Hilbert space shattering and disorder-free localization in polar lattice gases

Wei-Han Li,† Xiaolong Deng,† and Luis Santos‡

†Institute of Theoretical Physics, Leibniz University Hanover, Germany

Emerging dynamical constraints resulting from inter-site interactions severely limit the mobility of polar lattice gases. Whereas in absence of disorder hard-core Hubbard models with only strong nearest-neighbor interactions present Hilbert space fragmentation but no many-body localization for typical states, the \(1/r^3\) tail of the dipolar interaction results in Hilbert space shattering even for moderate interaction strengths, that leads to interaction-induced many-body localization. At half-filling, shattering just requires strong-enough next-to-nearest-neighbor interactions. Our results show that the study of the intriguing interplay between disorder- and interaction-induced many-body localization may be within reach of future experiments with magnetic atoms and polar molecules.

Recent years have witnessed a considerable attention on the dynamics of many-body quantum systems, a rich topic with both fundamental and practical relevance \([1, 2]\). Most quantum many-body systems are believed to thermalize as a consequence of the eigenstate thermalization hypothesis \([3–6]\). Prominent exceptions to this paradigm include integrable systems \([7]\) and many-body localization (MBL) in disordered systems \([8–10]\). Progress on MBL has been recently followed by interest on MBL-like phenomenology in absence of disorder \([11–28]\). Disorder-free localization occurs naturally due to dynamical constraints \([29–31]\). These constraints, which result in a finite number of conservation laws, induce Hilbert space (HS) fragmentation into disconnected subspaces that severely limits the dynamics \([32–38]\). HS fragmentation is also closely connected to quantum scars \([39]\).

Ultra-cold gases in optical lattices or reconfigurable arrays provide a well-controlled scenario for the study of many-body dynamics, including MBL \([40, 41]\), and quantum scars \([42]\). Recent experiments on tilted Fermi-Hubbard chains \([25]\) and in a trapped-ion quantum simulator \([27]\) have provided evidence of non-ergodic behavior in absence of disorder, unveiling the potential of ultra-cold gases for the study of disorder-free MBL and HS fragmentation. It is hence particularly relevant to find other promising ultra-cold scenarios for the study of fragmentation due to interaction-induced constraints. As shown below, polar lattice gases are a natural candidate.

Power-law interacting systems have been the focus of recent breakthrough experiments, including trapped ions \([43, 44]\), Rydberg gases \([42, 45]\), and polar lattice gases of magnetic atoms or polar molecules, with strong magnetic or electric dipole-dipole interactions (DDI). Experiments on polar lattice gases have already revealed inter-site spin-exchange in both atoms \([46]\) and molecules \([47]\), and realized an extended Hubbard model (EHM) with nearest-neighbor interactions \([48]\). These experiments have started to unveil the fascinating possibilities that inter-site DDI open for the quantum simulation of a large variety of models \([49]\). MBL in disordered spin models with power-law Ising and exchange interactions has attracted a growing attention in recent years \([50–57]\), and, very recently, disorder-free Stark-MBL has been revealed in trapped ions with long-range spin-exchange \([27]\). Inter-site interactions result as well in an intriguing dynamics in EHM \([58–65]\). In particular, nearest-neighbor (NN) dimers significantly slow-down the dynamics in one-dimensional (1D) polar lattice gases, and may induce quasi-localization \([15, 61]\).

In this Letter we show that strong-enough DDI lead to HS shattering, i.e. fragmentation into an exponentially large number of localized subspaces \([36]\). Especially relevant is the \(1/r^3\) tail of the DDI. In the absence of any tilting or overall potential, disorder-free systems with only NN interactions present HS fragmentation due to the conservation of the number of occupied NN bonds, but this does not result in MBL for typical states due to resonant motion \([32]\). The dipolar tail induces additional dynamical constraints for growing dipole strengths that disrupt resonant motion. Our study of localization as a function of disorder and dipole strength, shows that at half filling it suffices another emerging conservation law, that of occupied next-to-nearest neighbor (NNN) bonds, to induce HS shattering. As a result, interaction-induced disorder-free full MBL (FMUBL), or at least strong partial MBL (PMBL), results for a critical dipole strength within reach of future experiments in polar lattice gases.
Model. We consider a 1D polar lattice gas of hard-core bosons [66] well described by the EHM:

