I. INTRODUCTION

The Dicke model [1] is a paradigmatic model in the theory of light-matter interactions [2–5]. It describes a collection of $N$ identical two-level systems coherently coupled to the same bosonic mode $\hat{a}$, arising from the quantization of the electromagnetic field inside a cavity of volume $V$. As the name says, it was firstly introduced by Robert H. Dicke [1], with the aim of describing the “emission of coherent radiation” obtained by considering a “radiating gas as a single quantum-mechanical system”. He dubbed such process “super-radiant emission”.

In the thermodynamic limit ($N \to \infty$, $V \to \infty$, with $N/V$ constant) and when the light-matter coupling strength exceeds a critical value, the Dicke model undergoes an equilibrium second-order thermal phase transition [6, 7] between a normal and a “super-radiant” phase. In the zero-temperature limit, the phase transition persists and corresponds to a quantum phase transition [8, 9]. The super-radiant phase is characterized by a macroscopic number of photons, $\langle \hat{a} \rangle \sim \sqrt{N}$ and by a macroscopic number of excitations in the matter sector. To avoid confusion with the Dicke non-equilibrium super-radiant emission [1], we here follow Refs. 10 and 11 and dub the equilibrium super-radiant phase transition as “photon condensation”.

A careful derivation of the Dicke model from a microscopic condensed-matter model with electronic degrees of freedom leads to an additional diamagnetic term [12], proportional to $(\hat{a} + \hat{a}^\dagger)^2$, which is usually neglected by utilizing a (wrong) “weak-coupling argument”. It was soon understood [12–14] that such additional term is crucial to preserve the gauge invariance property of the model. Only when both terms generated by the minimal coupling substitution $\hat{p} \to \hat{p} + eA/c$, (i.e. the paramagnetic light–matter coupling and the diamagnetic term) are retained, does one have a gauge-invariant theory satisfying the Thomas-Reiche-Kuhn (TRK) sum rule [15–17]. And, when the TRK sum rule is satisfied, the occurrence of photon condensation in such generalized Dicke model is forbidden [12, 18, 19].

Despite its importance, the Dicke model is not exhaustive at all. In recent years, researchers have transcended it by studying interactions between matter degrees of freedom and quantized electromagnetic fields in a variety of other models and physical systems. Photon condensation has been predicted in many of these “beyond-Dicke” systems, including three-level systems [20, 21], graphene [22], ferroelectric materials [23], superconducting circuits [19, 24–26], and strongly correlated (a.k.a. quantum) materials [27].

A number of no-go theorems for photon condensation in a single-mode spatially-uniform cavity field have appeared in the literature [10, 28–32], showing that gauge invariance forbids photon condensation even in such class of “beyond-Dicke” systems. Often, theorems have been...
opposed by “go theorems” [19, 33, 34]. Photon condensation remains a rather controversial theoretical topic.

At present, the most general no-go theorem is reported in Ref. 10, where the authors showed that photon condensation is forbidden by gauge invariance for generic non-relativistic interacting electron systems coupled to a spatially-uniform cavity mode. The proof is based on linear response theory [35, 36] and uses the smallness of the order parameter $\alpha = \langle \hat{a} \rangle / \sqrt{N}$. It is therefore valid only for second-order phase transitions, where the order parameter is $\ll 1$ at the phase transition, and changes continuously.

It is by now clear that a natural path to overcome such theorem is to consider spatially-varying cavity fields [11, 37, 38]. In these fields photon condensation has been shown to occur and is essentially a magneto-static instability [11, 37-39]. Another possibility to bypass the hypothesis of such theorem is to consider a first-order phase transition [20, 21], where the order parameter $\alpha$ abruptly changes from zero (in the normal phase) to a finite value (in the photon condensate phase). As a matter of fact, that first-order phase transitions were a valuable possibility to overcome the no-go theorem was first discussed some time ago [24, 40]. Indeed, the authors of Refs. 24 and 40 stated that systems displaying first-order phase-transitions are valuable candidates to realize photon condensation. Quoting from Ref. 24, “In other words, for the multilevel case Viehmann, von Delft, and Marquardt [30] have implicitly considered only the case of second-order phase transitions [...], while superradiant transitions of the first order need to be considered”. Similarly, the authors of Ref. 40 stated that: “It thus remains to be seen whether [...] first-order [superradiant phase transitions] really do occur in nature”.

