We present a theoretical analysis of the dynamics of a one-dimensional spin-1/2 fermionic gas subject to weak two-body losses. Our approach highlights the crucial role played by spin conservation in the determination of the full time evolution. We focus in particular on the dynamics of a gas that is initially prepared in a Dicke state with fully-symmetric spin wavefunction, in a band insulator, or in a Mott insulator. In the latter case, we investigate the emergence of a steady symmetry-resolved purification of the gas. Our results could help the modelisation and understanding of recent experiments with alkaline-earth(-like) gases like ytterbium or fermionic molecules.

I. INTRODUCTION

Experiments with ultra-cold gases are often regarded as paradigmatic studies of closed many-body quantum systems [1]; yet, they always suffer from the continuous leakage of particles into the vacuum chamber. In general, losses are responsible for decoherence and for the disappearance of quantum coherence [2]. Several studies have pointed out that they can also induce interesting effects: they can be used as a diagnostic tool for strong correlations [3–6], they can purify and cool the gas [7–10], or induce strong quantum correlations [11–15]. These effects are just a simple instance of the fact that in most situations the coupling to an environment, if properly engineered, can be beneficial and can be exploited for quantum technology purposes [16–20]. The correct theoretical modelisation of the quantum dynamics induced by losses has thus emerged as an important problem and has recently attracted widespread attention [21–24].

Fermionic gases trapped in one-dimensional systems and subject to two-body losses feature a class of highly-entangled stationary states with a fully symmetric Dicke-like spin wavefunction, that could have important scientific and technological applications [25]. They have been the object of several experiments with molecular [26] and atomic gases [27], which however have not been able to certify the properties of the realised stationary state. Spin is conserved during the dissipative dynamics, and this is crucial for determining the steady properties. Various theoretical articles have addressed several aspects of the model and of its dynamics [20] but the impact of spin conservation on the full dynamics, beyond determining its stationary properties, has not been understood yet.

In this article we present a simple theoretical framework for describing the lossy dynamics of a one-dimensional fermionic gas with two-body losses that takes into account the exact conservation of spin. Even if most of the attention so far has focused on the strongly-dissipative regime, we address here the weakly-dissipative limit, which does not spoil the appearance of the highly-entangled stationary states. We highlight the crucial role played by spin in causing a non-trivial relaxation dynamics affecting in a qualitative way the long-time behaviour. The simplicity of the approach is a first step towards the modelisation of experimental data, which could be obtained using alkaline-earth (e.g. strontium) or alkaline-earth like (e.g. ytterbium [30]) atoms in the excited metastable state. We expect that our results may open the path to the realisation of a consistent theory for the fermionic dynamics in the Zeno limit, as recently done for bosons [21].

The article is organised as follows. In Sec. II we describe the setup. In Sec. III we derive a dynamical equation for the evolution of the particle density. Next, we compare our theoretical predictions with numerical simulations for three different class of initial states: Dicke states with fully-symmetric spin wavefunction (Sec. IV), band insulator (Sec. V) and Mott insulators (Sec. VI). In Sec. VII we discuss the effect of weak interactions. Finally, in Sec VIII we draw our conclusions.

II. THE SETUP

We consider a gas of spin-1/2 fermions trapped in a one-dimensional optical lattice with two-body contact interaction and two-body on-site losses. We introduce the fermionic operators $\hat{c}_{j,\sigma}^{(t)}$, which satisfy canonical anticommutation relations, and the Hamiltonian of the Hubbard model, which describes the gas in the single-band approximation:

$$\hat{H} = -J \sum_{j} \sum_{\sigma=\uparrow,\downarrow} \left( \hat{c}_{j,\sigma}^{\dagger} \hat{c}_{j+1,\sigma} + H.c. \right) + U \sum_{j} \hat{n}_{j,\uparrow} \hat{n}_{j,\downarrow}. $$

(1)

Here, $J$ is the hopping amplitude, $U$ is the interaction strength, and $\hat{n}_{j,\sigma} = \hat{c}_{j,\sigma}^{\dagger} \hat{c}_{j,\sigma}$ is the spin-resolved on-site lattice density operator.

The presence of local two-body losses is accounted for...
by the jump operators \( \hat{L}_j = \sqrt{\gamma} \hat{c}_{j,\uparrow} \hat{c}_{j,\downarrow} \), and the dynamics of the full density matrix \( \rho(t) \) is described by a Lindblad master equation:

\[
\dot{\rho}(t) = -\frac{i}{\hbar} [\hat{H}, \rho(t)] + \sum_j \hat{L}_j \rho(t) \hat{L}_j^\dagger - \frac{1}{2} \{\hat{L}_j^\dagger \hat{L}_j, \rho(t)\},
\]

where \([\cdot, \cdot]\) denotes the commutator and \( \{\cdot, \cdot\} \) the anti-commutator. In the experimental situations that we want to model, the ratio \( \gamma/U \) is fixed by atomic (or molecular) properties, and is of the order of the unity. The ratio \( \gamma/J \) is instead tunable at will by modulating the strength of the optical lattice potential.

