(Dated: March 23, 2021)

We discuss properties of interacting spinless fermions in a tilted optical lattice as modeled by Heisenberg spin chain in magnetic (or electric) field changing linearly across the chain. The system shows genuine features of strong localization for a sufficiently large tilt with distinct features different from disorder induced localization. In particular, Stark many-body localization is characterized in time dynamics by a linear increase of the entanglement entropy followed by a saturation at a constant, time independent value – both the number (classical) and the configuration (quantum) entropies saturate to a constant value. Similarly, the correlation with the initial state (the so called imbalance) stabilizes at a constant value (modulo large fluctuations coming from short time Bloch-type oscillations). The presence of an additional harmonic potential profoundly affects the dynamics of the model – its behavior resembles standard MBL characteristics – the logarithmic growth of the entanglement entropy in particular. In that case, we find strong revival phenomena associated with the manifold of equally spaced states, degenerate in the absence of the harmonic potential.

I. INTRODUCTION

Many-body localization (MBL) became a well established property of interacting many-body systems in sufficiently strongly disordered potentials. Seminal works [1, 2] started a chain of research resulting in hundred of research papers (to see some of the early works, consult [3, 4]) partially summarized in recent reviews [5–8]. In a single sentence, MBL is proposed as a robust counterexample to thermalization, localization is supposed to lead to the memory of the initial state in the closed system and is in violent contradiction with earlier advocated eigenstate thermalization hypothesis [9, 10]. Yet, a recent work [11] put the very existence of MBL in the thermodynamic limit in question stimulating an intensive debate [12–17] mainly based on results coming from exact diagonalization studies. The second approach considers time-dynamics with matrix product states methods [18–23]. The claims on the transition to MBL proposed in these approaches mimic experimental scenarios [24, 25] addressing long time dependence of certain correlation function (the so called imbalance, see below). Still these claims are of limited value due to finite systems sizes and, importantly, rather short evolution times taken into consideration, limited by the numerical methods based on time dependent variational principle (TDVP) mostly.

On the other hand, recent years brought several examples of strongly nonergodic behavior for specific initial states. For interacting Rydberg atoms dynamics pronounced long-time oscillations related to the so called scar states [26, 27] were observed. Nonergodic dynamics is being traced back to Hilbert-space fragmentation [28–31], and lack-of-thermalization in gauge theories [23, 32, 33] even in the absence of disorder.

Another prominent example considers Stark localization – where the presence of a static electric field resulting in a tilt in the many-body system may lead to localization as discovered recently [34, 35]. Both works, studying level statistics as well as the time dynamics of the imbalance, stress the similarity of the observed localization to standard disorder driven MBL despite the lack of any disorder in the system. Those observation was supplemented in [35] by the observation of logarithmic in time entropy growth for initial separable states. The authors of these works importantly realized, by a careful analysis of gap ratio statistics, a peculiarity of the constant tilt of the lattice problem where many exact degeneracies of the interaction-free system affect the statistical properties of levels even in the interacting case. To overcome this peculiarity, an additional harmonic potential was added to the system. This issue has been further analyzed in [36] where several possible experimental measures for Stark MBL (SMBL), in particular the DEER strategy, are discussed. It is pointed out that a pure linear tilt leads to an emergent conservation of the global dipole moment in the large field limit and relates the physics in tilted lattices to fractonic models [28, 29, 37]. This work ([36]) also extends the study of SMBL to bosons (see also [38]). The role of the harmonic confinement was further analyzed in [39] where it was shown, in particular, that a smooth site-dependent chemical potential leads to an effective local static field related to the derivative of this potential with respect to the spatial dimension. Thus adding a harmonic potential to a static tilt leads, in a mean field approximation, to a site-dependent modification of the electric field.

Experimentally, SMBL was studied on superconducting quantum processor [40] emulating a spin-1/2 chain in a triangular ladder. A significant insight has been provided by a recent experiment [41]. Characteristically, the experiment involves spinful fermions with spin-dependent...
tilt, more challenging for simulations yet easier achievable experimentally than the spinless fermion case. It was shown that the SMBL leads to a remarkable memory of the initial state with the imbalance that practically does not decay in time. This model immediately attracted the interest on the theoretic side with a recent suggestion of the existence of scarred states in the strong interaction limit [42]. SMBL was studied experimentally on superconducting quantum processor [40] emulating a spin-1/2 chain in a triangular ladder. To complete the picture, let us also note that SMBL is also addressed recently for open systems [43].

