Efficiency of stochastic coordinate proximal gradient methods on nonseparable composite optimization

I. Necora and F. Chorobura

Abstract This paper deals with large-scale composite optimization problems having the objective function formed as a sum of two terms, one has Lipschitz continuous gradient along random subspaces and may be nonconvex and the second term is simple, but possibly nonconvex and nonseparable. Under these settings we design a stochastic coordinate proximal gradient method which takes into account the nonseparable composite form of the objective function. This algorithm achieves scalability by constructing at each iteration a local approximation model of the nonseparable objective function along a random subspace with user-determined dimension. We outline efficient techniques for selecting the random subspace, yielding an implementation that has low cost per-iteration while also achieving fast convergence rates. We present a probabilistic worst-case complexity analysis for our stochastic coordinate proximal gradient method in convex and nonconvex settings, in particular we prove high-probability bounds on the number of iterations before a given optimality is achieved. To the best of our knowledge, this work is the first proposing a pure stochastic coordinate descent algorithm which is supported by global efficiency estimates for general nonseparable composite optimization problems. Preliminary numerical results also confirm the efficiency of our algorithm.

Keywords composite minimization · nonseparable objective function · stochastic coordinate descent · convergence rates
1 Introduction

This paper addresses stochastic (block) coordinate proximal gradient methods for large-scale composite optimization problems of the form:

\[ F^* = \min_{x \in \mathbb{R}^n} F(x) := f(x) + \psi(x), \]  

where \( f : \mathbb{R}^n \to \mathbb{R} \) is smooth (possibly nonconvex) and \( \psi : \mathbb{R}^n \to \mathbb{R} \) is simple and twice differentiable (possibly nonseparable and nonconvex). Optimization problems having this composite structure arise in many applications such as distributed control, signal processing, truss topology design, machine learning, traffic equilibrium problems, network flow problems and other areas [4,17,19]. Despite the bad properties of the sum, such problems, both in convex and nonconvex cases, can be solved by full gradient or Newton methods with the efficiency typical for the good part of the objective [24,25]. However, for large-scale problems, which is also the case in this paper, the usual methods based on full gradient and Hessian computations are prohibitive. In this case, it appears that a reasonable approach to solve such problems is to use (block) coordinate descent methods. These methods were among the first optimization algorithms studied in the literature, see e.g., [4].

State of the art. The main differences in all variants of (block) coordinate descent algorithms consist in the way we define the local approximation function over which we optimize and the criterion of choosing at each iteration the subspace over which we minimize this local approximation function. For updating one (block) variable, while keeping the other variables fixed, two basic choices for the local approximation function are usually considered: (i) exact approximation function, leading to coordinate minimization methods [4,2,13], and (ii) quadratic approximation function, leading to coordinate (proximal) gradient descent methods [3,11,16,20,26,28,30]. Furthermore, three classical criteria for choosing the coordinate search used often in these algorithms are the greedy, the cyclic and the random coordinate search, which significantly differs by the amount of computations required to choose the appropriate index. For cyclic coordinate search rates of convergence have been given only recently [2,3]. Convergence rates for coordinate descent methods based on the Gauss-Southwell rule were given e.g. in [30]. Another interesting approach is based on stochastic coordinate descent, where the coordinate search is random. Recent complexity results on stochastic coordinate descent methods were obtained in [26] for smooth functions and the extension to composite functions were given e.g., in [11,16,20,25]. However, all these papers studied optimization models where the second term, usually assumed nonsmooth, is separable, i.e. of the form \( \psi(x) = \sum_{i=1}^n \psi_i(x_i) \), with \( x_i \) is the \( i \)th component of \( x \).

Previous work. From our knowledge there exist very few studies on coordinate descent methods when the second term of the composite objective function is nonseparable. For example, [21,22,23,30] considers the composite optimization problem [1] with the additional linear constraints \( Ax = b \). Hence, nonseparability comes from the linear constraints \( Ax = b \), as \( \psi \) is assumed convex.
and separable (possibly nonsmooth). Under these settings, coordinate gradient descent methods where at the current feasible point \( x \) one needs to solve a subproblem over a subspace generated by the matrix \( U \in \mathbb{R}^{n \times p} \) using a part of the gradient of \( f \), \( \nabla f(x) \), i.e.:

\[
\min_{d \in \mathbb{R}^{p}} f(x) + \langle U^T \nabla f(x), d \rangle + \frac{1}{2} d^T H_U d \quad \text{s.t.} \quad AUd = 0,
\]

where \( H_U \) is an appropriate positive definite matrix and then update \( x^+ = x + Ud \). The matrix \( U \) is chosen according to some greedy rule or random. For this type of algorithms sublinear rates are derived in the (non)convex case and linear convergence is obtained for strongly convex objective.

For optimization problem (1), with \( f \) separable and \( \psi \) possibly nonseparable and nonsmooth, [15] proposes a coordinate descent type method of the form:

\[
z = \text{prox}_{\alpha \psi}(x - \alpha \nabla f(x)),
\]

where \( \text{prox}_{\alpha \psi} \) denotes the full proximal operator of the convex function \( \psi \) and then update \( x^+ \) as \( x_i^+ = z_i \) for all \( i \in I \subseteq [n] \) and keep the rest of the components unchanged. Although in this algorithm one needs to compute the full gradient of \( f \), \( \nabla f(x) \), and the full prox of \( \psi \), \( \text{prox}_{\alpha \psi} \), the update of the gradient \( \nabla f(x) \) can be done efficiently provided that \( f \) is separable, i.e. \( f(x) = \sum_{i=1}^{n} f_i(x_i) \). Linear convergence results are established when the cost function satisfies the Kurdyka-Lojasiewicz (KL) property without imposing convexity on the smooth function \( f \), only \( \psi \) needs to be convex. In [14] a modified variant of the proximal gradient iteration is considered:

\[
x^+ = \text{prox}_{\alpha \psi}(C(x - \alpha \nabla f(x))),
\]

where \( C(\cdot) \) is a correction map corresponding to the chosen random subspace at the current iteration. Also in this case one needs to compute the full prox \( \text{prox}_{\alpha \psi} \) and sketch the gradient \( \nabla f(x) \) on the selected subspace. For this algorithm linear convergence is derived, provided that the smooth term \( f \) is strongly convex. The paper most related to our work is [7], where a trust region algorithm is proposed based on iterative minimization within random subspaces for solving smooth nonconvex unconstrained problems, i.e. \( \psi = 0 \).