We introduce the operator associated with the total spin of the gas: \( \hat{S} = \frac{\hbar}{2} \sum_{j,\sigma,\sigma'} \hat{c}_{j,\sigma}^\dagger \hat{c}_{j,\sigma'} \), where \( \sigma_{\sigma'} \) is a vector whose components are the Pauli matrices. Since any two-body loss does not change the spin of the gas along any direction (the doubly occupied state has spin \( 0 \)), the dynamics (2) is spin conserving and the expectation value of the spin along any direction, \( \hat{S} \cdot \hat{n} \), is a constant of motion. It follows that also \( \langle \hat{S}^2 \rangle \) is a constant of motion. The main purpose of this article is to show how the presence of this constraint influences the dynamics.

### III. Population Dynamics for Weak Dissipation

We focus on the simplest experimental observable, \( \hat{N} = \sum_{j,\sigma} \hat{n}_{j,\sigma} \), and characterise how the number of fermions contained in the sample decreases in time because of loss processes. We will use the notation \( \langle \hat{A} \rangle_t \) to denote the time-dependent expectation value of the observable \( \hat{A} \), namely \( \langle \hat{A} \rangle_t \equiv \text{tr}[\rho(t) \hat{A}] \).

With simple algebraic passages, it is possible to show that \( \dot{N}(t) \equiv \langle \dot{N} \rangle_t \) obeys the following equation, which has an intuitive physical meaning:

\[
\frac{d}{dt} N(t) = -2\gamma \left\langle \sum_j \hat{n}_{j,\uparrow} \hat{n}_{j,\downarrow} \right\rangle_t.
\]

Since we cannot treat in an exact analytical way the r.h.s. of this equation, we perform a series of approximations that are well justified in the limit of weak dissipation, \( \hbar \gamma \ll J \). Note that this is also the limit of weak interactions, \( U \ll J \), and the first approximation that we perform, discussed extensively in Sec. VII, consists in completely neglecting interactions.

Using a semiclassical reasoning, we observe that in the limit \( \hbar \gamma \ll J \), losses act on time scales that are much longer than those characterising the unitary time evolution. In between two loss processes, the long unitary dynamics has acted and averaged out any time-dependent physical operator or correlator. We thus focus on the operator that is responsible for losses, \( \langle \sum_j \hat{n}_{j,\uparrow} \hat{n}_{j,\downarrow} \rangle \), and expand it in the basis of plane waves, \( \hat{c}_{k,\sigma} = L^{-\frac{1}{2}} \sum_j e^{-ikj} \hat{c}_{j,\sigma} \), that are the eigenmodes of the free-fermion dynamics:

\[
\left\langle \sum_j \hat{n}_{j,\uparrow} \hat{n}_{j,\downarrow} \right\rangle_t = \frac{1}{L} \sum_{k,q,w,z} \delta_{k+q,w+z} \left\langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{w,\uparrow} \hat{c}_{q,\downarrow}^\dagger \hat{c}_{z,\downarrow} \right\rangle_t.
\]

The Kronecker delta ensures that only momentum-conserving correlators are considered. The time-evolution of the correlators in (4) is easily written:

\[
\left\langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{w,\uparrow} \hat{c}_{q,\downarrow}^\dagger \hat{c}_{z,\downarrow} \right\rangle_t = e^{-\frac{i}{\hbar} (E_k + E_q - E_w - E_z + i \delta_{k,w} \delta_{q,z}) t} \left\langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{w,\uparrow} \hat{c}_{q,\downarrow}^\dagger \hat{c}_{z,\downarrow} \right\rangle_0
\]

and thus we pose that for characterising the lossy dynamics only the energy-conserving correlators should be retained, because their expectation value does not depend on time. This theoretical approach is reminiscent of several ideas put forward in the context of weakly-dissipative systems [22, 33], that have been largely employed in recent theoretical studies [23, 24].

This leads to an expression that can be further simplified by taking into account the conserved quantity \( \hat{S}^2 \) (see Appendix A for the explicit calculations):

\[
\dot{N}(t) = -\frac{2\gamma}{L} \left[ \frac{N(t)^2}{4} + \frac{N(t)}{2} + \frac{\text{Var} N_t}{4} - \frac{\langle \hat{S}^2 \rangle_0}{\hbar^2} - \langle \hat{\Pi} \rangle_t \right],
\]

where \( \text{Var} N_t = \langle \hat{N}^2 \rangle_t - \langle \hat{N} \rangle_t^2 \) and \( \hat{\Pi} = \sum_k \hat{n}_{k,\uparrow} \hat{n}_{k,\downarrow} \). This equation is the main result of our study: it highlights the crucial interplay between the number of particles, its variance, the spin of the gas, and density-density correlations.

#### A. Thermodynamic Limit

The terms which appear in the r.h.s. of Eq. (6) have different scalings in the thermodynamic limit. If we divide both members by \( L \) and focus on intensive quantities (whose limit is finite in the thermodynamic limit) such as the lattice density \( n(t) = \langle \hat{N}(t) \rangle/L \) or the lattice spin density \( s^2 = \langle \hat{S}^2 \rangle_0/L^2 \) we obtain the simpler equation:

\[
\dot{n}(t) = -2\gamma \left[ \frac{n(t)^2}{4} - s_0^2 \right].
\]

Note that a finite spin \( \langle \hat{S}^2 \rangle_0 \neq 0 \) could have zero value \( s_0 = 0 \) in the thermodynamic limit.

