI techniques could alleviate some of these issues by providing intelligent predictions and solutions for speeding up processes, extending the services landscape, and increasing revenue. However, it is important to note that employing AI in blockchain-based DT also has challenges that need to be addressed. In the following, we discuss these challenges.

4.4 Challenges for AI in Blockchain-based Digital Twins

Despite the afore-mentioned benefits of AI in blockchain-based DT, there are still challenges that need to be addressed before the realization of AI-driven blockchain-based DTs. In essence, we focus mainly on the data-related challenges faced by AI in blockchain-based DT. Identification of these challenges is important to avoid pitfalls of AI in such environments.

4.4.1 Need for Explainable AI.

Despite the wide success of AI-based systems that are capable of perceiving, learning, predicting, and acting autonomously, there is a reluctance to adopt these systems in practice due to the black-box nature of most of the AI model, and even more so when these models are used in critical infrastructure and environments. Decisions made by the resulting systems suffer from a loss of transparency and comprehensibility, particularly for the users who are not ML experts and hence can lead to a negative impact on the trustworthiness of the system. Hesitation is even higher in safety-critical industrial systems where explainability becomes crucial as slight dysfunction of an AI algorithm may lead to wrong decisions that could imply loss of life or economic disaster. Therefore, it is essential to remove the opaqueness of black-box-models by explaining their inner working. In this regard, explainable AI provides a set of techniques and methods to convert the black-box models to white-box approaches such that the overall process adopted by the algorithms and models to reach a decision can be explained and interpreted. To explain the existing ML models, transparent models (also called interpretable models) and post-hoc explainability are required to produce comprehensive details of the decisions and predictions made by the models [34]. Another solution to explainable AI is suggested by [18] where authors proposed that blockchain-based tracking of the data flow and complex behaviors of AI-based systems can establish more understanding of and confidence in the decisions made by the underlying systems. Additionally, human users can re-calibrate their trust in the system by tracing back the decision process and making justifications that are essential to identify which entity (human or machine) is faulty. To this end, the explainability and fairness of AI are primarily important.
4.4.2 Data Scarcity. Data serve as the lifeblood of AI models. To be able to learn the behavior and make accurate predictions, a sufficient (large) amount of data is necessary and oftentimes becomes the bottleneck for AI. The use of AI in DT should take this factor into account and uniform, consistent, healthy, and on-time data sources must be present to be fed to the AI models. Abstractly, there are two ways to generate data, i.e., data from the real environmental components (for instance sensors), and synthetically generated data. Sometimes data generation might take longer than the learning, therefore, it is essentially important to consider the scarcity challenge of the data. It is also worth mentioning that the data scarcity problem might be partially solved by using GANs; however, the overhead of using GANs (and their limitations such as mode collapse [3]) calls for efficient and sufficient data generation mechanisms. It is also worth mentioning that since DT uses simulation of the real-world, therefore data scarcity should be thoroughly considered while employing AI in DTs. On the other hand, data ownership is also important where big companies own the data and might be reluctant to share the data which will directly affect the efficacy of DTs.

4.4.3 Bias Problem. The bias problem is inherently related to the data that is input to AI. Therefore, it is safe to say that the fairness of the AI model is as good as the data provided to the model. There are many factors that contribute to the bias in data. These factors include the source of data, the environment in which it is collected, the context of data collection, and the way the data was collected. If the AI model is trained on the imbalanced data, then the outcome of the learning can be biased. Therefore, one of the dimensions of data quality is the balance as well. The same argument is true for AI in DT as well where the collected data should represent the real and complete scenario to be used for learning. To this end, the current literature focuses on fair representation of data and thus provides fairness in AI [9, 52].

4.4.4 Model Errors. Model errors are closely coupled with the bias in the data as discussed above. The bias causes prediction errors and thus compromising the efficacy of AI. Furthermore, training an AI (ML) model also includes error analysis which means that to make sure if the model is performing according to the expectation or if the prediction is not accurate (or wrong) on the provided test data. If the model is transparent, then the decision made by a classifier can be reverse-engineered and know the reason why did the model made a particular decision. However, in the case of a black-box model (most DL models), it will be infeasible to provide a justification for a particular decision taken by the model. Therefore, one parameter is the transparency of the model that should be taken into account. ML model errors can be explained at three different levels, prediction level, data level, and features [40]. The employment of AI in DT, thus, calls for efficient model error analysis before it can be used in production.