In this Article, we lay down a fully non-perturbative extension of the previous no-go theorems. On the one hand, we relax the hypothesis made in Ref. 10 that $\alpha$ is small at the critical point. The no-go theorem provided in this Article is therefore applicable also to first-order phase transitions. On the other hand, we retain the generality of Ref. 10 in that we consider interacting electron systems, and provide a proof that is non-perturbative in the strength of electron-electron interactions and therefore applicable to strongly correlated electron systems. Moreover, we show that photon condensation is forbidden even in the presence of spatially non-uniform cavity modes, whenever the matter system does not interact with the magnetic field of the cavity mode.

On the basis of our new no-go theorem, we conclude that the first-order phase transition phenomenology discussed in the pioneering works [20, 21] on three-level systems coupled to a cavity mode is incorrect. The reason is that in these models, the light-matter interaction is not derived from an underlying gauge-invariant model. Conversely, an ad-hoc diamagnetic term is added. Such addition, which was made to enforce the TRK sum-rule, is not always sufficient to prevent a breakdown of gauge invariance.

Since these models produce results in stark contrast with our general theorem, one may be tempted to conclude (mistakenly) that is not possible to write a correctly gauge invariant model for an $M$-level system coupled to light. We show in this Article that this is not case. While enforcing the TRK sum-rule alone was a reasonable approach at that time, nowadays more refined techniques to enforce gauge invariance in systems with an arbitrary but finite number of levels have been developed [41-43] and applied to a few solid-state systems [44, 45]. Such methods can be viewed as an application of lattice gauge theories [46]. Here, we employ these new tools to derive a fully gauge-invariant model describing a set of three-level systems coupled to a cavity mode. In accordance with the theorem, such model does not display photon condensation.

Our Article is organized as following. A non-perturbative extension of the no-go theorem for photon condensation published in Ref. 10 to the case of first-order phase transitions is presented in Sect. II. As an example, in Sect. III we present a detailed discussion of a system of three-level atoms inside a cavity, in the modern language of lattice gauge theory. Finally, in Sect. IV we provide a brief summary of our main results and a set of conclusions.

II. GAUGE INvariance, PHOTON CONDENSATION, AND NO-GO THEOREM

We consider a quantum many-body system of interacting electrons. Here we follow the notation of Ref. 44. In second quantization, the electronic Hamiltonian can be written as

$$\hat{H}_{el} = \hat{H}_0 + \hat{H}_{ee},$$

where the one-body part, $\hat{H}_0$, reads as following

$$\hat{H}_0 = \int d\mathbf{r} \hat{\psi}^\dagger(\mathbf{r}) h_0(\mathbf{r}) \hat{\psi}(\mathbf{r}),$$

with

$$h_0(\mathbf{r}) = -\frac{\hbar^2 \nabla^2}{2m} + V(\mathbf{r}),$$

while the electron-electron interaction contribution is given by

$$\hat{H}_{ee} = \int d\mathbf{r} \, d\mathbf{r}' \hat{\psi}^\dagger(\mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}') \mathcal{U}(|\mathbf{r} - \mathbf{r}'|) \hat{\psi}(\mathbf{r}') \hat{\psi}(\mathbf{r}).$$

Here, $V(\mathbf{r})$ and $\mathcal{U}(|\mathbf{r} - \mathbf{r}'|)$ represent a generic one-body and two-body interaction potential, respectively.

The electron system is invariant under a global phase transformation $\hat{\psi}(\mathbf{r}) \rightarrow e^{i\theta} \hat{\psi}(\mathbf{r})$, and the associate Noether current reads

$$\hat{J}(\mathbf{r}) = \hat{\psi}^\dagger(\mathbf{r}) (-i\hbar \nabla) \hat{\psi}(\mathbf{r}) + \text{H.c.}.$$
However, the system is not invariant under a local phase transformation, $\psi(r) \rightarrow e^{i\theta(r)}\hat{\psi}(r)$. Such invariance can be restored by introducing the interaction with the electromagnetic field, by employing a minimal coupling scheme. Considering the Coulomb gauge—the effects of the scalar potential being already described by $V(r)$ and $U(|r - r'|)$—the total light-matter Hamiltonian is given by:

$$\hat{H}_C = \int dr \hat{\psi}^\dagger(r)h_C(r)\hat{\psi}(r) + \hat{H}_{ee} + \hat{H}_{ph}, \quad (6)$$

where

$$h_C(r) = \hat{T}_A + V(r), \quad (7)$$

and

$$\hat{T}_A = \frac{1}{2m} \left[ -i\hbar \nabla + \frac{e}{c} A(r) \right]^2. \quad (8)$$

Here, $e > 0$ is the elementary electron charge, $c$ is the speed of light, and $A(r)$ is the space-dependent field operator vector describing the electromagnetic field in the Coulomb gauge. The Hamiltonian of the free field is given by

$$\hat{H}_{ph} = \frac{1}{8\pi} \int dr \left\{ \hat{\Pi}^2(r) + [\nabla \times \hat{A}(r)]^2 \right\}, \quad (9)$$

where $\hat{\Pi}(r)$ is the conjugate momentum.