It is important to stress that equation (7) could have been obtained by simpler means using a simple Gaussian ansatz for the density matrix (similar ideas appear in Refs. [24, 32]). We present a detailed derivation in Appendix B and report here the result:

\[
\dot{N}(t) = -\frac{2\gamma}{L} \left[ \frac{N(t)^2}{4} - \frac{\langle \hat{S}_x \rangle^2 + \langle \hat{S}_y \rangle^2 + \langle \hat{S}_z \rangle^2}{\hbar^2} \right].
\]
If we focus on intensive quantities and address the thermodynamic limit we observe that:

$$\lim_{L \to \infty} \frac{\langle S^2 \rangle}{L^2} = \lim_{L \to \infty} \frac{\langle \hat{S}_x \rangle^2 + \langle \hat{S}_y \rangle^2 + \langle \hat{S}_z \rangle^2}{L^2},$$

(9)

their difference $\sum_i \langle \hat{S}_i^2 \rangle - \langle \hat{S}_i \rangle^2$ being only $\sum_i \text{Var} S_i$, which is subleading. This implies that Eq. (7) does not take into account exactly the spin conservation.

We finally mention that Eq. (6) is a more refined version of Eq. (7) because it includes finite-size corrections. Whereas this might seem an unnecessary overshooting, testing this theory with numerical tools is demanding and we will present state-of-the-art numerical simulations for lattices up to $L = 10$. For these lattice lengths, in several cases the dynamics predicted by Eq. (7) is recognisable only at short times. This higher accuracy comes at the price of introducing two new variables, $\text{Var} N$ and $\langle \Pi \rangle_I$, for which we have not been able to write satisfactory simple dynamical equations; when necessary, we will show how to treat them.

B. Continuum limit

The study presented so far can be easily extended to a setup without the optical lattice of length $L$ (see also Ref. 27). Introducing the fermionic fields $\hat{\Psi}_\sigma(x)$, with $\sigma = \uparrow, \downarrow$, the atomic mass $m$ and the interaction parameter $g$, the Hamiltonian reads:

$$\hat{H}_c = \int \sum_\sigma \hat{\Psi}_\sigma^\dagger(x) \left( -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} \right) \hat{\Psi}_\sigma(x) dx +$$

$$+ g \int \hat{\Psi}_\uparrow^\dagger(x) \hat{\Psi}_\downarrow(x) \hat{\Psi}_\downarrow^\dagger(x) \hat{\Psi}_\uparrow(x) dx. \quad (10)$$

In order to include loss processes we introduce the jump operators $\hat{J}(x) = \sqrt{\xi} \hat{\Psi}_\uparrow(x) \hat{\Psi}_\downarrow(x)$ and the full Lindblad dynamics:

$$\dot{\rho}(t) = -\frac{i}{\hbar} [\hat{H}_c, \rho(t)] +$$

$$+ \int \hat{J}(x) \rho(t) \hat{J}(x)^\dagger - \frac{1}{2} \left\{ \hat{J}(x)^\dagger \hat{J}(x), \rho(t) \right\} dx. \quad (11)$$

We now focus on the weakly dissipative limit, characterised by a loss rate that is subleading with respect to the kinetic energy: $\xi \ll \hbar m$, where $n$ is the gas density. Note that this inequality cannot be satisfied at all times for a gas that loses completely its population; however, as we will see, the problem that we are studying is characterised, in certain regimes, by a finite steady density.

With calculations similar to those presented above, one obtains the following dynamical equation for the population $N(t) = \langle \int \sum_\sigma \hat{\Psi}_\sigma^\dagger(x) \hat{\Psi}_\sigma(x) dx \rangle$, in the weakly-dissipative limit:

$$\dot{N}(t) = -\frac{2\xi}{\hbar} \left[ \frac{N(t)^2}{4} + \frac{N(t)}{2} + \frac{\text{Var} N}{4} - \frac{\langle \hat{S}_i^2 \rangle_0}{\hbar^2} - \langle \Pi \rangle_I \right]. \quad (12)$$

The latter equation is identical to Eq. (6), where $\gamma$ has been replaced with $\xi$. The definitions of the total spin $\hat{S}^2$ and of the $\Pi$ observables are trivial generalisations of those presented above for a lattice. In the rest of the paper we will focus only on the lattice problem, although several results can be easily generalised to the continuum case.

IV. Dicke States and Stationary States

The first test for the population equation (6) consists in its application to states whose spin part is fully symmetric like in a Dicke state, and which are characterised by a spin quantum number $S = N/2$. It has been pointed out in Ref. 27 that Dicke states (we use from now on this short name to indicate any state with $S = N/2$) are dark states of the dissipative dynamics: since spin is conserved, and the minimal number of fermions that is necessary to create a spin-$S$ state is $2S$, no particle can be lost from a Dicke state without changing the spin quantum number – that is, the loss cannot take place.

Eq. (6) predicts that Dicke states are stationary. In order to prove this, we introduce the notation $| D_N \rangle$ for a generic Dicke state with $N$ particles and spin $S = N/2$; we do not care about the specific properties of the orbital part of the wavefunction. We show in Appendix C that for a generic linear superposition of Dicke states, $| \Psi_D \rangle = \sum_N c_N | D_N \rangle$, two properties hold:

$$\langle \Psi_D | \hat{S}_i^2 | \Psi_D \rangle = \hbar^2 \left( \frac{N^2 + \text{Var} N}{2} + N \right), \quad (13a)$$

$$\langle \Psi_D | \Pi | \Psi_D \rangle = 0. \quad (13b)$$

From these two properties we can deduce that Dicke states are stationary states of the dynamics: $\dot{N}(t) = 0$.