4.4.5 Social and Juristic Challenges of AI. AI and intelligent objects have become pervasive in everyday life permeating and augmenting both social and industrial aspects of people’s lives. It has also become evident how such technologies will increasingly start taking over jobs commonly performed by humans [74]. With such a widespread and substantial effect of AI on many fields including smart industry, cities, healthcare and diagnostics, transport, and scientific applications, several social and juristic issues and challenges arise that need to be seriously considered and properly addressed. Although in this section we focus on the general social and juristic challenges of AI and provide examples from the various domains, the results of using AI in the industrial setup will be (with some tweaks) similar. Some of these challenges involve decision-making whose consequences could have a vital impact on people’s lives. For instance, scenarios may occur in which an AI-empowered system will have to make a decision that involves conflicting interests of an individual vs. others (e.g., in autonomous driving [35]), or in which such systems may cause fatal outcomes (e.g., failing a surgery or diagnosis, involvement in war crimes). Even non-vital outcomes such as invading someone’s privacy or incurring any kind of loss or harm should be avoided. All of these scenarios bring about other questions of legal liability and the social status of such technologies. A carefully balanced regulation is necessary to allow for a broader acceptance of
AI-empowered technologies as effective. Regulations are also necessary to justify alternative replacement for human work and decision making, and not to hinder the development, flexibility, innovation, and thriving of these technologies [60].

Perc et al. [60] discussed social and juristic challenges of AI separately. Social challenges encompass situations in which the interests of a person do not agree with or could even be in conflict with the interests of others. Such scenarios in which decision making may not be defined for AI as clearly as in some other situations in which other people, are not involved. Similarly, in [7], Bonnefon et al. studied the dilemma of instilling moral principles into the process of decision making by intelligent machines; more specifically, the decision making process in which autonomous vehicles need to make a moral decision between sacrificing the user or saving pedestrians from being run over. Such a regulation would entail acceptance of self-sacrifice by users, and the study has found that even though people approve of such practice, they are less likely to own such autonomous cars and would prefer vehicles that prioritize the passengers’ safety above everything. An interesting conclusion is how trying to regulate in favor of so called “utilitarian” algorithms may actually result in more incidents while adoption of safer solutions is delayed.

Peysakhovich et al. [61] also discussed the problem of social dilemmas, and proposed a method that can be employed to evaluate the success of an AI strategy. They emphasized that designing intelligent agents that can learn how to solve social dilemmas is of paramount importance, and proposed utilization of Deep Reinforcement Learning (DRL) as an efficient approach for solving these kinds of challenges. Similarly, Nagler et al. [1] also investigated the problem of ethical dilemmas in AI that may involve life and death situations where AI will have to make decisions and proposed an extension to Asimov’s Laws of Robotics. They argued that the current algorithms are deterministic in nature which may actually lead to needless harmful outcomes and that in case an ethical dilemma is encountered, a chance should influence the decision, which would result in a greater chance for every human being to be considered equally important.

Perc et al. [60] further discuss juristic challenges of AI that arise from the ethical issues mentioned above. They point out that there are almost no fields of law that have not been affected by AI, including patenting and patent quality, joint infringement, the privacy of the consumers, automation taxing, and tort laws on which they specifically focus. The tort laws involve deliberate, negligent, and liability wrongdoings. The complex nature of AI gives rise to many challenges in the area of product liability for intelligent objects. Even though such products are designed with high reliability, they may still fail either inadvertently or by design, which can result in financial or property harm, injury, or loss of life. In some more complicated cases, the responsibility may not be clearly defined in the eyes of law (e.g., autonomously driving vehicles that can be overridden, remotely piloted aerial vehicles). However, even with these issues in mind, intelligent objects may still increase overall safety such as causing fewer car accidents or less medical harm due to negligence. In all these scenarios, the question of legal liability remains, and it is argued that intelligent objects should be held accountable according to negligence standards rather than strict liability. Nonetheless, legal experts still favor employing strict liability for the parties involved in the production, distribution, provisioning, and selling of intelligent objects. However, this does not change the fact that the more autonomous the systems get, the less they can be regarded as just tools in the hands of human actors. Perc et al. also mentioned an interesting topic of whether the intelligent objects will be able to sue, be prosecuted, or serve as witnesses. Currently, such objects are still considered property and as such cannot be considered for such processes, but these are all legitimate questions for the future of juristic issues for AI [60].