Using a probabilistic argument from [9], paper [7] derives a high-probability bound on the number of iterations such that the norm of the gradient is less than some given accuracy. Therefore, there is an open problem in the optimization literature whether it is possible to design a pure coordinate proximal gradient scheme for the general composite problem (1) (i.e., at each iteration the method sketches the gradient \( \nabla f(x) \) and computes the prox of \( \psi \) along some subspace), which is supported by global efficiency estimates. In this paper we (partially) solve this problem, i.e. we design for the general differentiable composite problem (1) a stochastic coordinate proximal gradient method that requires sketching the gradient \( \nabla f(x) \) on some random subspace and computing the prox of \( \psi \) also along this subspace. Moreover, using a probabilistic argument as in [14] and results from random matrix theory [18], we derive
high-probability convergence estimates for our algorithm in both convex and
nonconvex settings. More precisely, our contributions are:

Contributions. This paper deals with large-scale composite optimization prob-
lem [1] having the objective function formed as a sum of two terms, one has
Lipschitz continuous gradient along random subspaces and may be nonconvex
and the second term is simple, but possibly nonconvex and nonseparable. Under
these settings we design a stochastic coordinate proximal gradient method
which takes into account the nonseparable composite form of the objective
function. This algorithm achieves scalability by constructing at each iteration
a local approximation model of the nonseparable objective function along a
random subspace with user-determined dimension. We outline efficient tech-
niques for selecting the random subspace, yielding an implementation that has
low cost per-iteration (linear in the problem dimension) while also achieving
fast convergence rates. We present a probabilistic worst-case complexity anal-
ysis for our stochastic coordinate proximal gradient method in convex and
nonconvex settings, where in particular we prove high-probability bounds on
the number of iterations before a given optimality is achieved. The convergence
rates in probability in both convex and nonconvex settings are summarized in
the table below. In particular, sublinear rates are derived for nonconvex and
convex problems. Improved rates are given under the Kurdyka-Lojasiewicz
(KL) inequality (in the nonconvex case) and uniform convexity (in the con-
 vex case). Besides providing a general framework for the analysis of stochastic
coordinate proximal gradient schemes, our results (partially) resolve an open
problem in the optimization literature related to the convergence estimates for
coordinate descent algorithms on nonseparable (non)convex composite prob-
lems. Preliminary numerical results also confirm the efficiency of our algorithm.

\[

\hline
\end{array}
\]

Content. The paper is organized as follows. In Section 2 we present some
preliminary results, while in Section 3 we define our problem of interest and a
stochastic coordinate proximal gradient algorithm. The convergence rates in
probability are derived in Section 4 for the nonconvex case and in Section 5 for
the convex case. In the last section we provide detailed numerical simulations.
2 Preliminaries

In this section we present our basic assumptions for composite problem (1), some definitions and preliminary results. We consider the following problem setting. Let \( S = \{ S_\omega \} \) be family of (linear) subspaces of \( \mathbb{R}^n \). Intuitively, this set represents the directions that will be favored by the random descent. We assume that each subspace \( S_\omega \) is generated by the columns of a certain matrix \( U_\omega \in \mathbb{R}^{n \times p} \) and denote the family of such matrices by \( \mathcal{U} = \{ U_\omega \} \subset \mathbb{R}^{n \times p} \). For simplicity of the notation we consider the same dimension \( p \) for each subspace, although our results also hold for subspaces having different dimensions. Throughout the paper we assume that the set \( \mathcal{U} \) is bounded. Note that stochasticity enters in our algorithmic framework through a user-defined distribution on \( \mathcal{U} \) describing the ensemble of random matrices \( U \sim \mathcal{U} \), notation \( U_\sim \sim \mathcal{U} \). The basic idea of our algorithmic framework consists of a given \( x \in \mathbb{R}^n \), a sample matrix \( U \sim \mathcal{U} \) and a basic update of the form:

\[
x^+ = x + Ud.
\]

Throughout the paper the following assumptions will be valid:

**Assumption 1** For composite optimization problem (1) the following hold:

A.1: Given a family of matrices \( \mathcal{U} \subset \mathbb{R}^{n \times p} \), then for any \( U \in \mathcal{U} \) the function \( f \) is \( L_U \)-smooth along \( U \) (i.e., the gradient is Lipschitz continuous in the subspace generated by \( U \) with modulus \( L_U \)):

\[
\| U^T (\nabla f(x + Uh) - \nabla f(x)) \| \leq L_U \| h \| \quad \forall h \in \mathbb{R}^p.
\]  

A.2: The function \( \psi \) is simple and twice continuously differentiable (possibly nonseparable and nonconvex).

A.3: A solution exists for (1) (hence, the optimal value \( F^* > -\infty \)).