Eq. (7) takes into account the spin conservation in the thermodynamic limit, and predicts a stationary density

$$n_\infty = \frac{2}{\hbar} s_0. \quad (14)$$

Dicke states satisfy this relation; indeed, from the above formulas we obtain:

$$\frac{s_0^2}{\hbar^2} = \lim_{L \to \infty} \frac{\langle \Psi_D | \hat{S}_i^2 | \Psi_D \rangle}{\hbar^2 L^2}$$

$$= \lim_{L \to \infty} \left( \frac{N^2 + \text{Var} N + 2N}{4L^2} \right) = \frac{n^2}{4}. \quad (15)$$

The numerical analysis of the problem shows that for a one-dimensional Hubbard chain with periodic boundary conditions there are steady states that are not Dicke
states. A preliminary inspection shows that these states are not well captured by our theory; we leave for future work the generalisation of our study in order to capture these steady states. For this reason, all the numerical data presented in the article are obtained for systems with open boundary conditions, where the only steady states that we have found are Dicke states (we do not have a mathematical proof for this). This problem was also observed in Ref. [27].

V. BAND INSULATOR

We now discuss the dissipative dynamics of a band insulator, \(|\Psi_{\text{HI}}\rangle = \prod_{j} c_{j,\uparrow}^\dagger c_{j,\downarrow}^\dagger |0\rangle\), where any lattice site is doubly occupied and the initial population is \(2L\). The system is in a spin-0 state, \(\langle S^2 \rangle = 0\), and a simple calculation shows that \(\langle \Pi \rangle_0 = L\). The prediction for the dynamics of the lattice density \(n(t)\) in the thermodynamic limit is easily obtained from Eq. (7):

\[
n(t) = \frac{2}{1 + \gamma t}.
\]

The full solution of Eq. (7) is more challenging because it is not obvious how to give a prediction for the time-dependence of \(\text{Var}N_t\) and \(\langle \Pi \rangle_t\) (we could not derive closed expressions for their time-derivatives and a Gaussian expansion gives wrong predictions, possibly because here we are looking for beyond-Gaussian effects).

We can use Eq. (6) to get insights into the long-time dynamics of a finite system, since when \(N(t)\) tends to zero we have \(N(t)^2 \ll N(t)\). In this limit it is possible to model the number of particles as a Bernoullian distribution, where with probability \(p\) the system has 2 particles, and with probability \(1 - p\) it is empty. For such a distribution, \(N = 2p\), \(\text{Var}N \sim 4p\) and thus we estimate that, in the long-time limit, \(\text{Var}N_t \sim 2N(t)\). Concerning \(\langle \Pi \rangle\), we can bound it in the following way: since \(\Pi\) is a non-negative operator, \(\langle \Pi \rangle \geq 0\); since \(\hat{n}_{k,\uparrow} \hat{n}_{k,\downarrow} \leq \hat{n}_k/2\), we can write that \(\langle \Pi \rangle < N/2\). We thus obtain that the long-time scaling is exponential: \(N(t) \sim \exp(-t/\tau)\), with \(L/(2\gamma) < \tau < L/\gamma\). In all cases, \(\tau\) depends on the size, which is compatible with the fact that in the thermodynamic limit we expect an algebraic decay.

We verified these predictions with exact numerical simulations of the full master equation using the stochastic quantum trajectories approach [34] (for \(L > 4\)): we have used the python-based QuTiP package [35, 36] that allowed us to push our analysis up to \(L = 10\) sites with high statistics \((N_{\text{traj}} \geq 10^3, N_{\text{traj}}\) being the number of trajectories). The results of our numerical simulations (with open boundary conditions) are shown in Fig. 1, where we consider four values of \(\hbar \gamma / J\), ranging from \(10^{-2}\) to 10. Note that here and in the subsequent figures we omitted the error bars, since the statistical errors associated with the averaging over the trajectories remains negligible on the scales of the various plots, up to densities \(n \lesssim 10^{-2}\).

For \(\hbar \gamma / J \leq 1\) we observe a universal behaviour even at small sizes. Data are affected by important finite-size effects and indeed no collapse of curves at different \(L\) has been observed (see Appendix D). The comparison with the prediction in (10) is satisfactory only at short times and it improves for increasing lattice size. For \(L = 10\) there is a quantitative agreement until the density decreases to \(n \sim 0.4\). For longer times, we observe the appearance of an exponential decay, as predicted in the previous paragraph.