In summary, although AI has a huge potential to improve people’s lives in a vast number of areas, there are still many ethical and juristic questions that have to be efficiently addressed before AI technology can be pervasively employed.
5 RESEARCH AND DEPLOYMENT CHALLENGES

In the quest to enforce secure data management in the Industry 4.0 era, the following technical, logistical, and social challenges of blockchain-based DTs schemes require further investigation. In this section, we highlight the open-ended challenges that hinder the successful implementation of blockchain-supported DTs in the industry. These challenges open new avenues for future research in these directions. Fig. 9 presents the detailed taxonomy of the current and future research and deployment challenges for blockchain-driven DTs. We summarize the challenges along with causes and possible solutions in Table 3.

5.1 Technical Issues

Here we discuss technical challenges with reference to blockchains, DTs, and their integration.

5.1.1 Representation of Digital Twins. “High-fidelity” model is one of the critical challenges for a virtual model that represents the real-world situation. For instance, in a production unit, the quintessential DT for a robotic arm should mirror an exact image of all the behavior and functionalities of the physical component, synchronized in real-time throughout its lifecycle [79]. However, in industry, uncertain scenarios transpire due to the dynamism and complexity of underlying (sub)systems, machinery malfunctioning, human errors, hidden vulnerabilities, erroneous data, knowledge gaps, and variability, fuzziness, and uncertainty of physical asset. Moreover, while maintaining backward compatibility, a corresponding evolution of the models is required as the physical object evolves over time [71]. Therefore, to enable DTs to unearth the unknown unknowns, a pragmatic approach must be adopted by integrating cognitive DT solutions.

Considering representativeness and contextualization in DTs, feature simplifications or generalizations are possible, provided that they do not affect the behavior in the specific context under a specific environment [55]. In this regard, replication modes are used for tracing physical objects and reproducing activities by emulating their behavior [15]. Initiating replicas in the framework or in the application space poses issues. For example, depending on the time period defined by the application, all replicas of a physical object should have the same status as that of the physical object. Otherwise, it may lead to the problem of synchronization and consistency of information between the physical object and its different replicas. To solve such issues, one possible solution is to integrate transaction management functions through blockchain. Other issues that may arise with replication are temporal dependencies and the need for input knowledge (such as events and activities) in advance to produce the same stimuli. Also, it requires experts to solve complex and intertwined problems.
To emphasize socio-technical design implications, Barricelli et al. [6] focused on Human Work Interaction Design (HWID) and End-User Development (EUD) to bridge the communication gaps among domain experts, designers, and stakeholders. In this regard, DTs must be equipped with well-designed and accessible interfaces such that it appears indistinguishable from the physical asset and allows end-user (domain experts or non-informatic experts) to intuitively create, modify, test, and operate digital artifacts.

### 5.1.2 Data-related Challenges

Data challenges mainly emerge due to the following four factors: i) types of data to collect, ii) rate of data collection, iii) data storage, and iv) merging of disparate data types. The first issue requires a trade-off between excessive data volumes and limited data volumes, i.e., too few data may result in inaccurate predictions, and too many data may result in mired down in details or may pose decision paralysis due to information overload [79]. The second issue involves the frequency at which data samples are collected. For instance, recording vibrations from a turbine gearbox every minute would miss shorter glitches but sampling every second could result in too much data thereby causing transmission bottlenecks [83]. Furthermore, the duration for which data is stored needs to be determined as high volumes of rapid measurements lead to high storage cost but at the same time, long-term data are required for modeling [44]. Therefore, depending on the system requirements, it is important to define the spatiotemporal granularity of the data. The third issue corresponds to storing big data on the blockchain that requires careful consideration of factors such as high cost associated with high volumes of rapid measurements, block size, latency, etc. Alternative storage mechanisms and solutions include off-chain storage, storing only data hash to reduce storage costs, or removable blockchain designs [21]. Despite these solutions, the big data storage problem considering the volume and velocity of data are still open issues. The fourth issue involves disparate data types that are hard to merge, for instance, vibrations, temperatures, videos, or images all have different data types, formats, structure, and scale. Under such scenarios, missing or erroneous data can distort results and obscure faults, timings can get out of step during data sampling at different rates, and averaging fine data may lead to loss of details [83]. In a nutshell, to embed viable and size-efficient data into the ecosystem, the data-related challenges including volume, variety, veracity, generation rate, spatio-temporal resolution of sensor data, and efficient processing, archival, and retrieval require further investigation.