\[ H = -t \sum_j (b_j^\dagger b_{j+1} + \text{H.c.}) + \sum_j \epsilon_j n_j + \sum_{i<j} V_{ij} n_i n_j, \]

where \( V_{ij} = \frac{V}{|i-j|^n} \), \( b_j(b_j^\dagger) \) is the annihilation (creation) operator at site \( j \), \( (b_j^\dagger)^2 = 0 \), \( n_j = b_j^\dagger b_j \) the number operator, and \( t \) the hopping amplitude. The random on-site energy \( \epsilon_j \) is uniformly distributed in the interval \([−W, W]\). Our results are based on exact diagonalization of Eq. (1)

**NN model.** In order to assess the relevance of the dipolar tail, we first review the NN model, with \( V_{ij} = W_1 \delta_{j,i+1} [32, 67] \). In this model, a dynamical constraint emerges for growing \( V/t \), becoming exact for \( V \rightarrow \infty \), given by the conservation of the number of NN bonds, \( N_{\text{NN}} = \sum_j (n_j n_{j+1}) \). As a result, the HS fragments, constraining the dynamics of initial Fock states (FSs). Crucially, although isolated clusters of \( s \) consecutive occupied sites move only in \( s \)-th order, i.e. with \( s^s/V^{s+1} \), and are thus strictly immobile at \( V = \infty \), hoppings \( b_j^\dagger b_{j+1} \) may occur if \( n_{j+2} = n_{j−1} \). A cluster can hence move by two sites to the right (left) through a sequence of resonant particle moves if it encounters a singlon (i.e. an occupied site without nearest neighbors) moving from the right (left): \( |\ldots\bullet\ldots\bullet\ldots\rangle \rightarrow \ldots |\ldots\bullet\ldots\bullet\ldots\rangle \). For open boundary conditions (OBC) this mechanism eventually delocalizes the center of mass of an arbitrarily long cluster in a region \( j_0 + 2N_R < j < j_0 + 2N_L \), with \( j_0 \) the initial cluster position, and \( N_R \) (\( N_L \)) the number of singlons initially at its right (left). If the singlon density is finite, i.e. if the number of singlons scales with the system size \( L \), the clusters delocalize in a region that grows with \( L \). As a result, MBL at vanishingly small disorder is prevented for typical states even for \( V = \infty \) [32].

Fragmentation. HS fragmentation is analyzed as follows [68]. We obtain for \( W = 0 \) the eigenstates \( \{|\alpha\rangle = \sum_f \psi_\alpha(f)|f\rangle \rangle \) where \( |f\rangle = \prod_{l=1}^L n_l(f) \rangle \rangle \) are the FSs with population \( n_l(f) = 0 \) in site \( l \), and \( N = \sum_{l=1}^L n_l \). Given an eigenstate \( \{|\alpha\rangle \)\), we determine the FSs contributing to it (up to a threshold \( |\psi_\alpha(f)| > t^2/V \)). We then determine the eigenstates with significant support on those FSs, and iterate by proceeding similarly with each of those eigenstates. Convergence is achieved after few iterations. In this way we determine the blocks of FSs connected with each other, and the block of eigenstates with support on them. We order the FSs and the eigenstates such that connected states are bunched in consecutive positions. For large-enough \( V/t \), this procedure provides at \( W = 0 \) the size of the Krylov subspace [11, 37] that would connect to a state \( |f\rangle \) if allowed an infinite time. Since even very weak coupling (in high-order in perturbation theory in \( t/V \)) admixes many-body states with degenerate energies, this procedure may significantly overestimate the Krylov subspace necessary to describe the evolution of a given FS for a finite time, since for finite times some states in the blocks did not yet connect.

Figure 1(a) shows our results for an NN model with \( N = 6, L = 12, W = 0, V/t = 50 \), and OBC. HS fragmentation is obvious. Dashed lines indicate states with the same \( 0 \leq N_{\text{NN}} \leq 5 \). The block with \( N_{\text{NN}} = 5 \) (barely visible in Fig. 1(a)) contains for \( V \rightarrow \infty \) frozen states with a 6-particle cluster, and hence no singlon. With periodic boundary conditions (PBC), the block with \( N_{\text{NN}} = 5 \) (also barely visible in Fig. 1(a)) consists of two frozen density waves (DWs), \( |\ldots\bullet\ldots\bullet\ldots\rangle \). With OBC, it contains 7 resonant states. Blocks with \( 2 \leq N_{\text{NN}} \leq 4 \) show sub-blocks, formed by states with different cluster distribution, disconnected under unitary dynamics.