We use our numerical simulations to link \(\text{Var}N_t\) and \(\langle \Pi \rangle_t\) to \(N(t)\); motivated by the data shown in Appendix D we propose:

\[
\langle \Pi \rangle_t \approx \frac{N(t)}{L} + \frac{L - 2}{4} \frac{N(t)^2}{L^2},
\]

\[
\text{Var}N_t \approx 2 \left[ N(t) - 2 \langle \Pi \rangle_t \right]
\approx \left( 1 - \frac{2}{L} \right) \left( 2N(t) - \frac{N(t)^2}{L} \right).
\]

We substitute these expressions in Eq. (6) and obtain the following solution:

\[
n(t) = \frac{4 \left( 1 - \frac{2}{L} \right)}{L \exp \left( \frac{L - 2}{2} \frac{2t}{L^2} \right) - 1} + 2 - \frac{4}{L}.
\]

This curve is the theoretical prediction plotted in Fig. 1 which provides a satisfactory description of our numerics.
VI. MOTT INSULATOR

A. Thermodynamic limit

We now consider an initial state with one particle per site, namely, a Mott insulator. Because of the spin, the manifold of such states spans a subspace of dimension $2^L$. Conservation of spin during the dynamics takes here a non-trivial form because the spin of the gas can range from 0 to $L/2$. We can easily discuss the dynamics in the thermodynamic limit: the asymptotic number of particles is $n_\infty = \frac{2}{\gamma s_0}$ and the dynamics is given by:

$$n(t) = n_\infty \tanh \left[ \frac{n_\infty \gamma t}{2} + \operatorname{arctanh} \left( \frac{1}{n_\infty} \right) \right]. \quad (19)$$

This result displays in a clear way the interplay between spin-conservation and dissipative dynamics. Not only the stationary properties of the gas are determined by the initial spin of the gas: the dynamics too is determined by it, since stationary properties are approached with a typical decay time

$$\tau = \frac{2}{\gamma n_\infty} = \frac{\hbar}{\gamma s_0} \quad (20)$$

FIG. 2. Time derivative of the population $\dot{N}(t)$ for $L = 8$ and $\hbar \gamma / J = 10^{-1}$. Black solid line: calculation of $\dot{N}(t)$ using Eq. (6) and employing the numerical values for $N(t)$, $\text{Var} N_t$ and $\langle \Pi \rangle_t$ obtained with $N_{\text{traj}} = 2000$ quantum trajectories. Red thin line: numerical derivative of the $N(t)$ computed with $N_{\text{traj}} = 2000$ quantum trajectories and using the Euler method.

Since this latter result has been obtained using the numerical data, we perform a direct investigation of whether Eq. (6) is a good tool for describing the population dynamics. We compute the numerical derivative of the data displayed in Fig. 2 for $L = 8$ and $J / \hbar \gamma = 10$ using Euler’s method and we compare the obtained curve with the prediction given by the r.h.s. of Eq. (6). The comparison is shown in Fig. 3 and the agreement is excellent, showing that Eq. (6) has a general validity even at small sizes. This confirms the general validity of the approximations employed to derive Eq. (6).

FIG. 3. Dissipative dynamics of a Néel state for $L = 4, 6, 8$ and $10$ for $\hbar \gamma / J = 0.1$. The time-dependent population given in Eq. (21) is in black. The green curve is a fit to the dynamics using Eq. (19) and taking $n_\infty$ as the only fitting parameter.

that depends on spin, and that is shorter for larger spin values.

The link between the stationary number of particles and the typical decay time has already been highlighted in Ref. [30], although the authors do not mention its connection with spin.

B. Finite-size effects

If we consider a Mott insulator with $N = L$ particles initialised in an eigenstate of $S^2$ with quantum number $S$, the asymptotic number of particles can be exactly characterised for any size assuming that the final state is a Dicke state. In this case we expect that the stationary state has a well defined number of particles given by the relation $N_\infty = 2S$.

When the initial Mott insulator is not an eigenstate of $S^2$, we expect the final state to be a linear superposition of Dicke states with different number of particles ($\text{Var} N > 0$) and spin. Assuming stationarity, $\dot{N} = 0$, and recalling that for a linear superposition of Dicke states $\langle \Pi \rangle = 0$, we obtain:

$$N_\infty \leq \sqrt{\frac{4 \langle S^2 \rangle}{\hbar^2}} + 1 - 1. \quad (21)$$

It is simple to verify that the bound is saturated when the initial state is an eigenstate of $S^2$.

C. Typical decay time and spin

In order to test these predictions we performed several numerical simulations of the full master equation for an
It is shown that in this situation Eq. (19) provides an excellent description of the decay time $t$ as approximated by $\tau$. We observe that, since the initial state is not an eigenstate of $\hat{S}^2$, the bound (21) is satisfied but not saturated. It is shown that in this situation Eq. (19) provides an excellent description of the dynamics taking only $n_\infty$ as fit parameter.

We further investigate the typical time-scale with which the asymptotic number of particles is approached. The results shown in Fig. 4 show a clear exponential approach to the stationary value. We have investigated whether the analytical formulas given in Eq. (20) can give a quantitative prediction to the typical decay time $\tau$. As shown in the plot, the formula

$$\tau = \frac{hL}{\gamma \sqrt{\langle S^2 \rangle}}$$

(22)

gives a remarkably good description of the numerical data. Less accurate results are instead obtained with the formula $\tau = 2/(\gamma n_\infty)$; the discrepancy is solely ascribed to finite-size effects and is expected to disappear in the thermodynamic limit.