Unlike typical cases analyzed in the literature where either \( f \) or \( \psi \) is assumed separable (convex) [3,11,16,15,26,20,28], we consider the case where both terms are nonseparable (nonconvex), respectively. The function \( \psi \) is simple if its restriction to any subspace from \( S \) is proximal easy. Moreover, a function \( \psi \) is convex along a given family of subspaces \( S \) if for any fixed \( x \in \mathbb{R}^n \) and any matrix \( U \in \mathcal{U} \) generating a subspace from the family \( S \) the function:

\[
\phi(d) = \psi(x + Ud)
\]

is convex on its corresponding domain. Note that if \( \psi \) is twice differentiable, then it is convex along a given family of subspaces if \( U^T \nabla^2 \psi(x) U \) is positive semidefinite matrix for any \( x \) and \( U \) in the family of matrices \( \mathcal{U} \) generating \( S \). One can easily notice that there are nonconvex functions \( \psi \) which are convex along a given family of subspaces.

An immediate consequence of Assumption 1 [A.1] is the following:
Lemma 1 If Assumption [1] [A1] holds, then we have the relation:

\[ |f(x + Uh) - f(x) - (U^T \nabla f(x), h)| \leq \frac{L_U}{2} \|h\|^2 \quad \forall h \in \mathbb{R}^p. \]  

(3)

Proof See Appendix for a proof.

Note that when \( f \) has gradient Lipschitz with global Lipschitz constant \( L \), we also have Assumption [1] [A.1] valid with \( L_U = L \|U\| \) since:

\[ \|U^T (\nabla f(x + Uh) - \nabla f(x))\| \leq \|U\| \|\nabla f(x + Uh) - \nabla f(x)\| \leq L \|U\| \|h\|. \]

Another example when Assumption [1] [A.1] holds is given in the next lemma:

Lemma 2 If \( f \) is twice differentiable, then (2) holds if and only if the following relation holds:

\[ \|U^T \nabla^2 f(x)U\| \leq L_U \quad \forall x \in \mathbb{R}^n. \]  

(4)

Proof See Appendix for a proof.

Let us also recall the definition of a uniform convex function.

Definition 1 A differentiable function \( \psi \) is uniformly convex of order \( q > 1 \), if there exists \( \sigma_q > 0 \) such that the following relation holds:

\[ \psi(y) \geq \psi(x) + \langle \nabla \psi(x), y - x \rangle + \frac{\sigma_q (q - 1)}{q} \|y - x\|_q^{q-1} \quad \forall x, y \in \mathbb{R}^n. \]  

(5)

Note that for \( q = 2 \) in [1] we recover the usual definition of a strongly convex function. One important class of uniformly convex functions is \( \psi(x) = \frac{1}{q} \|x - \bar{x}\|^{q} \), where \( \bar{x} \) is given, see e.g. [27]. Minimizing both sides of (5), we also get:

\[ \psi^* = \min_{y \in \mathbb{R}^n} \psi(y) \geq \min_{y \in \mathbb{R}^n} \left\{ \psi(x) + \langle \nabla \psi(x), y - x \rangle + \frac{\sigma_q (q - 1)}{q} \|y - x\|_q^{q-1} \right\} \]

\[ = \psi(x) - \frac{1}{q} \left( \frac{1}{\sigma_q} \right)^{q-1} \|\nabla \psi(x)\|^q \quad \forall x \in \mathbb{R}^n. \]  

(6)

For nonconvex functions the usual notion replacing uniform convexity (6) is the Kurdyka-Łojasiewicz (KL) property, which captures a broad spectrum of the local geometries that a nonconvex function can have [3].

Definition 2 A differentiable function \( \psi \) satisfies Kurdyka-Łojasiewicz (KL) property if for every compact set \( \Omega \) on which \( \psi \) takes a constant value \( \psi_* \), there exist \( \delta, \epsilon > 0 \) such that one has:

\[ \kappa'(\psi(x) - \psi_*) \|\nabla \psi(x)\| \geq 1 \quad \forall x: \text{dist}(x, \Omega) \leq \delta, \psi_* < \psi(x) < \psi_* + \epsilon, \]

where \( \kappa: [0, \epsilon] \to \mathbb{R} \) is a concave differentiable function satisfying \( \kappa(0) = 0 \) and its derivative \( \kappa' > 0 \).
When $\kappa$ takes the form $\kappa(t) = \sigma_q \left( \frac{1}{q-1} \right)^{\frac{1}{q-1}} t^{\frac{1}{q-1}}$, with $q > 1$ and $\sigma_q > 0$ (which is our interest here), the KL property establishes the following local geometry of the nonconvex function $\psi$ around a compact set $\Omega$:

$$\psi(x) - \psi_* \leq \sigma_q \|
abla \psi(x)\|^q \quad \forall x: \text{dist}(x, \Omega) \leq \delta, \psi_* < \psi(x) < \psi_* + \epsilon. \quad (7)$$

Note that the relevant aspect of the KL property is when $\Omega$ is a subset of critical points for $\psi$, i.e. $\Omega \subseteq \{x: \nabla \psi(x) = 0\}$, since it is easy to establish the KL property when $\Omega$ is not related to critical points. The KL property holds for a large class of functions including semi-algebraic functions (e.g. real polynomial functions), vector or matrix (semi)norms (e.g. $\| \cdot \|_p$ with $p \geq 0$ rational number), logarithm functions, exponential functions and uniformly convex functions, see [5] for a comprehensive list.