**Localization.** We employ the inverse participation ratio (IPR) to analyze localization. In order to relate directly with experiments, in which FSs may be created using quantum microscope techniques, we evaluate the IPR in Fock space. For a given FS \( |f\rangle \) we define \( \text{IPR}_f = \sum_{\alpha} |\psi_\alpha(f)|^4 \). For an initial \( |f\rangle \), IPR provides the long-time survival probability of the many-body state \( |\psi(\tau)\rangle \) in the initial state, \( |\langle f|\psi(\tau \rightarrow \infty)|^2 \rangle \). Hence, strong localization is characterized by \( \text{IPR}_f \sim O(1) \).

We analyze localization in the NN model for growing \( W \) by comparing \( \text{IPR}_f \) with the effective HS dimension \( \Lambda_f \) for \( W = 0 \) of the particular FS. For \( V/t > 10 \), \( \Lambda_f \) equals the dimension of the HS sub-block. For \( V/t < 4 \), no fragmentation occurs and we hence fix \( \Lambda_f \) as the dimension of the whole HS. For \( 4 < V/t < 10 \), blocks with fixed \( N_{\text{NN}} \) develop, but the sub-block structure is not yet fully formed, and we hence set \( \Lambda_f \) as the dimension of the block of states with fixed \( N_{\text{NN}} \). Delocalized states present
IPR\_f \sim O(\Lambda_f^{-1}). We hence characterize the localization by the fractal dimension, \( D_f = -\ln(\text{IPR}_f)/\ln(\Lambda_f) \), where \( D_f \simeq 0 \) (\( D_f \sim O(1) \)) implies localization (delocalization) \[69\]. Note, again, that our procedure for determining the connected blocks underestimates, especially at low disorder, localization at finite times.

Localization as a function of \( W \) vary from sub-block to sub-block (and even within the same sub-block \[32\]). For a given \( V/t \) we determine for each sub-block the average \( \bar{D}_f \) finding the block with the largest \( \bar{D}^{\text{max}}_f \). For low filling factors, \( \bar{D}^{\text{max}}_f \) corresponds, quite naturally, to the block with \( N_{\text{NN}} = 0 \). Note that when \( \bar{D}^{\text{max}}_f \sim 0 \) the whole spectrum can be considered as localized. This procedure permits to establish approximately the critical disorder \( W_c \) for the onset of FMBL, or at least very strong PMBL. Figures 2(a) and (b) show, respectively, \( \bar{D}^{\text{max}}_f \) for a filling factor \( \rho = 1/2 \) and 1/4. For \( V/t \rightarrow 0 \), the system undergoes Anderson localization at vanishingly small disorder. For growing \( V/t \), the critical disorder \( W_c \) grows up to a maximal value and then decreases due to the reduced mobility of clusters, resulting in a re-entran shape, in agreement with Ref. \[67\]. However, \( W_c \) does not decrease to zero even for \( V \rightarrow \infty \) due to the above mentioned resonant swaps (our results for \( V \rightarrow \infty \) are in good agreement with Ref. \[32\]). Figure 3 shows for \( W/t = 0.025 \) the proportion of states with \( D_f < 0.4 \), which provides a good estimation of the statistical relevance of localized eigenstates. For \( V/t > 10 \), the number of localized states increases, saturating for \( V/t \gtrsim 20 \) at a small value, which vanishes at \( W = 0 \) (except for a very limited number of frozen states). For lower \( \rho \), the proportion of localized states is further reduced by the increasingly relevant role of states with \( N_{\text{NN}} = 0 \).