We finally perform a set of numerical simulations to test whether this latter relation between the decay time and the spin is true in general. We consider as initial state an uncorrelated Mott insulator where, on each lattice site, the spin $\hat{S}_i$ is randomly oriented. In order to construct such a state, we randomly draw two angles, $\theta_i$ and $\phi_i$, which identify a generic direction on the Bloch sphere, for every lattice site $i$. The goal of this procedure is not to sample in a uniform way the set of uncorrelated Mott insulators, but to generate states with widely vari-

D. Symmetry-resolved purity

When starting from a Mott insulator, the system features a non-trivial dynamics also in terms of the purity of the total density matrix:

$$P_{\text{tot}} = \text{tr} \left[ \rho(t)^2 \right].$$

(23)

Since the density matrix is reconstructed via the independent dynamics of $N_{\text{traj}}$ quantum trajectories [34], we have that

$$\rho(t) = \frac{1}{N_{\text{traj}}} \sum_{i=1}^{N_{\text{traj}}} |\psi_i(t)\rangle \langle \psi_i(t)|,$$

(24)

where $|\psi_i(t)\rangle$ is the $i$-th trajectory at time $t$. Thus, combining Eq. (24) with Eq. (23) we get (from now on we
P(n) 
P(\rho_n) / P(\rho_n)_{\text{min}}

FIG. 6. Symmetry-resolved purity for the particle sectors $n = 2, 4, 6$ (solid lines) and purity of the full density matrix (dashed line). Data are obtained for a typical set of parameters $J/\gamma = 10h$, $L = 8$, and $N_{\text{traj}} = 10^3$.

will omit the time dependence

\[
P_{\text{tot}} = \frac{1}{N_{\text{traj}}} \sum_{s} \sum_{i,j=1}^{N_{\text{traj}}} \langle s | \psi_i \rangle \langle \psi_i | \psi_j \rangle \langle \psi_j | s \rangle \\
= \frac{1}{N_{\text{traj}}^2} \sum_{i,j=1}^{N_{\text{traj}}} |\langle \psi_i | \psi_j \rangle|^2 \tag{25}
\]

where \(\{s\}\) is an orthonormal basis of the Hilbert space and in the second line we used that \(\sum_s |s\rangle \langle s| = I\).

The dynamics of a single quantum trajectory is governed by an effective non-Hermitian Hamiltonian \(\hat{H}_{\text{eff}} = \hat{H} - i\gamma/2 \sum_{i=1}^{L} \hat{L}_i \hat{L}_i\) and by the stochastic quantum jumps determined by the jump operators \(\hat{L}_i\) [34]. While the evolution induced by \(\hat{H}_{\text{eff}}\) conserves the number of particles, the quantum jumps do not: they couple the \((n-2)\)-particle sector of the Hilbert space. For this reason, if the initial state is an eigenstate of \(\hat{N}\), each quantum trajectory \(|\psi_i(t)\rangle\) will have at any time a well defined (although time dependent) number of particles. We can thus label the trajectories with a double index, \(|\psi_{n,\alpha}\rangle\), where \(n\) is the particle sector and \(\alpha\) labels the trajectories belonging to the \(n\)-th subspace. Note that \(n\) depends on time.

Using the fact that \(\langle \psi_{n,\alpha} | \psi_{m,\beta} \rangle = 0\) for \(n \neq m\) we write:

\[
\rho = \bigoplus_n p_n \rho_n \quad , \quad p_n = \frac{N_n}{N_{\text{traj}}} \tag{26}
\]

where \(N_n\) is the number of trajectories belonging to the \(n\)-particle sector and

\[
\rho_n = \frac{1}{N_n} \sum_{\alpha} |\psi_{n,\alpha}\rangle \langle \psi_{n,\alpha}| \quad , \quad \text{tr}[\rho_n] = 1. \tag{27}
\]

We can thus link the total purity \(P_{\text{tot}}\) to the symmetry-resolved purities \(P(\rho_n)\), i.e. the purities of the symmetry-resolved density matrices:

\[
P_{\text{tot}} = \sum_n p_n^2 P(\rho_n). \tag{28}
\]

We now study the time-evolution of the total purity and of the symmetry-resolved purities for an initial Mott insulator with Néel order; we perform numerical simulations for \(L = 8\) and \(\hbar \gamma/J = 0.1\). In Fig. 6 we show the dynamics of the symmetry-resolved purities for the sectors \(n = 2, 4\) and \(6\) (the purities for \(n = 8\) and \(n = 0\) are trivial and equal 1) and the behaviour of the occupation probabilities \(p_n\). The plot of \(P_{\text{tot}}\) (dashed line in the top panel) shows that for \(n = 2\) and \(6\) the symmetry-resolved purity is larger than the total one at long times, i.e. \(P(\rho_n) > P_{\text{tot}}\).

In Fig. 7 we show the symmetry-resolved purity normalized by its minimum possible value for a given \(n\)-particle subspace, i.e. the purity of a fully mixed state \(P(\rho_n)_{\text{min}} = 1/\dim(\mathcal{H}_n)\), where \(\dim(\mathcal{H}_n) = (L_n/2)^2\) is the dimension of the \(n\)-particle subspace of the Hilbert space (with \(S_z = 0\)). Remarkably, the asymptotic dynamics features purities which are larger by orders of magnitude with respect to \(P(\rho_n)_{\text{min}}\). This is related to the fact that, despite our system is subject to particle losses, the non-trivial interplay between spin conservation and dissipation leads to the creation of a non-trivial dark subspace for all possible number of particles \(n\). It is interesting to observe that differently from what reported in Ref. [37] the purification process here is not transient, but takes place in the long-time limit.
VII. THE EFFECT OF WEAK INTERACTIONS

We now discuss the validity of the approximation introduced in Sec. [II] concerning the complete neglect of the interaction term in the Hubbard Hamiltonian. The discussion presented in this article focuses on the limit of weak dissipation \( h \gamma \ll J \), that in most experimental situations coincides with the limit of weak interactions \( U \ll J \). In Fig. 8 we show numerical simulations performed with a finite value of the interaction constant, \( U = h \gamma \). Dashed lines: corresponding dynamics for \( U = 0 \). The plot highlights the collapse of the curves for \( U \neq 0 \) and \( U = 0 \) in the weakly dissipative limit.