In this work, for simplicity, we will consider a single mode decomposition of the fields $[44]$

$$\hat{A}(r) = \hat{A}_0(r)(\hat{a} + \hat{a}^\dagger), \quad (10)$$

$$\hat{\Pi}(r) = i\hat{\Pi}_0(r)(\hat{a} - \hat{a}^\dagger), \quad (11)$$

where $\int dr (\nabla \times \hat{A}_0(r))^2/(2\pi) = \int dr \hat{\Pi}_0^2(r)/(2\pi) = \hbar\omega_{\text{ph}}$, where $\omega_{\text{ph}}$ is the resonance frequency of the cavity mode, and $\hat{A}_0(r), \hat{\Pi}_0(r)$ are the mode functions $[44]$. 

In terms of the single-mode photon creation ($\hat{a}^\dagger$) and annihilation ($\hat{a}$) operators, the field Hamiltonian reduces to

$$\hat{H}_{ph} = \hbar\omega_{\text{ph}}\hat{a}^\dagger \hat{a}. \quad (12)$$

A transformation of both the electronic and electromagnetic fields of the form

$$\hat{\psi}(r) \rightarrow e^{i\theta(r)}\hat{\psi}(r) \quad (13)$$

$$\hat{A}(r) \rightarrow \hat{A}(r) - \frac{\hbar c}{e} \nabla \theta(r), \quad (14)$$

leaves the Hamiltonian (6) invariant, in agreement with the gauge principle. We observe that Eq. (6) neglects the Zeeman coupling between the electron’s spin and the magnetic component of the electromagnetic field. However, the absence of this term is assured whenever the magnetic field is null or can be neglected in the spatial region where the field interacts with the electron system, as, e.g., in the dipole approximation.

Whenever the interaction of the matter system with the magnetic field can be neglected, the vector potential entering the interaction terms can be locally expressed as the gradient of a scalar field

$$\mathbf{A}_0(r) = \nabla \chi(r). \quad (15)$$

In the dipole approximation, $\chi(r)$ can be written as $\chi(r) = \mathbf{r} \cdot \mathbf{A}_0$, with $\mathbf{A}_0$ spatially uniform. Applying strictly the dipole approximation (uniform vector potential) to semiconductors implies a complete neglect of propagation effects inside the medium. In order to neglect the interaction of the electron system with the magnetic field, in an extended system such as a semiconductor, one can divide the whole medium into many cells of the same volume $V_{\text{cell}}$ and apply the dipole approximation at each cell $[48, 49]$. The cell should be much smaller than the field wavelength (the usual choice is to take the unit cell of the crystal as such a unit). Such relaxation of the dipole approximation can be realized using (15).

In this case, the minimal coupling replacement can also be implemented by applying the following unitary transformation to the electronic field $[44]$:

$$\hat{U}\hat{\psi}(r)\hat{U}^\dagger = e^{-i(e/\hbar\chi(r))(\hat{a} + \hat{a}^\dagger)}\hat{\psi}(r), \quad (16)$$

where

$$\hat{U} = \exp \left[ -i\frac{e}{\hbar \chi}(\hat{a} + \hat{a}^\dagger) \int dr \hat{\psi}^\dagger(r)\chi(r)\hat{\psi}(r) \right]. \quad (17)$$

Under the Coulomb gauge condition $\chi(r)$ is a generic harmonic function, i.e., $\nabla \cdot \mathbf{A}_0(r) = \nabla^2 \chi(r) = 0$. We stress that only the electronic field $\hat{\psi}(r)$ has to be transformed under Eq. (17) while the photonic field $\hat{a}$ is unchanged. We emphasize that, in this case, the magnetic component $\mathbf{B}$ of the cavity electromagnetic field is zero, i.e., $\mathbf{B}(r) \equiv \nabla \times \mathbf{A}_0(r) = \nabla \times \nabla \chi(r) = 0$.