**Polar lattice gas.** – Whereas in the NN model a growing \( V/t \) just reinforces the conservation of \( N_{\text{NN}} \), in polar gases it leads to additional emerging constraints, starting with the conservation of NNN bonds, \( N_{\text{NNN}} = \sum_j (n_j n_{j+2}) \). For \( V \rightarrow \infty \) it seems intuitive that, even for \( W \rightarrow 0 \), all FSs become eigenstates, leading to a strictly frozen dynamics for any initial condition (there are however exceptions as mentioned below). More interestingly, however, is that disorder-free MBL (or at least very strong PBML) may be attained, especially at \( \rho = 1/2 \), at a finite \( V/t \) within experimental reach. This stems from the emerging conservation of \( N_{\text{NNN}} \) that prevents the resonant motion characteristic of the NN model, and that results in the formation of clusters of particles beyond NN, e.g. |...○○○○○○○...|. The severe constraint posed by the simultaneous conservation of \( N_{\text{NN}} \) and \( N_{\text{NNN}} \) only requires \( V/8 \gg t \), and, hence, the HS shattering and disorder-free MBL discussed below occurs for relatively moderate \( V/t \) values. For lower \( \rho \) one expects a larger critical \( V \) for strong disorder-free MBL. However, for lower \( \rho \), an additional mechanism provided by the dipolar tail becomes relevant: cluster motion is handicapped by even distant particles since the dipolar tail between clusters or clusters and singlons may outcompete the very low hopping rate \( t^s/V^{s−1} \) of \( s \)-particle clusters. Although, due to the small systems we consider, we cannot provide a detailed analysis of low \( \rho \), recent results on the dynamics of NN dimers suggest that strong disorder-free MBL should be attainable for \( V/t \sim 50 \) even for \( \rho \sim 0.2 \) \[61\].

The HS shatters, as depicted in Fig. 1(b) for \( N = 6 \), \( L = 12 \), \( W = 0 \), and \( V/t = 50 \). For \( V/t = 50 \), only the NN and NNN parts of the dipolar tail are relevant, but at \( \rho = 1/2 \) the emerging conservation of \( N_{\text{NNNN}} \) is enough to shatter the HS. HS shattering results in disorder-free localization. Following the procedure discussed above, we have obtained \( \bar{D}_f \) for the different FSs, employing the effective HS dimension \( \Lambda_f \) calculated for the clean NN model. As shown in Fig. 3, starting at \( V/t \sim 10 \) the dipolar tail results in a much stronger PMBL, with only a small number of rare delocalized states for \( V/t \gtrsim 50 \) at \( \rho = 1/2 \). Our results for \( \bar{D}^{\text{max}}_f \) (Fig. 4) resemble those of the NN model (Fig. 2) at low \( V/t \), including the reentrant localization and the ergodic region at low disorder \[71\], but starting at \( V/t \sim 20 \) HS shattering results in strong disorder-free MBL. As mentioned above, our method overestimates delocalization for finite times, and hence we expect stronger disorder-free localization even for lower \( V/t \) in finite-time experiments.

**Dynamics.** – As in other systems with kinetic constraints, the particle dynamics strongly depends on the initial condition if the system has PMBL. As discussed above, the DDI leads for \( \rho = 1/2 \) and \( V/t \gtrsim 20 \) to disorder-free MBL, where most initial FSs remain strongly localized, whereas in the NN model they quickly delocalize. This is well illustrated by the evolution of the initial state |...○○○○○○○○○○○...| (we employ exact time evolution of Eq. (1) and PBC to remove boundary effects). This half-filled state delocalizes in the NN model
due to singlon swaps, which allow to break the central trimer into two dimers: $|\cdot \circ \cdot \cdot \circ \cdot \circ \circ \cdot \cdot \cdot \circ \cdot \cdot \cdot |$ and then delocalize each dimer, e.g. $|\cdot \circ \circ \circ \cdot \cdot \cdot |$. All these processes are resonant in the NN model even for $V = \infty$. In contrast, a sufficiently large DDI, renders the breaking of the initial trimer non-resonant, since it does not preserve $N_{NNN}$. Moreover, the formation of beyond-NN clusters further hinders the particle dynamics.