The reason why we can safely neglect interactions but not dissipation lies in the separation of time scales between unitary hopping dynamics (very fast) and dissipative/interaction dynamics (slow). Our theoretical analysis is a perturbative treatment of dissipation, and the population equation (6) is linear in \( t \). In this case:

- \( k = q = w = z \). In this case: \( \langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{w,\uparrow}^\dagger \hat{c}_{q,\downarrow} \hat{c}_{z,\downarrow} \rangle_t = \langle \hat{n}_{k,\uparrow} \hat{n}_{q,\downarrow} \rangle_t \).
- \( k = w, q = z \), and \( k \neq q \). In this case: \( \langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{w,\uparrow}^\dagger \hat{c}_{q,\downarrow} \hat{c}_{z,\downarrow} \rangle_t = \langle \hat{n}_{k,\uparrow} \hat{n}_{q,\downarrow} \rangle_t \) with \( k \neq q \).
- \( k = z, q = w \), and \( k \neq q \). In this case: \( \langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{w,\uparrow}^\dagger \hat{c}_{q,\downarrow} \hat{c}_{q,\downarrow} \rangle_t = \langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{k,\downarrow}^\dagger \hat{c}_{q,\downarrow} \rangle_t \) with \( k \neq q \).

In summary:

\[
\frac{d}{dt} N(t) = -\frac{2\gamma}{L} \left( \langle \hat{\Pi} \rangle_t + \sum_{k \neq q} \langle \hat{n}_{k,\uparrow} \hat{n}_{q,\downarrow} \rangle_t + \langle \hat{c}_{k,\uparrow}^\dagger \hat{c}_{k,\downarrow} \hat{c}_{q,\downarrow}^\dagger \hat{c}_{q,\downarrow} \rangle_t \right). 
\]
We now simplify the latter expression by introducing the explicit expressions for the the spin operators. From the relations:
\[
\sum_k \hat{n}_{k\uparrow,\downarrow} = \frac{\hat{N}}{2} \pm \frac{\hat{S}_z}{\hbar}, \quad \sum_k \hat{c}^\dagger_{k\uparrow} \hat{c}_{k\downarrow} = \frac{\hat{S}_z + i\hat{S}_y}{\hbar}; \quad (A2)
\]
one easily obtains that:
\[
\frac{\hat{N}^2}{4} - \frac{\hat{S}_z^2}{\hbar^2} = \sum_{k,q} \hat{n}_{k\uparrow,\downarrow} \hat{n}_{q\downarrow,\uparrow}; \quad (A3a)
\]
\[
\frac{\hat{S}_z^2 + \hat{S}_y^2 + \hbar \hat{S}_z}{\hbar^2} = \sum_{k,q} \hat{c}^\dagger_{k\uparrow} \hat{c}_{k\downarrow} \hat{c}^\dagger_{q\downarrow} \hat{c}_{q\uparrow}. \quad (A3b)
\]
Having the care of splitting the sums \(\sum_{k,q}\) as \(\sum_{k=q} + \sum_{k\neq q}\) one obtains Eq. (6).

**Appendix B: Gaussian density matrix: a dynamical equation for the thermodynamic limit**

We start from Eq. (11) and focus on \(\langle \hat{c}^\dagger_{k\uparrow} \hat{c}_{w\uparrow} \hat{c}^\dagger_{q\downarrow} \hat{c}_{z\downarrow}\rangle_t\).

We now assume that the density matrix is Gaussian and that Wick’s theorem applies:
\[
\langle \hat{c}^\dagger_{k\uparrow} \hat{c}_{w\uparrow} \hat{c}^\dagger_{q\downarrow} \hat{c}_{z\downarrow}\rangle_t \sim \langle \hat{c}^\dagger_{k\uparrow} \hat{c}_{w\uparrow}\rangle_t \langle \hat{c}^\dagger_{q\downarrow} \hat{c}_{z\downarrow}\rangle_t + \langle \hat{c}^\dagger_{k\uparrow} \hat{c}_{z\downarrow}\rangle_t \langle \hat{c}^\dagger_{q\downarrow} \hat{c}_{w\uparrow}\rangle_t. \quad (B1)
\]

Of all the correlators which appear here, we only retain those which do not have an explicit time dependence because dissipation is weak and they average to zero between two dissipative events. Thus:
\[
\dot{N}(t) = -\frac{2\gamma}{L} \sum_{k,q} \left( \langle \hat{n}_{k\uparrow,\downarrow}\rangle_t \langle \hat{n}_{q\downarrow,\uparrow}\rangle_t - \langle \hat{c}^\dagger_{k\uparrow} \hat{c}_{k\downarrow}\rangle_t \langle \hat{c}^\dagger_{q\downarrow} \hat{c}_{q\uparrow}\rangle_t \right). \quad (B2)
\]
By using the expressions (A2), we finally obtain the dynamical equation in (7).