The Hamiltonian in Eq. (6) can be rewritten as

$$\hat{H}_C = \hat{H}_{ph} + \hat{U}(\hat{H}_0 + \hat{H}_{ee})\hat{U}^\dagger$$

$$= \hat{H}_{ph} + \hat{H}_{ee} + \hat{U}\hat{H}_0\hat{U}^\dagger. \quad (18)$$

We further define

$$\hat{H}_{\text{el-ph}} \equiv \hat{U}\hat{H}_0\hat{U}^\dagger - \hat{H}_0. \quad (19)$$

In writing Eq. (18), we have used that the unitary transformation $\hat{U}$ does not alter the electron-electron interaction contribution to the Hamiltonian $[44]$.

We now use the property $[10, 11]$ that, in the thermodynamic limit (number of electrons $N \to \infty$, volume $V \to \infty$, with $N/V = \text{constant}$), entanglement between matter and photonic degrees of freedom in the ground state has no effect on extensive thermodynamic quantities, such as the total energy of the system. Hence, with
the sole aim of studying the occurrence of photon condensation, the system’s ground state can be written in the following approximate factorized form:

$$|\Psi\rangle = |\psi\rangle|\phi\rangle,$$  \hfill (20)

where $|\psi\rangle$ and $|\phi\rangle$ are matter and light quantum states. (We hasten to stress that the exact wave function is not of the factorized form (20). But, as long as we are interested in extensive quantities—i.e. quantities that scale linearly in $N$—we can use the approximate form (20), since $[\hat{H}_{el}/N, \hat{H}_{el-ph}/N] \to 0$ and $[\hat{H}_{ph}/N, \hat{H}_{el-ph}/N] \to 0$. See Refs. 10 and 11). Moreover, using this property, it has been shown that in the thermodynamic limit, $|\phi\rangle$ is a coherent state: $|\alpha\rangle = \alpha \sqrt{N} |\phi\rangle$, where $\alpha$ is the photonic order parameter. A finite value of $\alpha$ corresponds to the superannulated phase (photon condensation), while $\alpha = 0$ in the normal phase.

We start by considering the expectation value

$$\langle \phi | \hat{T}_A | \phi \rangle = -\frac{\hbar^2 \nabla^2}{2m} + i\frac{\hbar e}{mc} A_0(r) \cdot \nabla \langle \phi | \hat{a} + \hat{a}^\dagger | \phi \rangle$$
$$+ \frac{e^2}{2mc^2} \tilde{A}_0^2(r) \langle \phi | (\hat{a} + \hat{a}^\dagger)^2 | \phi \rangle,$$  \hfill (21)

where we used $\nabla \cdot A_0(r) = 0$ (Coulomb gauge) and $A_0(r) \equiv |A_0(r)| = \frac{1}{r} \sqrt{\frac{2\pi \hbar c^2}{\Omega_{ph}}}$, where $f(r)$ is an arbitrary function fulfilling the normalization condition $\int dr f^2(r)V = 1$.

We obtain

$$\langle \phi | \hat{T}_A | \phi \rangle = \frac{1}{2m} \left[ -i\hbar \nabla + \frac{e}{\hbar} \tilde{A}_0(r) \right]^2$$
$$+ \frac{e^2}{2mc^2} \tilde{A}_0^2(r),$$  \hfill (22)

where we defined $\tilde{A}_0(r) = A_0(r) \sqrt{N}$ and $\tilde{A}_0^2(r) \equiv |\tilde{A}_0(r)|$. In the thermodynamic limit, the last term in Eq. (22) goes to zero.

In the absence of a magnetic field interacting with the electron system and following the same steps from Eq. (6) to Eq. (18), we obtain, in the thermodynamic limit,

$$\frac{\hat{H}_{el}^{MF}}{N} \equiv \frac{\langle \phi | \hat{H}_C | \phi \rangle}{N} = \hbar \omega_{ph} |\alpha|^2 + \hat{H}_{ee} + \hat{U}_a \hat{A}_0 \hat{A}_0^\dagger,$$  \hfill (23)

where

$$\hat{U}_a = \exp \left[ -i \frac{e}{ch} (2\text{Re}[\alpha]) \int dr \hat{\psi}^\dagger(r) \hat{\chi}(r) \hat{\psi}(r) \right]$$  \hfill (24)

and $\hat{\chi}(r) = \chi(r) \sqrt{N}$.