### 3 A stochastic coordinate proximal gradient algorithm

For minimizing the composite optimization problem (1), where $f$ and $\psi$ are assumed nonseparable functions (both possibly nonconvex), we propose a pure stochastic coordinate descent algorithm that requires sketching the gradient $\nabla f(x)$ on some random subspace and computing the prox of $\psi$ also along this subspace. Hence, our Stochastic Coordinate Proximal Gradient (SCPG) algorithm is as follows:

**Algorithm 1 (SCPG):**

Give $U \subseteq \mathbb{R}^{n \times p}$ a family of matrices and starting point $x_0 \in \mathbb{R}^n$. For $k \geq 0$ do:

1. Randomly sample $U_k \sim U$ and choose $H_{f,U_k} > 0$.
2. Solve the following subproblem:

$$d_k = \arg \min_{d \in \mathbb{R}^p} f(x_k) + \langle U_k^T \nabla f(x_k), d \rangle + \frac{H_{f,U_k}}{2} \|d\|^2 + \psi(x_k + U_k d). \quad (8)$$

3. Update $x_{k+1} = x_k + U_k d_k$.

Note that for $U_k = I_n$, SCPG recovers Algorithm (4.8) in [27]. Moreover, regardless of the properties of the two functions $f$ and $\psi$, the subproblem (8) is convex provided that $\psi$ is convex when restricted to the subspace generated by the matrix $U_k$. In particular, the subproblem (8) is convex when $\psi$ is convex. Throughout the paper, we assume that the level set:

$$\mathcal{L}_F(x_0) = \{x: F(x) \leq F(x_0)\}$$

is bounded. Let us denote the restriction of the function $\psi$ over the subspace generated by the matrix $U_k$ by:

$$\phi_k(d) = \psi(x_k + U_k d).$$
Then, we notice that our algorithm requires computation of the proximal operator of the function $\phi_k$ at the sketching gradient $U_k^T \nabla f(x_k)$:

$$d_k = \arg \min_{d \in \mathbb{R}^p} \phi_k(d) + \frac{H_f U_k}{2} \|d + H_f^{-1} U_k^T \nabla f(x_k)\|^2 = \text{prox}_{H_f^{-1} U_k \phi_k} \left(-H_f^{-1} U_k^T \nabla f(x_k) \right).$$

Our key concept in the analysis of algorithm SCPG is related to the quality of our subspace selection.

**Definition 3** The matrix $U_k \in \mathbb{R}^{n \times p}$ is well-aligned if

$$\|U_k^T \nabla F(x_k)\| \geq \alpha \|\nabla F(x_k)\|,$$

for some $\alpha \in (0, 1)$ independent of the iteration $k$.

The notation of well-aligned iterations has been also used in [7] for derivative-free methods in nonlinear least-squares optimization. In our convergence analysis we will use the set of well-aligned iterations in $K$ iterations, with $K$ fixed, denoted $A_K$, i.e.:

$$A_K = \{k \in [K] : U_k \text{ is well-aligned} \}.$$

In the sequel we also consider the following assumption related to well-alignment (subspace quality):

**Assumption 2** At each iteration $k$ our subspace selection $U_k$ is well-aligned for some fixed $\alpha \in (0, 1)$ with probability at least $1 - \delta$, with $\delta \in (0, 1)$, independently of the filtration $\mathcal{F}_k := \{U_0, \ldots, U_{k-1}\}$.

Fortunately, the random matrices theory [18] provides us many examples of classes of matrices that are probabilistic well-aligned. Below we discuss some classes of such matrices: random orthogonal matrices and Johnson-Lindenstrauss matrices (see also [7, 18]).

### 3.1 Random orthogonal matrices

First, we consider the class of matrices $\mathcal{U}$ containing matrices $U$ randomly generated with orthonormal columns. We have the following probabilistic result for this class (see Theorem 9 in [18]).

**Lemma 3** Let the columns of $U \in \mathbb{R}^{n \times p}$ form an orthonormal basis for a randomly generated $p$ dimensional subspace of $\mathbb{R}^n$. Then, for any fixed vector $\nu \in \mathbb{R}^n$, we have:

$$\mathbb{P}\left(\left\|U^T \nu\right\| \geq \left(\frac{2}{n} - \sqrt[3]{\frac{2}{n}}\right) \|\nu\|\right) > 1 - 3e^{-\theta^2/64} \quad \forall \theta \in (0, 1).$$
Note that if we fix some $\delta \in (0, 1)$ and then set
\[
\theta = \frac{8\sqrt{\log(3/\delta)}}{\sqrt{p}},
\]
we get
\[
P \left[ \|U^T \nu\| > \left( \frac{p}{n} - \theta \frac{p}{\sqrt{n}} \|\nu\| \right) \right] > 1 - \delta.
\]
In our case, choosing $\nu = \nabla F(x_k)$, then Assumption 2 holds if
\[
\frac{p}{n} - \frac{8\sqrt{\log(3/\delta)}}{\sqrt{n}} \geq \alpha \quad \iff \quad p \geq \alpha n + 8\sqrt{\log(3/\delta)n}.
\]
In particular, if we take $\alpha = \frac{1}{\sqrt{n}}$, we have:
\[
p \geq \sqrt{n} + 8\sqrt{\log(3/\delta)n} \sim \sqrt{n}.
\]
Hence, in this case the dimension of the subspace, $p$, depends on the dimension $n$ of the original problem \(1\), i.e. $p \sim \sqrt{n}$.

### 3.2 Johnson-Lindenstrauss embeddings

We can also consider for $U$ the class of Johnson-Lindenstrauss embeddings, i.e. $U \in \mathcal{U}$ is a Johnson-Lindenstrauss transform (JLT). For these matrices we can improve the requirement on $p$. Recall that a random matrix $U \in \mathbb{R}^{n \times p}$ is an $(1 - \alpha, \delta)$ JLT if for any vector $\nu \in \mathbb{R}^n$, we have:
\[
P \left[ \alpha \|\nu\|^2 \leq \|U^T \nu\|^2 \leq (2 - \alpha)\|\nu\|^2 \right] \geq 1 - \delta.
\]
Some common examples are:

(JLT-1): If $U$ is a random Gaussian matrix with independent entries normally distributed, $U_{ij} \sim \mathcal{N}(0, 1/p)$, and $p = \mathcal{O}\left((1 - \alpha)^{-2}\log(\delta)\right)$, then $U$ is an $(1 - \alpha, \delta)$ JLT.