**Appendix C: Proof of relations (13) for Dicke states**

In this appendix we prove the relations (13a) and (13b) that characterise Dicke states listed in Sec. IV.

Relation (13a) is simple and follows from the definition of Dicke state: \(\langle \Psi_D | \hat{S}_z^2 | \Psi_D \rangle = \hbar^2 \sum_N |c_N|^2 \frac{N(N+1)}{2} = \frac{\hbar^2}{4} \langle \Psi_D | \hat{N}^2 | \Psi_D \rangle + \frac{\hbar^2}{4} \langle \Psi_D | \hat{N} | \Psi_D \rangle\).

We first show relation (13b) for a generic Dicke state with well-defined number of particles \(N\) and that is also an eigenstate of \(\hat{S}_z\) with eigenvalue \(\hbar m\), \(|D_{N,m}\rangle\). The repeated application of the spin-raising operator turns \(|D_{N,m}\rangle\) into a fully polarised state: \(\langle \hat{S}_+ \rangle_{\hbar} = m |D_{N,m}\rangle \propto |D_{N,m\downarrow}\rangle\). Since this state is fully polarised, \(\hat{P}|D_{N,m\downarrow}\rangle = 0\). By using the following expression for the spin-raising operator: \(\hat{S}_+ = \sum_k \hat{c}^\dagger_{k\uparrow} \hat{c}_{k\downarrow}\), it is not difficult to show that

\[\hat{P}|D_{N,m\downarrow}\rangle = 0\] because \(\hat{P}\hat{S}_+ = \hat{S}_+ \hat{P} = 0\). With this relation we can show that \(\hat{P}|D_{N,m}\rangle = 0\). From this we obtain that in general \(\hat{P}|D_{N}\rangle = 0\) and thus that also \(\hat{P}|\Psi_D\rangle = 0\). This concludes the proof. \(\Box\)

**Appendix D: Additional data for the band-insulator dynamics**

In this appendix we present some additional data from our quantum trajectory simulations of the band-insulator dissipative dynamics. In Fig. 9 we plot the same data as in Fig. 7 at fixed \(J/\hbar\gamma\) and varying \(L\). We observe the importance of finite-size effects and the absence of any collapse at the sizes that we could consider numerically.

In Fig. 10 we plot the numerically-computed \(\text{Var}\hat{N}_t\) and (\(\Pi\))_t and compare them to the expressions proposed in Eqs. (17a).

**Appendix E: Additional data on the calculation of the purity**

We now comment on the convergence of the results presented in Sec. V with respect to the number of stochastic trajectories. From Eq. (24) it is clear that the degree of accuracy in the reconstruction of the density matrix depends on \(N_{\text{traj}}\). In particular, as \(N_{\text{traj}}\) is increased we can account for more statistically-independent realisations of the dynamics; intuitively, one expects \(P(\rho_n)\) to be a monotonically decreasing function of \(N_{\text{traj}}\). This
Decomposing the symmetry-resolved purity in terms of diagonal and off-diagonal overlaps we get that

\[
\mathcal{P}(\rho_n) = \frac{1}{N_n} + \frac{1}{N_n^2} \sum_{\alpha \neq \beta} |\langle \psi_{n,\alpha} | \psi_{n,\beta} \rangle|^2. \tag{E1}
\]

Since we are interested in the \(N_n \to \infty\) limit, we observe that the limiting value of the purity can be obtained by only studying the second addend of the r.h.s.

We now make the assumption that \(N_n \propto N_{\text{traj}}\) and that the \(|\psi_{n,\alpha}\rangle\) are randomly distributed in the dark subspace \(\mathcal{H}_n^{\text{Dark}}\), so that the off-diagonal overlaps scale as \(|\langle \psi_{n,\alpha} | \psi_{n,\beta} \rangle|^2 \sim 1/\dim(\mathcal{H}_n^{\text{Dark}})\) for \(\alpha \neq \beta\). In the limit \(N_n \to \infty\) we obtain:

\[
\mathcal{P}(\rho_n) \simeq \frac{1}{\dim(\mathcal{H}_n^{\text{Dark}})}. \tag{E2}
\]

In our specific case, we can estimate the dimension of the dark subspace by counting the number of antisymmetric orbital wavefunction to be associated to the fully-symmetric spin part of the wavefunction, a Dicke state with \(S = n/2\) and \(S_z = 0\). Thus, \(\dim(\mathcal{H}_n^{\text{Dark}}) = (\binom{L}{n})\). Eq. (E2) provides a very good estimation of the asymptotic value of the symmetry-resolved purity as shown in Fig. 11, where also the convergence with \(N_{\text{traj}}\) is shown.

By numerical inspection, the asymptotic purity value is \(\mathcal{P}(\rho_n) = 2/(\binom{L}{n})\); we do not understand the reason for the 2 factor appearing in the formula, that points at a lack of ergodicity and to the fact that the only half of the dark subspace is explored by the dynamics. We pose that this is due to the specific spin structure of the initial Néel state, and that a Mott insulator with randomly-oriented spins would explore the full dark state; we leave a more systematic study to the future.

Finally, we stress that this numerical computation is quite heavy in terms of memory since it requires requires to allocate \(N_{\text{traj}}\) wave functions of the many-body system for many values of \(t\), this limits our analysis to \(N_{\text{traj}} = 1250\).

---