The ground-state (GS) energy $E_{GS}$ is given by the expectation value of $\hat{H}_{el}^{MF}$ over the matter state $|\psi\rangle$:

$$E_{GS} = \frac{\langle \psi | \hat{H}_{el}^{MF} | \psi \rangle}{N} = \frac{\langle \psi' | \hat{U}_a^\dagger \hat{H}_C^{MF} \hat{U}_a | \psi' \rangle}{N} = \hbar \omega_{ph} |\alpha|^2 + \frac{\langle \psi' | \hat{H}_{el} | \psi' \rangle}{N},$$  \hfill (25)
III. THE NO-GO THEOREM FOR THREE-LEVEL SYSTEMS

In this Section we consider a system composed of three-level ladder atoms showing that, in agreement with our general theorem, it does not display a transition to a photon condensate state (when placed in a spatially-uniform cavity field $A$).

In order to derive a fully gauge invariant model for a system of three-level atoms interacting with a spatially-uniform cavity field, we first show (Sect. IIIA) that a generic $M$-level system can be mapped into a tight-binding model on a lattice with $M$ sites. In the second part of this Section (Sect. IIIB), we use the mapping combined with lattice gauge theory to derive a gauge-invariant model of a system of three-level atoms. Finally, we prove that such system does not display photon condensation.

A. $M$-level systems: a mapping onto a tight-binding lattice

It has been shown that, in the dipole approximation, a two-level atom interacting with the electromagnetic field can be equivalently described as a double-well system, where only the two lowest energy eigenstates are considered, which in turn corresponds to a two-site system [42]. Here we extend this idea to a generic $M$-level system, showing that it can be mapped onto a linear chain of sites connected by hopping processes (i.e. a tight-binding lattice).

The Hamiltonian $\hat{h}_0$ of any $M$-level system can be written in the basis of the eigenstates, $|n\rangle$ as,

$$\hat{h}_0 = \sum_{n=0}^{M-1} \epsilon_n |n\rangle \langle n| .$$

In the Coulomb gauge, and in the case of a single-mode spatially uniform vector potential $A(r) = A_0 (\hat{a} + \hat{a}^\dagger)$, such system can be coupled to $A$ as following:

$$\hat{h} = \hat{U} \hat{h}_0 \hat{U}^\dagger ,$$

where

$$\hat{U} = e^{-i (\epsilon / hc) A_0 \hat{x} (\hat{a} + \hat{a}^\dagger)} ,$$

$\hat{x}$ being the position operator. For sake of simplicity, we assumed a linearly polarized field, i.e. $A_0 = A_0 \hat{x}$.

It is now useful to define the following operator,

$$\hat{R} = - \frac{e}{hc} A_0 \hat{x} ,$$

(30)

with the property

$$\hat{U} = e^{i \hat{R} (\hat{a} + \hat{a}^\dagger)} .$$

(31)

In the basis of the eigenstates $|n\rangle$, $\hat{R}$ can be expressed as

$$\hat{R} = \sum_{n_1=0}^{M-1} \sum_{n_2=0}^{M-1} R_{n_1, n_2} |n_1\rangle \langle n_2| .$$

(32)

Since $\hat{R}$ is an Hermitian operator, it defines a basis of eigenvectors $|m\rangle$ such that:

$$\hat{R} |m\rangle = \lambda_m |m\rangle .$$

(33)

Recalling Eq. (30), the states $|m\rangle$ are also eigenvectors of the position operator, i.e. $\hat{x} |m\rangle = x_m |m\rangle$, with $\lambda_m = -e/(hc) A_0 x_m$. As we will show momentarily, this local basis of eigenstates of the position operator $\hat{x}$ defines a natural lattice representation of the Hamiltonian $\hat{h}$.

We now introduce the unitary transformation $\hat{O}$, which connects the energy basis $|n\rangle$ with the position basis $|m\rangle$. Its matrix elements will be denoted by the symbol $O_{m,n} \equiv \langle m|n\rangle$. By definition, the following property holds true:

$$\delta_{m_1, m_2} \lambda_{m_1} = \sum_{n_1=0}^{M-1} \sum_{n_2=0}^{M-1} O_{m_1, n_1} R_{n_1, n_2} O^\dagger_{n_2, m_2} .$$

(34)

As this identity shows, the transformation $\hat{O}$ diagonalizes the position operator $\hat{R}$.