### 5.2 Logistical Issues

In the following, we outline some logistical challenges faced by the adoption of blockchain-based DTs in the industrial domain.

#### 5.2.1 Expenditures on Infrastructure

The adoption of emerging technological trends, such as IoT, High-performance computing (HPC), blockchain, DTs, AI, etc. aids in reducing operational costs, reinforce productivity, provide predictive and preventive maintenance of industrial machines, and attain higher operational efficiency. However, owing to such innovations, companies have to spend a considerable amount of capital on the day-to-day management of networked devices (maybe geographically dispersed). Such practices require the balancing of the cost-benefit analysis. Otherwise, it could drain operational resources for managing industry assets and business processes. Despite the significance of DTs in reducing risks, increasing safety, and improving efficiency, many enterprises realize that the connectivity, computing, bandwidth, and storage required to process massive volumes of data involved in creating DTs are cost-prohibitive [79]. Likewise, for blockchain technology, perceived risks associated with the immature technology, high costs of initial implementation, and the likelihood of disrupting existing practices may pose significant challenges to businesses. Another addition to the Capital EXPenditures (CapEXs) and Operational EXpenditures (OpEXs) involves the issue to train security specialists and institutions with the state-of-the-art applied tools and knowledge of the data used to establish the model. Otherwise, improper or missing influencing factors can lead to fallacious results on which the critical security decisions and actions...
are based [15]. In such situations, shifting to the new paradigm is more beneficial for medium-to-large scale industries in contrast to small-scale industries. However, sooner or later, small-scale industries have to adopt the current technologies as they may scale in the future or ultimately due to technological obsolescence.

5.2.2 Standardization Barriers and Efforts. Due to the lack of applicable laws, the absence of unifying data and model standards, and integration problems into business processes, an internationally operational framework and infrastructure for DTs is still a long way away. Typically incompatibilities exist throughout the entire development process and life cycle. For instance, scattered ownership of data involves different data interfaces, proprietary file formats, object definitions, encoding, and sharing of knowledge strewn throughout the product lifecycle. Moreover, it includes a multitude of vendors, contractors, and customers of all sizes and specializations that do not necessarily use the same software/tools, etc. Therefore, the impetus to create DT standard requires improved interoperability where each step of the workflow ingests artifacts from the previous stage and output artifacts that can be consumed by the following phase [62]. With firm guidelines for cross-disciplinary standardization, a universal non-proprietary design and development platform for DTs should be developed with user-friendly and API-based interfaces on which all models can run without data monetization or fixed vendor partnerships.

The common denominator among blockchain platforms is their reliance on a distributed and decentralized peer-to-peer network. They nevertheless vary substantially in terms of the underlying data structure, scalability solutions, fault tolerance, degree of decentralization, and consensus approaches. The disadvantages due to non-interoperable blockchain implementations are manifold, for example, information restrictions, highly fragmented industrial ecosystems, stand-alone and disconnected networks, to name a few. In essence, allowing seamless integration of data by enforcing open data structure and processing harmonization through common linked data language and multiple agile, scalable and mergeable blockchain ledgers for logging different data types can minimize obstacles in the widespread adoption of blockchain. The Enterprise Ethereum Alliance (EEA), the International Organization for Standardization (ISO), the standardization sector of the International Telecommunications Union (ITU-T), the World Wide Web Consortium (W3C), and the Society for Worldwide Interbank Financial Telecommunication (SWIFT) carried out notable efforts in this regard.