(JLT-2): We say that $U$ is an $s$ hashing matrix if it has exactly $s$ nonzero entries per row (indices sampled independently), which take values $\pm 1/\sqrt{s}$ selected independently with probability $1/2$. Then, any $s$-hashing matrix $U$ with $s = \mathcal{O}\left((1 - \alpha)^{-1}\log(\delta)\right)$ and $p = \mathcal{O}\left((1 - \alpha)^{-2}\log(\delta)\right)$ is $(1 - \alpha, \delta)$ JLT.

Since $\alpha^2 \leq \alpha$ for all $\alpha \in (0, 1)$, we have for any $U$ which is $(1 - \alpha, \delta)$ JLT:
\[
P \left[ \|U^T \nu\| \geq \alpha \|\nu\| \right] \geq 1 - \delta.
\]
Then, for $\nu = \nabla F(x_k)$, Assumption 2 holds if $U$ is any $(1 - \alpha, \delta)$ JLT. Moreover, in the previous examples the dimension of the subspace $p$ satisfies:
\[
p \geq (1 - \alpha)^{-2}\log(\delta).
\]
Hence, for JLT matrices the value of $p$ is independent of the dimension $n$ of the original problem \(1\).
4 Convergence analysis: nonconvex case

In this section we derive convergence rates for algorithm SCPG when the smooth function \( f \) is nonconvex and nonseparable, and \( \psi \) is simple, but nonseparable, nonconvex and twice differentiable. Let us first recall a basic result related to the optimality conditions for a composite optimization problem, see e.g., [27].

**Lemma 4** Given the general composite optimization problem:

\[
\min_{x \in \text{dom } \phi} \theta(x) + \phi(x),
\]

where \( \theta \) is differentiable and \( \phi \) is convex on the convex domain \( \text{dom } \phi \). Then, if \( y^* \) is a (local) minimum, we have the following optimality condition:

\[
\langle \nabla \theta(y^*), y - y^* \rangle + \phi(y) \geq \phi(y^*) \quad \forall y \in \text{dom } \phi.
\] (10)

Next lemma shows that our algorithm is a descent method. For simplicity, let us denote for some \( \eta U_k > 0 \):

\[
H_{f,U_k} = \begin{cases} 
L_{U_k} + \eta U_k & \text{if } \psi \text{ convex along subspaces from } U, \\
L_{U_k} + \eta U_k & \text{otherwise}.
\end{cases}
\]

**Lemma 5** If Assumption 4 holds, then the iterates of algorithm SCPG satisfies the following descent inequality:

\[
F(x_{k+1}) \leq F(x_k) - \frac{\eta U_k}{2} \|d_k\|^2.
\] (11)

**Proof** First consider that \( \psi \) is convex along the subspaces generated by matrices from \( U \). Using the optimality condition (10) for \( d_k \) with the functions:

\[
\theta(d) = f(x_k) + \langle \nabla f(x_k), U_k d \rangle + \frac{H_{f,U_k}}{2} \|d\|^2
\]

\[
\phi(d) = \psi(x_k + U_k d),
\]

we get:

\[
\langle U_k^T \nabla f(x_k) + H_{f,U_k} d_k, d - d_k \rangle + \psi(x_k + U_k d) \geq \psi(x_k + U_k d_k) \quad \forall d \in \mathbb{R}^p.
\]

From the previous optimality condition for \( d = 0 \), we further obtain:

\[
-\langle U_k^T \nabla f(x_k) + H_{f,U_k} d_k, d_k \rangle + \psi(x_k) \geq \psi(x_k + U_k d_k) = \psi(x_{k+1}).
\]

Using Assumption 4 and 3, we obtain:

\[
f(x_{k+1}) + \psi(x_{k+1}) \leq f(x_k) + \langle \nabla f(x_k), U_k d_k \rangle + \frac{L_{U_k}}{2} \|d_k\|^2 + \psi(x_{k+1}).
\] (12)
generates of algorithm SCPG satisfy the following relation:

**Lemma 6**

If Assumptions 1 and 2 hold and \( H \) is such that \( H \) is bounded, then the gradients of the objective function \( F \) are differentiable, then from the optimality condition of \( d_k \) have we that:

\[ U_k^T (\nabla f(x_k) + \nabla \psi(x_{k+1})) + H_{f,U_k} d_k = 0. \]  

Moreover, \( \nabla F(x_k) := \nabla f(x_k) + \nabla \psi(x_k) \). Using (14) and Assumptions 1 and 2 we get that for all \( k \in \mathbb{K} \):

\[
\alpha \| \nabla F(x_k) \|^2 \leq \| U_k^T \nabla F(x_k) \|^2 = \| U_k^T (\nabla f(x_k) + \nabla \psi(x_k)) \|^2 \\
= \| U_k^T (\nabla \psi(x_k) - \nabla \psi(x_{k+1})) - H_{f,U_k} d_k \|^2 \\
\leq 2 \| U_k^T (\nabla \psi(x_{k+1}) - \nabla \psi(x_k)) \|^2 + 2 H_{f,U_k}^2 \| d_k \|^2 \\
= 2 \| U_k^T (\nabla \psi(x_k + U_k d_k) - \nabla \psi(x_k)) \|^2 + 2 H_{f,U_k}^2 \| d_k \|^2,
\]

This proves our statement. \( \Box \)

From previous lemma we see that one can choose a larger stepsize when \( \psi \) is convex along the subspace generated from \( U \), since \( H_{f,U_k} > L_{U_k}/2 \). Otherwise, we should choose \( H_{f,U_k} \) satisfying \( H_{f,U_k} > L_{U_k} \). Let us also define \( H_{\psi,U_k} = \max_{x \in \text{conv}(\mathcal{L}_F(x_0))} \| U_k^T \nabla^2 \psi(x) U_k \| < \infty \), provided that the sublevel set \( \mathcal{L}_F(x_0) \) is bounded.