The lattice representation of the matter Hamiltonian $\hat{h}_0$ is given by

$$\hat{h}_0 = \sum_{m_1=0}^{M-1} \sum_{m_2=0}^{M-1} t_{m_1, m_2} |m_1\rangle \langle m_2| ,$$

(35)

where the hopping matrix $t_{m_1, m_2}$ is defined by

$$t_{m_1, m_2} = \sum_{n=0}^{M-1} O_{m_1, n} \epsilon_n O^\dagger_{n, m_2} .$$

(36)

We are now in the position to write the Hamiltonian $\hat{h}$ (defined by Eq. (28)) in terms of the eigenvectors $|m\rangle$ of the position operator:

$$\hat{h} = \sum_{m_1=0}^{M-1} \sum_{m_2=0}^{M-1} e^{i \lambda_{m_1} (\hat{a} + \hat{a}^\dagger)} t_{m_1, m_2} e^{-i \lambda_{m_2} (\hat{a} + \hat{a}^\dagger)} |m_1\rangle \langle m_2|$$

$$= \sum_{m_1=0}^{M-1} \sum_{m_2=0}^{M-1} e^{-i \epsilon (hc) (x_{m_1} - x_{m_2}) (\hat{a} + \hat{a}^\dagger)} t_{m_1, m_2} |m_1\rangle \langle m_2| .$$

(37)

This is the main result of this Section. It shows that the coupled Hamiltonian $\hat{h}$ has the exact same form of a tight-binding lattice model coupled to light via the Peierls substitution. Actually, the Peierls method was developed to study electron systems interacting with static magnetic fields, in the framework of the tight-binding approximation. The Peierls substitution can be regarded
as an anticipation of lattice gauge theory, which is the general method developed by Wilson for studying non-perturbative relativistic gauge theories on a lattice [50], or in condensed matter physics, to analyze quantum simulations of lattice gauge theories [46]. Here we have shown that the two methods coincide provided that one operates in the position basis $|m\rangle$. Hence, in the lattice basis, the Peierls substitution is the most general tool to couple matter with a single cavity mode.

### B. The case of a three-level ladder atom

In the previous Section, we showed the Hamiltonian of a generic $M$-level system can be expressed in a local lattice basis. In this basis, the coupling between matter and light is implemented through the Peierls substitution.

We now consider the particular case of a three-level ladder atom, which can be described as a three-site system with inversion symmetry. In this Section we show that, in stark contrast to the conclusions of Refs. 20 and 21, such system does not display photon condensation.

The bare Hamiltonian of a single three-level ladder atom, expressed in the lattice representation (see Eq. (35)), reads

$$\hat{h}_0 = \sum_{i=-1}^{1} \epsilon_i |i\rangle \langle i| + t(|-1\rangle \langle 0| + |0\rangle \langle 1| + \text{H.c.}) \, .$$  

(38)

We consider here a system with parity symmetry, so that the selection rules for a three-level ladder atom apply: $\epsilon_{-1} = \epsilon_1$. From now on, we also fix $\epsilon_{-1} = \epsilon_1 = 0$. According to gauge lattice theory, the interaction with the electromagnetic field can be obtained by introducing the Wilson parallel transporter [50]. The resulting Hamiltonian, after applying the dipole approximation (uniform field), is

$$\hat{h}_{\text{tot}} = \hat{H}_{\text{ph}} + \hat{h} \, ,$$  

(39)

where $\hat{H}_{\text{ph}}$ is the free-photon Hamiltonian and $\hat{h}$ is the atomic Hamiltonian, now invariant under arbitrary (site-dependent) phase transformations:

$$\hat{h} = \epsilon_0 |0\rangle \langle 0| + [t e^{-i\gamma (\hat{a}^\dagger + \hat{a})} (-1) \langle 0| + |0\rangle \langle 1| + \text{h.c.}] \, ,$$  

(40)

accordingly to Eq. (37). Here, $\gamma = -edA_0/(\hbar c)$ with $d$ the distance between two adjacent sites. For simplicity, we assume a single mode optical resonator: $\hat{H}_{\text{ph}} = \hbar \omega_{\text{ph}} \hat{a}^\dagger \hat{a}$, with the field coordinate $\Lambda = A_0 (\hat{a}^\dagger + \hat{a})$, where $A_0$ is the vacuum fluctuation amplitude.