5.2.3 Skepticism in Blockchain Technology. Many current research works are raising concerns about the practical adoption of blockchain technology in the industry. Some of their concerns include how to ensure the reliability of data from the participating entities and/or sensors [90] considering the connection between the physical and digital world, latency issues with the increasing number of nodes in the network [32, 64], lack of information leading to the existence of gray markets [5], security concerns due to quantum computing [24], lack of privacy and GIGO problem [4], decision paralysis due to information overload, high energy consumption [95], throughput and latency issues [50], lack of standardization and shifting to new infrastructure from legacy systems [77], etc. [80]. Paradoxically, blockchain technology supports the full gamut of industrial applications while struggling to address such challenges.

Additionally, problems stemming from the blockchain “black-box” nature force consumers to trust the integrity and fairness of the processes without understanding the technical underpinnings. Innovation hubs and maker spaces organize webinars, workshops, tutorials, and certifications that can enable the teams to learn blockchain technology and explore its use-cases in their respective areas, for example, learning platform provided by IBM [37].

5.3 Social Issues

There are several risks involved with the proliferation of the blockchain and DTs on an individual level which eventually summed up as issues in their integration. In the following, we discuss the social challenges faced by the integration of blockchain-based DTs.
5.3.1 Ethical and Legal Issues. Due to industry rivalry, companies often do not want to share commercially sensitive information with their competitors. Moreover, commercial pressures dissuade companies from sharing models, smaller firms lose out, resulting in monopolies or oligopolies. For instance, giant companies such as Siemens, GE, IBM, etc. own most of the DTs. Additionally, on one hand, due to a lack of common space between academia and industry, data scientists, cybersecurity experts, engineering, and business strategists cannot communicate and share knowledge and software. On the other hand, researchers and practitioners patent or even hoard knowledge, ensuing limited access to the data. Such problems call for a platform managed by government funding agencies, consortia of private corporations, or by a coalition of universities to reconcile issues about data governance, data ownership, and openness [83]. In this regard, a close-knit team of specialists spanning disciplines should collaborate, build precise DTs, and share data and models on a public database for widespread usage. Currently, such examples include openVertebrate (share data and models of vertebrate anatomies), Siemens NX software (package design, simulation, and manufacturing tools), LlamaZOO (develop interactive 3D visualization, digital twinning, and training solutions for Industry 4.0 through VR/AR), and IBM Model-Based Systems Engineering (streamline product design and development). Some of the open challenges such as how to resolve the ownership rights in scenarios related to DTs of retired or former human workers, or regulations for using healthcare data with consent and anonymously, still need to be addressed. Also, these challenges motivate the design of blockchains for DTs that protect sensitive information while providing sufficient transparency.

5.3.2 Environmental Impact. Inefficient by design, blockchain consensus protocols are considered the Achilles’ heel in terms of energy constraints. The high cost incurred on the consensus phase is due to massive electricity consumption in performing compute-intensive mining phase (running cryptographic algorithms); draws a worrying figure for energy footprints. For example, with an estimated energy expenditure of almost 10 TWh, Ethereum matches the total energy consumption of some nations [17]. To curtail such an impact on the environment, possible solutions involve switching from energy-hungry to less power-consuming consensus mechanisms, such as TreeChain [20] or deploying blockchains featuring miner-free solutions, such as IOTA [63, 78].

6 CONCLUDING REMARKS

Due to the involvement of multiple entangled entities and on-going intricate industrial processes, industries have to consider several challenging factors for maximizing their revenues, such as cost management, risk prognosis, and improving efficiency. Therefore, to maximize industrial efficiency, one of the promising solutions is to create a digital twin that mirrors every facet of the underlying system or process in order to analyze, predict, and optimize all operations before its real-world implementation. Driven by data collected and accessed from heterogeneous data sources and data silos owned by multiple participating entities calls for a secure distributed infrastructure. In this regard, leveraging blockchain allows industries to manage data on a distributed ledger that securely records product lifecycle data management events. Thus, DTs improve system maintenance by focusing more on preventing problems rather than on solving problems while blockchain provides the creation of secure DT frameworks.

In this survey, we have conducted a detailed and comprehensive review of the design and implementation issues of the current state-of-the-art blockchain-based DTs solutions in the industry. Furthermore, we also identified a set of future research and deployment challenges with an open-ended discussion in the adoption of blockchain-based DTs by the industry. We conjecture that this survey provides close insights to researchers
to overcome the challenges and pave the way for the standardization of blockchain-based DTs in industrial applications.