On the other hand, the tilted lattice, due to shattered Hilbert space [28, 29], supports long-lived nonergodic states in form of extended domains as pointed out in [44] also for relatively small tilt when the majority of separable initial states thermalizes fast. Their existence may be traced back to a peculiar feature of the Heisenberg model – the domain containing spins with the same orientation (up or down oriented spins) is practically frozen in the dynamics for the time dependent on the length of the domain. So local thermalization occurs at domain wall only [44, 45].

As revealed by this, already quite long introduction, last two years brought a lot of insight into the disorder-free SMBL. The aim of this work is to clear some misunderstandings about the SMBL and to provide a physical picture of it. In particular, we point out strong differences that exist between SMBL and the standard MBL induced by disorder. We show that the entanglement entropy growth starting from an initially separable state is linear in time in SMBL until a saturation level is reached. This is in contrast to MBL where a characteristic logarithmic growth of the entanglement entropy till the saturation level is a real hallmark of the phenomenon [46]. This result is obtained both for small system sizes via an exact diagonalization as well as for large systems with TDVP. While the imbalance (to be defined in the next section) slowly decays in MBL (the power of this decay was used recently to estimate the MBL crossover limit [21, 23]) we show that in SMBL it really saturates to a finite value for finite system sizes as shown also qualitatively in [34–36]. Thus the unsolved vivid debate about the fate of MBL in the thermodynamic limit [11–17] becomes irrelevant for SMBL which seems to survive the thermodynamic limit.

Adding the additional weak harmonic potential on top of the constant tilt markedly affects the dynamics of the system. Then, at intermediate times a logarithmic growth of the entanglement entropy is indeed observed, as in disorder-driven MBL. Such a harmonic confinement modifies the local tilt of the lattice. Whether this similarity to standard MBL is related to the fact that emerging global dipole conservation for a tilted lattice (or quadrupole conservation for purely harmonic potential [28, 30]) is broken still remains an open question.

II. THE MODEL

We consider a standard system in MBL studies, namely the one-dimensional (1D) Heisenberg spin chain with the Hamiltonian

\[ H = J \sum_{i=0}^{L-1} \vec{S}_i \cdot \vec{S}_{i+1} + \sum_{i=0}^{L} \mu_i S_i^z, \]  

with \( \vec{S}_i \)'s being spin-1/2 operators and \( \mu_i \) being the on-site potential. In typical MBL studies [7, 13, 47, 48], \( \mu_i \) is a diagonal disorder (a magnetic field along z-axis) drawn from random uniform distribution. We consider instead \( \mu_i = F l + A l^2 / L^2 \) where \( F \) is the magnitude of the linear tilt and \( A \) is (twice) the curvature of the additional harmonic potential. Note that while for \( F = 0 \) case it may be convenient to center the harmonic potential with respect to the chain (so it forms a confining potential [38, 39]). Here we follow a different setting following [35, 36]. We also set \( J = 1 \) as the energy unit.

We consider time dynamics starting from the initial Néel state with every second spin pointing up, and every second down (remaining in the conserved total \( S^z = 0 \) sector). While [35] averaged the dynamics over different possible states, we choose the Néel state that corresponds, after Jordan-Wigner transformation, to an equivalent density wave state with every second site being occupied and other being empty in the spinless fermion representation in analogy to the experimental situation [25]. This also allows us to avoid states with extended domains [44, 45] that may results in atypical localization due to frozen spins.

We characterize the state of the system by considering the spin correlation function which, for the Néel state, is equivalent to the imbalance of occupations between odd and even sites in the fermionic picture:

\[ I(t) = \frac{N_o(t) - N_e(t)}{N_o(t) + N_e(t)} = \frac{4}{L} \sum_{l} \langle \vec{S}_l^z(t) \rangle \langle \vec{S}_l^z(0) \rangle, \]  

where \( N_i, i = o, e \), denote the total occupation of even and odd sites. We use also the entanglement entropy in the middle of the chain by splitting the system in two parts A and B of equal length \( L/2 \). Defining the reduced density matrix \( \rho_A = \text{Tr}_B |\psi\rangle \langle \psi| \) where \( |\psi(t)\rangle \) is the time evolved state of the system, the entanglement entropy reads \( S = -\sum_i \lambda_i \ln(\lambda_i) \) where \( \lambda_i \) are the eigenvalues of \( \rho_A \). Interestingly, the entanglement entropy may be split into the sum of classical number entropy \( S_N \) and the quantum configuration entropy \( S_C \): \( S = S_N + S_C \) [49, 50] with