The Hamiltonian in Eq. (40) can also be written as

$$\hat{h} = \hat{U}_1 \hat{h}_0 \hat{U}_1^\dagger \, ,$$  

(41)

where

$$\hat{U}_1 = \exp \left(-i \frac{\epsilon}{\hbar c} \hat{x}_L \hat{A} \right) \, ,$$  

(42)

and $\hat{x}_L$ is the lattice coordinate, i.e. $\hat{x}_L = d \sum_j j |j\rangle \langle j|$. Let us now consider a collection of $N$ identical, non-interacting three-level ladder atoms. The total Hamiltonian

$$\hat{H} = \hat{H}_{\text{ph}} + \epsilon_0 \hat{\Sigma}_{0,0} + t e^{-i\gamma (\hat{a}^\dagger + \hat{a})} (\hat{\Sigma}_{-1,0} + \hat{\Sigma}_{0,1} + \text{h.c.}) \, ,$$  

(43)

where

$$\hat{\Sigma}_{i,j} = \sum_{k=1}^{N} |i_k\rangle \langle j_k| \, .$$  

(44)

Equation (43) can be written compactly as

$$\hat{H} = \hat{H}_{\text{ph}} + \hat{U}_0 \hat{H} \hat{U}_0^\dagger \, ,$$  

(45)

where

$$\hat{H}_0 = \epsilon_0 \hat{\Sigma}_{0,0} + t (\hat{\Sigma}_{-1,0} + \hat{\Sigma}_{0,1} + \text{h.c.})$$  

(46)

and

$$\hat{U}_0 = \exp \left(i \gamma \sum_{j=1}^{N} \hat{\Sigma}_{j,j} \right) \, .$$  

(47)

We now study the Hamiltonian $\hat{H}$ in the mean-field approximation, which corresponds to neglecting correlations between the cavity modes and electrons:

$$|\Psi\rangle = |\psi\rangle |\phi\rangle \, .$$  

(48)

As discussed above, such disentangled state yields the exact leading term of extensive thermodynamic quantities of the total system in the limit $N \to \infty$. Here $|\phi\rangle$ is a coherent state of the field, $\hat{a} |\phi\rangle = \alpha \sqrt{N} |\phi\rangle$, where $\alpha$ is the photonic order parameter. A finite value of $\alpha$ corresponds to the photon condensate state, while $\alpha = 0$ corresponds to the normal phase. The atomic mean-field Hamiltonian $\hat{H}^\text{MF}_a = \langle \phi | \hat{H} | \phi \rangle$ is given by

$$\hat{H}^\text{MF}_a = \hbar \omega_{\text{ph}} N |\alpha|^2 + \epsilon_0 \hat{\Sigma}_{0,0} + t \{ \Lambda (\hat{\Sigma}_{-1,0} + \hat{\Sigma}_{0,1}) + \text{h.c.} \, ,$$  

(49)

where

$$\Lambda = \langle \phi | e^{-i\gamma (\hat{a}^\dagger + \hat{a})} | \phi \rangle \, .$$  

(50)

By using the Baker-Campbell-Hausdorff formula, $e^{-i\gamma (\hat{a}^\dagger + \hat{a})} = e^{\gamma/2 - i\gamma \hat{a}^\dagger + i\gamma \hat{a}}$, we find $\Lambda = e^{\gamma_0/2N} e^{-i\gamma_0 (\alpha + \alpha^*)}$, where $\gamma_0 = \gamma \sqrt{N}$. In the limit $N \to \infty$, we find that $\Lambda = e^{-i\gamma_0 (\alpha + \alpha^*)}$. Introducing this result in Eq. (49) and following the same steps that led from Eq. (40) to Eq. (41), we can re-write Eq. (49) as:

$$\hat{H}^\text{MF}_a = \hbar \omega_{\text{ph}} N |\alpha|^2 + \hat{U}_\alpha \hat{H}_0 \hat{U}_\alpha^\dagger \, ,$$  

(51)

where

$$\hat{U}_\alpha = \exp \left[ i \gamma_0 (\alpha + \alpha^*) \sum_j \hat{\Sigma}_{j,j} \right] \, .$$  