Using the well-aligned assumption, we prove next that the gradients of the objective function \( F \) evaluated along the well-aligned iterations are bounded by the coordinate directions \( \| d_k \| \).

**Lemma 6** If Assumptions 1 and 2 hold and \( \mathcal{L}_F(x_0) \) is bounded, then the iterates of algorithm SCPG satisfy the following relation:

\[
\| \nabla F(x_k) \|^2 \leq \frac{2}{\alpha} \left( \frac{H_{\psi,U_k}^2 + H_{f,U_k}^2}{\alpha} \right) \| d_k \|^2 \quad \forall k \in \mathbb{K}. \]  

**Proof** Since \( f \) and \( \psi \) are differentiable, then from the optimality condition of \( d_k \) we have:

\[
F(x_{k+1}) = f(x_k) + \langle \nabla f(x_k), U_k d_k \rangle + \frac{L_{U_k}}{2} \| d_k \|^2 - \langle U_k^T \nabla f(x_k), d_k \rangle - H_{f,U_k} \| d_k \|^2 + \psi(x_k)
\]

Combining this with inequality (12), we get:

\[
F(x_{k+1}) \leq f(x_k) + \langle \nabla f(x_k), U_k d_k \rangle + \frac{L_{U_k}}{2} \| d_k \|^2 + \psi(x_k + U_k d_k) \leq \psi(x_k).
\]

Similarly, if \( \psi \) is nonconvex along the given family of subspaces generated from \( U \), from (13), we have:

\[
\langle U_k^T \nabla f(x_k), d_k \rangle + \frac{H_{f,U_k}}{2} \| d_k \|^2 + \psi(x_k + U_k d_k) \leq \psi(x_k).
\]

This proves our statement. \( \Box \)
where we used that \( \|a + b\|^2 \leq 2\|a\|^2 + 2\|b\|^2 \) in the second inequality. Since \( \psi \) is twice differentiable, by mean value theorem there exists \( \bar{x}_k \in [x_k, x_k + Ujd_k] \) such that:

\[
\|U_k^T (\nabla \psi(x_k + Ujd_k) - \nabla \psi(x_k))\| = \|U_k^T \nabla^2 \psi(\bar{x}_k)Ujd_k\| \\
\leq \|U_k^T \nabla^2 \psi(\bar{x}_k)Ujd_k\|. 
\]

Moreover, by Lemma 5, \( x_k, x_k + Ujd_k \in \mathcal{L}_F(x_0) \), hence \( \bar{x}_k \in \text{conv}(\mathcal{L}_F(x_0)) \). Since, by our assumption \( \mathcal{L}_F(x_0) \) is bounded, then its convex hull \( \text{conv}(\mathcal{L}_F(x_0)) \) is also bounded. Using the fact that \( \psi \) is twice continuously differentiable, we have that there exist \( H_\psi, U \) such that:

\[
\|U_k^T \nabla^2 \psi(\bar{x}_k)Ujd_k\| \leq H_\psi Ujd_k \text{ for all } \bar{x}_k \in \text{conv}(\mathcal{L}_F(x_0)).
\]

This proves our statement.

Now, using a probabilistic argument as in \[9\] (see also \[7,12\] for a similar framework used however for other types of optimization algorithms), we get that with high-probability the number of well-aligned iterations is bounded from below.

**Lemma 7** If Assumptions \[\mathcal{A}_0\] and \[\mathcal{E}\] hold, then with high-probability the following bound on the number of well-aligned iterations holds:

\[
P[|\mathcal{A}_K| \geq (1 - \beta)(1 - \delta)(K + 1)] \geq 1 - e^{-\frac{\beta^2}{2}(1 - \delta)(K + 1)} \quad \forall \beta \in (0, 1). \tag{15}
\]

**Proof** Let \( T_i \) be the indicator function for the event \( U_i \) is well-aligned. Then, \( |\mathcal{A}_K| = \sum_{i=0}^{K} T_i \). Since \( T_i \in \{0, 1\} \), denoting \( p_i := P[T_i = 1|x_i] \), then for any \( t > 0 \) and \( i = 0, 1, \ldots, K \), we have:

\[
E[e^{-t(T_i-p_i)|x_i}] = pe^{-t(1-p_i)} + (1-p_i)e^{tp_i} = e^{tp_i}(1-p_i + p_ie^{-t}) \\
= e^{tp_i}e^{\log(1-p_i+p_ie^{-t})} = e^{tp_i+\log(1-p_i+p_ie^{-t})} \\
\leq e^{\frac{t^2p_i}{2}}
\]

where the inequality follows from the relation:

\[
y + \log(1 + p + pe^{-y}) \leq \frac{y^2p}{2} \quad \forall p \in [0, 1], \ y \geq 0, \tag{16}
\]

see Appendix for the proof. Using basic properties of conditional expectations and the fact that \( T_i \) only depends on \( x_i \) and not on the previous iterations (see Assumptions \[\mathcal{E}\]), we then get:

\[
E[e^{-t(|\mathcal{A}_K| - \sum_{i=0}^{K} p_i)}] = E\left[e^{-t\sum_{i=0}^{K} (T_i - p_i)}\right] \\
= E\left[e^{-t\sum_{i=0}^{K-1} (T_i - p_i)} E\left[e^{-t(T_K - p_K)|x_K}\right]\right] \\
\leq e^{\frac{t^2p_K}{2}}E\left[e^{-t\sum_{i=0}^{K-1} (T_i - p_i)}\right] \\
= e^{\frac{t^2p_K}{2}}E\left[e^{-t\sum_{i=0}^{K-1} (T_i - p_i)} E\left[e^{-t(T_{K-1} - p_{K-1})|x_{K-1}}\right]\right] \\
\leq e^{\frac{t^2p_K}{2}} e^{\frac{t^2p_{K-1}}{2}} \cdots E\left[e^{-t\sum_{i=0}^{K^{-2}} (T_i - p_i)}\right] \leq e^{\frac{t^2}{2}(\sum_{i=0}^{K} p_i)}.
\]
By Markov inequality and (17), we have:

\[
\mathbb{P}\left[ e^{-t(|A_K| - \sum_{i=0}^{K} p_i)} \geq e^{t\lambda} \right] \leq e^{-t\lambda} \cdot \mathbb{E}\left[ e^{-t(|A_K| - \sum_{i=0}^{K} p_i)} \right] \\
\leq e^{-t\lambda} \cdot e^{\frac{t^2}{2} \left( \sum_{i=0}^{K} p_i \right)} = e^{\frac{t^2}{2} \left( \sum_{i=0}^{K} p_i \right) - t\lambda}. \tag{18}
\]

On the other hand, one can note that:

\[
|A_K| \leq \sum_{i=0}^{K} p_i - \lambda \iff t\lambda \leq -t|A_K| + t \sum_{i=0}^{K} p_i \iff e^{-t(|A_K| - \sum_{i=0}^{K} p_i)} \geq e^{t\lambda}.
\]

Hence, we get:

\[
\mathbb{P}\left[ |A_K| \leq \sum_{i=0}^{K} p_i - \lambda \right] = \mathbb{P}\left[ e^{-t(|A_K| - \sum_{i=0}^{K} p_i)} \geq e^{t\lambda} \right]. \tag{19}
\]

Combining (18) and (19), we further get:

\[
\mathbb{P}\left[ |A_K| \leq \sum_{i=0}^{K} p_i - \lambda \right] \leq e^{\frac{t^2}{2} \left( \sum_{i=0}^{K} p_i \right) - t\lambda}.
\]

Taking \( t = \frac{\lambda}{\sum_{i=0}^{K} p_i} \), we obtain:

\[
\mathbb{P}\left[ |A_K| \leq \sum_{i=0}^{K} p_i - \lambda \right] \leq e^{-\frac{\lambda^2}{2 \left( \sum_{i=0}^{K} p_i \right)}}.
\]

Finally, taking \( \lambda = \beta \sum_{i=0}^{K} p_i \) for some \( \beta \in (0, 1) \), we have:

\[
\mathbb{P}\left[ |A_K| \leq (1 - \beta) \sum_{i=0}^{K} p_i \right] \leq e^{-\frac{\beta^2 \left( \sum_{i=0}^{K} p_i \right)}{2}}.
\]

and consequently

\[
\mathbb{P}\left[ |A_K| \geq (1 - \beta) \sum_{i=0}^{K} p_i \right] \geq 1 - e^{-\frac{\beta^2 \left( \sum_{i=0}^{K} p_i \right)}{2}}. \tag{20}
\]

From Assumption 2, \( p_i \geq (1 - \delta) \) for all \( i = 0, 1, \ldots, K \). Therefore, we get:

\[
(1 - \beta) \sum_{i=0}^{K} p_i \geq (1 - \beta)(1 - \delta)(K + 1).
\]
Since the event \( \{|A_K| \geq (1 - \beta)(1 - \delta)(K + 1)\} \) is contained in the event \( \{|A_K| \geq (1 - \beta)\sum_{i=0}^{K} p_i\} \), from (20) we obtain:
\[
P \left[ |A_K| \geq (1 - \beta)(1 - \delta)(K + 1) \right] \geq P \left[ |A_K| \geq (1 - \beta)\sum_{i=0}^{K} p_i \right] 
\geq 1 - e^{-\beta^2 \frac{\sum_{i=0}^{K} p_i}{2}}.
\]
Since we also have \( \sum_{i=0}^{K} p_i \geq (1 - \delta)(K + 1) \), we get our statement (15).

### 4.1 Sublinear convergence

Before proving the sublinear rate of algorithm SCPG in the general case, we need to define the following constants (recall that we assume \( U \) bounded):
\[
H_{\psi,U_k} \leq H_{\psi,\text{max}} \quad \text{and} \quad H_{f,U_k} \leq H_{f,\text{max}} \quad \forall k \geq 0,
\]
and
\[
\eta_{\text{min}} = \min_{k \in \mathbb{N}} \eta_{U_k} \quad \text{and} \quad C = \frac{\alpha \eta_{\text{min}}}{4 \left( H_{f,\text{max}}^2 + H_{\psi,\text{max}}^2 \right)}.
\]

Now we are ready to prove a high-probability sublinear bound for the minimum norm of subgradients generated by algorithm SCPG.

**Theorem 1** If Assumptions 1 and 2 hold and \( \mathcal{L}(x_0) \) is bounded, then for the SCPG sequence \( (x_k)_{k \geq 0} \) we have with high-probability the following rate:
\[
P \left[ \min_{0 \leq i \leq K} \|\nabla F(x_i)\|^2 \leq \frac{F(x_0) - F^*}{C(1 - \beta)(1 - \delta)(K + 1)} \right] \geq 1 - e^{-\beta^2 \frac{(1 - \delta)(K + 1)}{2}} \tag{22}
\]
for all \( \beta \in (0,1) \).