\[ S_N(t) = -\sum_{n=0}^{N} p_n \log(p_n) \]  

\[ S_C(t) = -\sum_{n=0}^{N} p_n \sum_{i} \rho_i^{(n)} \log(\rho_i^{(n)}). \]
where we denoted by $p_n$ the probability of populating the $n$-particle sector in subsystem $A$ and by $\rho^{(n)}$ the corresponding block of the density matrix $\rho$ for the subsystem $A$, such that $\rho = \sum_n p_n \rho^{(n)}$. The number entropy describes a real transfer of particles between the subsystems considered and the configuration entropy, $S_C$, quantifies the possible arrangements of particles on each side of the system.

III. SMALL SYSTEM SIZES

Let us start with small systems of size up to $L = 16$ amenable to exact diagonalization. In fact, for a pure deterministic potential no averaging over disorder realizations as in case of random potentials is possible. Thus we have, at our disposal, single realization which may be diagonalized or propagated in a quasi-exact fashion with Chebyshev propagation scheme [51, 52] up to $L = 22$ easily for very long times. Such systems are discussed here while the large system sizes are postponed to the next Section. As announced in the previous section we consider the time dynamics of the Néel initial state. Fig 1 shows a typical imbalance as a function of time for a few values of the static tilt, $F$. Observe quite large fast changes of $I(t)$ which reflect short range jumps of fermions (spin flips in the spin language) between nearby sites. Similar fast oscillations are typically averaged out via disorder averaging in MBL studies – here we consider a disorder free system and single realizations show pronounced fast oscillations. To get the information beyond these rapid changes we apply a high frequency filter that effectively averages our fast oscillations. The filter smoothly cuts out large frequencies in the Fourier transform of the signal. The effective, time-averaged signal is also shown in Fig. 1. After an initial transient regime, the imbalance saturates quite fast to non-zero values indicating nonergodic dynamics.

Let us now add to the chemical potential an additional harmonic term leading to $\mu_l = Fl + Al^2/L^2$. Observe that a simple mean field [53] reasoning would lead to an effective local field being $F_{loc} = F + 2Al/L^2$. For positive $A$, the more to the right a given site is, the stronger local field it feels. Thus, since for a static $F$, the imbalance increases with $F$ one expect the similar behaviour as a function of $A$ for a constant $F$ - compare Fig. 2 – indeed such a trend is observed.

More surprising and instructive is the analysis of the entanglement entropy. Here we consider mostly the strongly localized case for $F >> 1$ and split the entanglement entropy as described in the previous section into the classical and quantum components. Before doing so let us recall that one of the hallmarks of MBL is the logarithmic growth of the entanglement entropy for initially separable states [46, 54]. Fig. 3 shows that the growth

FIG. 1. The imbalance as a function of time for $L = 16$ at few values of the static tilt $F$ as indicated. The imbalance shows large fast oscillations – the thick lines are obtained by filtering out high frequencies in the time signal.

FIG. 2. The final imbalance dependence on the curvature $A$ of the harmonic potential added on top of the linear tilt $F$. An added harmonic potential adds an effective local field growing along the chain leading to the growth of the imbalance with $A$.

FIG. 3. The entanglement entropy between left and right half of the system for $L = 16$ as a function of time for pure tilt with different $F$ values as indicated. Fast initial growth is followed by a saturation. As before, the thick lines represent the filtered data after applying a low-pass filter in the frequency domain.
of the entanglement entropy for SMBL is quite different. Firstly, as for imbalance we observe strong oscillations. Those have been avoided in [35] by considering initial states with the same occupations at the cut defining the calculated entanglement. We prefer to consider the Néel state as an initial state and filter out fast oscillations. After averaging them out using high frequency cut-off filter, we observe that the entropy growth is not logarithmic but rather linear. Then the growth saturates at $F$-dependent value at a relatively short time. This behavior is different from MBL as noted already earlier [35, 36].