(52)
The GS energy $E_{\text{GS}}$ is given by the expectation value of $\hat{H}$ over $|\psi\rangle$, which, in the mean-field approximation, corresponds to the expectation value of $\hat{H}_a^{\text{MF}}$ over $|\psi\rangle$. Since unitary transformations do not modify the spectrum of eigenvalues,

$$
\frac{E_{\text{GS}}}{N} = \langle \psi | \hat{H}_a^{\text{MF}} | \psi \rangle = \langle \psi' | \hat{U}_a \hat{H}_a^{\text{MF}} \hat{U}_a^{-1} | \psi' \rangle = \hbar \omega_{\text{ph}} |\alpha|^2 + \frac{1}{N} \langle \psi' | H_0 | \psi' \rangle,
$$

(53)

where $|\psi'\rangle = \hat{U}_a |\psi\rangle$. The ground-state energy has a well-defined minimum at $\alpha = 0$ and for $|\psi'\rangle$ corresponding to the ground state of the atomic system in the absence of light: $H_0 |\psi'\rangle = E_0 |\psi'\rangle$, as found in the general case [see Eq. (25)]. This is the second important result of this Article. Provided that gauge invariance is fully taken into account (and not only by enforcing the TRK sum rule), an ensemble of $N$ three-level ladder atoms, coupled to a spatially-uniform cavity mode, does not display photon condensation as a first-order phase transition. Key to our proof is the structure of the Hamiltonian $\hat{h}$, which is connected to the bare Hamiltonian $\hat{h}_0$ via a unitary transformation, i.e. Eq. (28). Hence, this procedure can be further generalized to an arbitrary $M$-level system coupled to a cavity mode.

**IV. SUMMARY AND CONCLUSIONS**

In this Article we have first presented a generalization of the no-go theorem of Ref. 10 to the case of phase transitions, of any order, between a normal and a photon condensate state. In particular, the order parameter $\alpha$ cannot be assumed to be small (and vary continuously) at first-order phase transitions, which are therefore not covered by the proof given in Ref. 10. The no-go theorem of Ref. 10 was indeed specifically designed to apply to second-order phase transitions. We have shown that an arbitrary system, minimally coupled to a longitudinal (or spatially-uniform) cavity mode, corresponding to zero magnetic field, cannot display photon condensation. This is in agreement with the findings of Refs. 11, 37, and 38 where it was shown that photon condensation can occur in a spatially-varying cavity field, and that it is formally equivalent to a magneto-static instability.

By employing lattice gauge theory, we have then derived a fully gauge invariant model for a system of three-level ladder atoms. It has been shown that this approach is essential to ensure gauge invariance when the matter system is truncated, for example, to only two energy levels [42]. Here, we show that this approach allows to save gauge invariance in presence of more general truncated electron systems. In this work, we also show that, adopting this approach, general correct results, as the no-go theorem for photon condensation, can be recovered, even for electron systems described in truncated Hilbert space. Indeed, our model of three-level ladder atoms does not display a transition (of any order) to a photon condensate state, in agreement with the general theorem and in stark contrast to the conclusions reached by the authors of Refs. 20 and 21. Since the actual theoretical description of realistic electron systems requires unavoidable approximations, the lattice gauge theory approach is of utmost importance in order to guarantee that approximations do not spoil gauge invariance.

We note that the conclusions reached in this Article apply to light-matter interacting systems whose interaction is described by the minimal (or Zeeman) coupling replacement. However, our conclusions have to be carefully reconsidered when applied to systems like superconducting artificial atoms coupled to microwave resonators, since these do not display the coordinate-momentum interaction resulting from the minimal coupling replacement [19]. One may argue that, at a microscopic level, also these systems interact according to the gauge principle and hence via the minimal (or Zeeman) coupling replacement [30]. However, we observe that, in several circuit-QED systems, artificial atoms interact with the electromagnetic resonator via a magnetic flux. Our no-go theorem naturally does not apply to this class of systems, where a magnetic field is present.

Finally, we would like to mention that the lattice gauge theory approach employed here can be fruitfully applied to condensed matter lattice models, such as the Hubbard model [51], the Falikov-Kimball model [52] and even more complicated multi-orbital system. While our general theorem holds irrespectively of all the microscopic details, it would be interesting to study strongly interacting systems in the presence of a cavity magnetic field, transcending the hypothesis of our theorem. For such an investigation, it is crucial to use a correctly gauge invariant model, which can be obtained with the methods of lattice gauge theory. Lattice gauge theory is in general necessary to correctly describe quantum materials strongly coupled with light, not only in the context of photon condensation [10, 27, 37, 44], but also in studying other light induced phenomena, such as ferroelectricity [53], light-induced topological properties [54, 55], photon mediated superconductivity [56–59], and photochemistry [60–65].