Analogous to MBL experiments based on the evolution of DWs [25, 40], and similar to recent trap ion experiments [27], we may define the homogeneity parameter as $\eta(\tau) = 2 N_0 / \tau - 1$, where $N_0 = \sum_{j} f_{0}(n_j)$ is the number of particles in the set $f_0$ of initially occupied sites. Homogeneity of the on-site populations results in $\eta(\tau) = 0$. We depict in Fig. 5(a) $\eta(\tau)$ for $V/t = 50$. Homogeneous is quickly reached for the NN model at $\tau \sim 1/t$ (tiny residual values are due to finite size), whereas for a polar gas, $\eta$ plateaus at a large value, indicating strong localization, which is already evident in our calculations for $V/t \approx 20$. A longer-time evolution reveals the appearance of a second delocalization stage after the localization plateau, related to higher-order processes that result in an eventual weak coupling, exponentially small in $V/t$, between resonant Fock states. The two-stage dynamics is also evident in the evolution of the entanglement entropy, $S_{NN}$, calculated from a partition of the system to one half (Fig. 5(b)). The time-scale of the onset of the second stage scales exponentially with $V/t$, being observable for moderate $V/t \approx 30$ but already prohibitively long for typical experiments for $V/t > 50$. In contrast to MBL in the presence of disorder and to Stark MBL, the lack of local integrals of motion results in the absence of any logarithmic growth of $S_{NN}$, which plateaus during the localization, and only grows due to the eventual delocalization at finite $V/t$.

Although at $\rho = 1/2$ almost all FSs are strongly localized for $V/t > 50$, some interesting states remain delocalized even for very large $V/t$. This is particularly the case of a DW with a single domain wall, e.g. $|\cdot \cdot \cdot \circ \cdot \cdot \cdot \circ \cdot \cdot \cdot \circ \cdot \cdot \cdot \cdot \cdot \circ \cdot \cdot \cdot |$. The wall moves resonantly while preserving the DDI to all neighbors, delocalizing for any arbitrary $V$. Note, however, that for OBC the boundaries induce, due to the dipolar tail, an effective confinement for the domain wall, preventing it to reach a distance $(V/t)^{1/3}$ from the lattice edges. This relevant effect of the dipolar tail results in an additional localization mechanism in experiments, especially in small lattices.

Conclusions.— 1D polar lattice gases are characterized by HS shattering and disorder-free MBL. This is crucially due to the dipolar tail $1/r^3$, which for growing $V/t$ induces further emerging constraints, disrupting resonant transport characteristic of the NN model. Strong MBL should be attainable at half-filling for $V/t \sim 20$. For magnetic atoms, although recent experiments have achieved only $V/t \approx 2$ [48], the use of Feshbach molecules of lanthanide atoms (doubling the dipole moment) [72] and/or subwavelength [73, 74] or UV lattices may significantly boost the $V/t$ ratio. For example, for $^{164}$Dy in an UV lattice with $180\text{nm}$ spacing and depth of $23\text{ recoil energy}$, $|V|/t \approx 30$, with $t/h \approx 93\text{s}^{-1}$. Localization could then be probed in few seconds, well within experimental lifetimes. Polar molecules offer exciting possibilities for the realization of EHM with large $V/t$ even without the need of a special lattice, due to their much stronger DDI, orders of magnitude larger than that of magnetic atoms [75]. Note that, although we have focussed on 1D systems, we expect that emerging kinetic constraints also lead to strong disorder-free localization in two dimensions. Our work hence shows that the study of the interplay between disorder- and interaction-induced localization is well within reach of future experiments on polar lattice gases. Moreover, our results have a more general applicability, being potentially relevant for other disorder-free systems with more general long-range interactions, in particular trapped ions [27], where intriguing localization properties may result from the interplay between power-law exchange and Ising terms.

FIG. 4. Localization in the polar lattice gas. $D_{\rho}^{\max}$ as a function of $V/t$ and $W/t$ for $N = 8$, $L = 16$ (a), and $N = 5$, $L = 20$ (b). Blue regions are parameter regimes where FMBL (or at least very strong PMBL) is expected.

The hard-core constraint requires large-enough on-site interactions, which may demand the use of Feshbach resonances.

This definition is only problematic for large $V/t$ for some states, that for $W = 0$ and $V \to \infty$ remain frozen in the NN model (in particular states without singlons), which have by definition $\Lambda_f = 1$. However, the definition is unproblematic for the bulk of states with a finite density of moving particles, which for $W = 0$ are characterized by blocks whose $\Lambda_f$ grows with the system size.

For $V \to \infty$, the calculation of $D_{f}^{\text{max}}$ for different system sizes indicates that $W_c/t \simeq 4$, in good agreement with Ref. [32].