Let us analyse this growth in more detail considering different entropy components, the classical, number entropy $S_N$ and the quantum, configuration entropy $S_C$. It is the number entropy that strongly fluctuates, especially in the localized regime. It is quite understandable as even in a localized situation one may expect a fast nearest neighbor spin flipping (particle transfer in the fermionic language). The resulting behavior in the localized regime is depicted in Fig. 4. We observe a clear three stages for low value of $F$: the initial transient is followed by the log-growth and eventually a saturation. For higher $F$ values the log phase of the growth is practically absent.

The saturation of the number entropy at later times makes the localization observed distinctly different from disorder induced MBL where a very slow $S_N(t) \sim \ln(\ln t)$ is observed [55, 56].

The quantum, configuration part of the entanglement entropy behaves in a more spectacular way - c.f. Fig. 5. For a pure constant tilt ($A = 0$) we observe two stages – a fast linear growth is followed by a saturation at the $F$ dependent level. In the presence of an additional harmonic potential the configuration entropy growth slows down showing an almost perfect logarithmic growth at large $A$. Thus the quantum part of the entanglement entropy also reveals that the SMBL is different from a standard MBL. The initial linear growth seems to be a manifestation of the short time spreading of the initial Néel state within the quasi-degenerate (exactly degenerate in the $F \rightarrow \infty$ limit) manifold consisting of eigenstates with the same local dipole moment $D = \sum F_i S_i^z$ [35, 36, 57]. This degeneracy is removed by the additional harmonic term in the potential.

The apparent change of the character of time growth of the configuration entropy for pure tilt and in the presence of an additional harmonic potential suggests strongly that the harmonic trap does not only contribute a local, site dependent field – the interpretation we used explaining qualitatively the results presented in Fig. 2 – similar idea underlined the explanation of the localized and delocalized phase separation in a harmonic trap [53] (see also [57]). Our small system allows for a detailed analysis of this concept. To this end, we look first at the time dynamics of configuration entropy at the central bond in Fig. 6 where the tilt $F$ and curvature $A$ are chosen in such a way to assure the same $F_{loc} = 6.5$ at the central bond. Note that $A$ is sufficiently small to modify the field at a given site by at most by 10%. Yet the time dynamics of the configuration entropy at this bond is strongly different in the presence and in the absence of the harmonic potential. For pure tilt we observe (again) a fast linear growth followed by a saturation, while the presence of a sufficient harmonic potential leads to MBL-like logarithmic in time growth of the entanglement entropy.

Moreover one can also observe that the configuration entropy growth for positive and negative $A = \pm 4$ are very similar. Inspecting the bond resolved data at long times $t > 10^5$ we find the same trend across all the bonds, not just the central one. For $A = 0$ the behavior is consistently different indicating that the presence of absence of the harmonic part has a huge importance for
the growth and dynamics of the entanglement across the system. Thus the “local field” concept is not applicable in that case.

Let us note that we have checked that the differences observed are not limited to total $S_z = 0$ sector for which one may expect that a particle-hole symmetry affects the dynamics. Removing one or two particles around the center or at other place in the chain does not modify the observations reported.

IV. LARGE SYSTEMS

The study of larger systems is possible entirely within the necessarily approximate time-dynamics schemes such as time-evolving-block-decimation (TEBD) [58], time-dependent density matrix renormalization group tDMRG [59], or more recent numerical schemes based on time dependent variational principle (TDVP) [60–62]. The early studies involved TEBD [58, 63–65] that allowed for relatively efficient simulation of interacting systems also in the context of MBL [18–20, 66]. Recently TDVP was used by the Karlsruhe group to estimate the onset of MBL in large systems [21, 67] – for a discussion see [68]. The latter work critically inspected applicability of TEBD and TDVP for accurate description of time-dynamics in systems of realistic size. In this work, we mostly use a hybrid variation of the TDVP scheme [23, 62, 68, 69], where we first use two-site version of TDVP. At this stage the (auxiliary) bond dimension grows up to a prescribed $\chi_{\text{max}}$ value. Reaching $\chi_{\text{max}}$, we switch to the one-site version (avoiding errors due to a truncation of singular values in the two-site version [62, 69]). Typically for large $F$, in the localized regime, we often do not reach $\chi_{\text{max}}$ so the simulations are fully converged (up to numerical errors). For TEBD we use an efficiently parallelized home made package that utilizes the recent breakthrough for Lie-Trotter-Suzuki decomposition [70].

Disappointingly, the execution times needed for propagation using TDVP of realistic system sizes in a static tilt case were found empirically to be quite long compared to disordered scenarios. This may be related to the fact the in presence of static fields the energy levels of the Hamiltonian are spread covering a broad range of energies and local Lanczos exponentiations in the TDVP scheme require large Krylov space to converge. On the other hand the simulations, in the absence of disorder, require just a single run, with no disorder averaging. That, with a necessary patience, allows us to study system sizes and times unprecedented till now.

To test the accuracy of our studies we compare the simulations performed with TDVP, where due to the sweeping procedure, an efficient parallelization of the code seems difficult, with TEBD where such a parallelized code with higher order Suzuki-Trotter scheme is possible. Fig. 7 shows that the imbalance evolution in time for a state in the localized regime is essentially the same using TDVP and TEBD propagation schemes. Since, as shown in [68] TEBD overestimates the imbalance while TDVP underestimates it, the agreement of both schemes assures that the results obtained are fully converged. Note that even deep in the localized regime we have to use slightly larger auxiliary space dimension for TEBD, as described in the caption of Fig. 7 - the possible growth in the execution time is compensated by efficient parallelization possible for TEBD. Note also that we do not observe any sign of the accumulated Trotter errors which haunts TEBD implementation [63] – presumably because of high order decomposition used [70].

The large system studies presented by us have two main aims. One of them is to show that indeed SMBL occurs for large system sizes with properties similar to that described above for smaller systems, in particular the approximately linear growth of the entanglement entropy. Secondly we intend to study in detail the effect of an additional harmonic potential – large systems allow us for novel observations – we shall discuss in detail the quantum revivals observed in the imbalance and the entanglement growth (see below).

Consider first the “experimental” evidence for SMBL i.e., the existence of a non-zero imbalance at large times indicating the preservation of the memory about the initial state of time evolution. The imbalance at saturation occurring at large times is presented in Fig. 8. The data are averaged over quite large time interval to wash out the rapid oscillations of the time-dependent signal (as shown in the inset). Data are obtained with TDVP with $\chi_{\text{max}} = 512$. The errors indicated in the figure are due to these fast oscillations and are standard statistical errors. The data indicate that the crossover to delocalized phase appears at $F \approx 1$, in agreement with the data for small system sizes obtained from level statistics [34, 35]. One should, however, keep in mind that the accuracy of long time TDVP simulations close to the transition deteriorates so the critical $F$ value should be taken with caution as the result of the compromise in the numerics between duration of the time propagation and the limitation on the assumed auxiliary space dimension, $\chi_{\text{max}}$.

The corresponding entanglement entropy growth on the middle bond are shown in Fig. 9. Strong high frequency oscillations can be averaged out leading to solid lines. Two time-regimes may be clearly identified. The first is the region of a linear growth of entropy with time which extends to larger times for bigger $F$. The second regime, for sufficiently long times and larger $F$ corresponds to an apparent saturation of the entanglement entropy. Data for $F = 3$ and larger clearly saturate while for lower $F = 2$ we observe a fast linear growth for short times followed by a slow linear drift without saturation. We cannot determine whether this drift is linear or logarithmic in time due to a limited time span and small changes of the entropy.

For even stronger tilts $F$ the entropy reveals relatively larger fast oscillations as shown in Fig. 10. It is the classical number entropy which is responsible for oscillations
in the localized regime. It is thus related to a transfer of a single particle across the analyzed bond and is similar in its origin to Bloch oscillations. On the other hand, the quantum part of the entanglement entropy, the configuration entropy, shows smooth practically linear increase in time with a slight bending upwards. Note that for large $F = 6$ value shown, this growth is quite small in the absolute sense. Still the growth has no logarithmic character postulated for a genuine MBL phase.

Let us inspect in more detail the influence of the harmonic bending on this entanglement growth. Fig. 11 shows that the presence of the harmonic trap significantly changes the fast linear growth followed by saturation into the logarithmic MBL-like growth.
Entropies $S_I(t)$, $S_C(t)$

FIG. 10. Time dependence of the entanglement entropies in the localized regime. The classical part, the number entropy reveals fast oscillations corresponding to the single particle transfer across the bond studied. Configuration (quantum) entropy is growing in time at least linearly with little fluctuations. This behavior is the characteristic for a constant tilt case. Here we choose $L = 50$ and $F = 6$.

Sloows down the configuration entropy growth (similarly to the behavior of small systems – compare Fig. 6. As described in the caption of the figure, the slow-down of the entropy growth appears for both positive and negative curvature $A$ showing that a simple local mean field description [39] does not, even, approximately work as far as time evolution of entanglement entropy is concerned. Despite the fact that we are deep in the localized regime ($F = 6$) the dynamics on a given bond is not local and is affected by other nearby bonds.

Observe also that the configuration entropy shows significant slow (large period) oscillations on top of the slow growth. These oscillations are related to the similar behavior observed in the time dependence of the imbalance as presented in Fig. 12.

That figure shows the time dependence of the imbalance for different system sizes and different curvatures of the harmonic potential. Since $F = 10$ is quite large imbalance saturates very fast at the high value about 0.98 showing, however, regular revivals. We have verified that the period of the revivals does not depend of $F$, the resulting curves are similar for $F = 6$ or $F = 4$ at different saturation level. For each system size the $A$ value is chosen in such a way that a local field at the end of the chain is increased from $F_{loc} = 10$ to $F_{loc} = 11$. To a good precision the the period of the revivals equals $T = \pi L^2 / 2A$ as if corresponding to equally spaced levels with spacing $\omega = 2\pi / T = 4A / L^2$. Indeed by a direct evaluation (calculations were performed at small $L = 12, 14$ sizes) one may check that the (quasi)degenerate (for $A = 0$) manifold of states having the same global dipole moment $D$ splits in the presence of the additional harmonic potential of curvature $A$ into the set of almost equally spaced levels with the spacing $\omega / 2$. However, only every second state

in this manifold has a non-zero overlap with the initial Néel state contributing to the dynamics – thus indeed the relevant spacing is equal to $\omega$. Another important point to note is that since the emerging dipole conservation becomes exact only in the large $F$ limit, such revivals with period $T = \pi L^2 / 2A$ become more pronounced with increasing $F$. Of course the observed phenomenon

FIG. 11. Quantum configuration entropy reveals that the picture of “local field” resulting from a harmonic bending of the tilt has limitations also for large system sizes. All three curves correspond to the configuration entropy on the central bond $b = 25$ of the $L = 50$ chain for the same tilt $F = 6$ but different curvatures. The configuration entropy grows fast in (super)linear fashion for $A = 0$. The growth is suppressed for both positive $A$ (leading to the “local mean” field of $F_{loc} = 6.8$) as well, as surprisingly for negative $A$ (local field $F_{loc} = 5.2$). Since higher local tilt does not corresponds to lower entanglement entropy, the result shows the breakdown of the local field picture and the importance of the emergent global conservation of dipole moment for the early state evolution of the entanglement, which is in agreement with small system size data.

FIG. 12. The imbalance for large $F = 10$ and the additional harmonic potential saturates at a constant value revealing, however, pronounced revivals that occur at the period $T = \pi L^2 / 2A$ as shown for different system sizes. The revivals are due to splitting of the (quasi)degenerate total dipole manifold in the presence of a harmonic addition to the potential. For further discussion see text.
has nothing to do with many-body quantum scars which may occur in the delocalized regime (see e.g., the proposition in tilted Fermi-Hubbard model [42]) - the regularity observed here appears in fully localized regime and is related to breaking of the global dipole conservation law.

V. CONCLUSIONS

We performed a detailed analysis of localization in disorder-free potentials considering both the pure static field and the system with an additional weak harmonic potential. We have studied both small system sizes where exact diagonalization and Chebyshev propagation enables accurate results for very long times as well as large systems studied with the help of matrix product states algorithms. By a detailed analysis of the entanglement entropy we have verified that the character of localization in pure static field is different from standard disorder induced MBL, in particular a fast initial growth of the entanglement entropy in a static field followed by a full saturation is different from the logarithmic growth known from MBL. Similarly while the number entropy may occur in the delocalized regime, in fully localized regime, in the appearance of the characteristic revivals in the imbalance.

ACKNOWLEDGMENTS

This work benefited from the invaluable input of Dominique Delande who contributed dominantly to the TEBD parallelized code applied. Equally important were discussions with Piotr Sierant on various aspects of this work. We acknowledge both contributions. The numerical computations have been possible thanks to High-Performance Computing Platform of Peking University as well as PL-Grid Infrastructure. The TDVP simulations have been performed using ITensor library (https://itensor.org). This research has been supported by National Science Centre (Poland) under projects 2017/25/Z/ST2/03029 (T.C.) and 2019/35/B/ST2/00034 (J.Z.)