**Proof** From Lemma 6 and (21), we have
\[
\frac{\eta_{\text{min}}}{2} \sum_{i=0}^{K} \|d_i\|^2 \leq \sum_{i=0}^{K} \frac{\eta_{U_k}}{2} \|d_i\|^2 \leq \sum_{i=0}^{K} (F(x_i) - F(x_{i+1}))
\]
\[= F(x_0) - F(x_{K+1}) \leq F(x_0) - F^*. \tag{23}
\]
If we assume that the set of indexes corresponding to well-aligned iterations are given by \( A_K = \{k_0, \ldots, k_J\} \). Then, from Lemma 6 it follows that:
\[
\frac{J}{2} \|d_{k_i}\|^2 \leq \sum_{i=0}^{J} \frac{\alpha \eta_{\text{min}}}{4 \left( H_{f,U_{k_i}}^2 + H_{\psi,U_{k_i}}^2 \right)} \|\nabla F(x_{k_i})\|^2 
\leq \sum_{i=0}^{J} \frac{\eta_{\text{min}}}{2} \|d_{k_i}\|^2 \leq \frac{\eta_{\text{min}}}{2} \sum_{i=0}^{K} \|d_i\|^2 \leq F(x_0) - F^*.
\]
Therefore, we get:

\[
|A_K| \min_{0 \leq i \leq K} \| \nabla F(x_i) \|^2 \leq \frac{1}{C} (F(x_0) - F^*).
\] (24)

Finally, from Lemma 7 we get:

\[
\mathbb{P} \left[ \min_{0 \leq i \leq K} \| \nabla F(x_i) \|^2 \leq \frac{|A_K| \min_{0 \leq i \leq k} \| \nabla F(x_i) \|^2}{1 - \beta (1 - \delta)(K + 1)} \right] \geq 1 - e^{- \frac{\epsilon^2}{2} (1 - \delta)(K+1)}
\] (25)

Hence, from (24) and (25) the statement (22) follows.

Alternatively, the convergence rate from previous theorem can be stated in terms of a given accuracy \( \epsilon > 0 \) and probability \( \gamma \), i.e. for

\[
K \geq \max \left\{ \frac{F(x^0) - F^*}{\epsilon^2 \cdot C(1 - \delta)(1 - \beta)} - 1, \frac{2}{\beta^2(1 - \delta)} \ln \frac{1}{\gamma} - 1 \right\}
\]

we have

\[
\mathbb{P} \left[ \min_{0 \leq i \leq K} \| \nabla F(x_i) \| \leq \epsilon \right] \geq 1 - \gamma.
\]

This convergence rate, where the probability \( \gamma \) enters logarithmically in the estimate, is similar to the ones derived in the literature for random coordinate descent [26,28]. Recall that we can consider \( 1 - \delta \approx 1 \) and chose \( \beta \) such that \( \max \left( \frac{1}{\beta^2}, \frac{1}{1 - \beta} \right) \) is small, e.g., \( \beta = \frac{\sqrt{5} - 1}{2} \) (the golden number). It is important to note that the high-probability sublinear bound from the previous theorem holds for objective functions having both terms \( f \) and \( \psi \) nonconvex and nonseparable.

Usually, in the coordinate descent, where \( U \)'s are submatrices of the identity matrix \( I_n \) and \( \psi \) is separable, the complexity estimates are expressed in terms of the number of blocks (i.e., the ratio between the dimension of the original problem and of the subproblems) [3,11,16,26,20,23,28]. In our notations, this ratio is given by \( N = n/p \). Moreover, the existing works for separable \( \psi \) have derived convergence rates that depend linearly on such \( N \). Let us also analyze the dependence on \( N \) of the convergence rate (22) of Theorem 1 for algorithm SCPG in the optimality given by the square norm of the gradient:

*Matrices \( U_k \) are orthogonal.* If we choose \( \alpha = 1/\sqrt{n} \), we have \( p \sim \sqrt{n} \) and then \( N \sim \sqrt{n} \). From (22) we get that with high-probability the rate is of order:

\[
\mathcal{O} \left( \frac{N \left( H^2_{\text{f, max}} + H^2_{\psi, max} \right)}{k} \right)^{n_{\text{min}}^{-1}}
\]
Matrices $U_k$ are Johnson-Lindenstrauss transform. In this case $\alpha$ has no dependence on $p$ or $n$. If we choose $\alpha = 1/2$ we have $p \geq 4|\log(\delta)|$. From (22) we see that with high-probability the rate is of order:

$$O\left(\frac{H^2_{f,\text{max}} + H^2_{\psi,\text{max}}}{\eta_{\text{min}}^2}k\right).$$

In conclusion, when $U_k$ are orthogonal matrices our convergence estimates are linear in $N$ (as in the coordinate descent literature), and there is no explicit dependence on $N$ for Johnson-Lindenstrauss matrices.

4.2 Better convergence under KL

In this section we prove convergence rates for our algorithm when $F$ satisfy the KL property (in particular, $F$ is uniformly convex). Consider $(x_k)_{k \geq 0}$ the sequence generated by algorithm SCPG and $(x_{k_j})_{j \geq 0}$ the subsequence of $(x_k)_{k \geq 0}$ such that the iteration $k_j$ is well-aligned. Let us denote the set of limit points of the sequence $(x_{k_j})_{j \geq 0}$ by $\Omega(x_0)$. Next lemma derives some basic properties for $\Omega(x_0)$.

**Lemma 8** If Assumption 4 holds and the sublevel set $\mathcal{L}_f(x_0)$ is bounded, then $\Omega(x_0)$ is compact set, $F$ is constant on $\Omega(x_0)$ and $\nabla F(\Omega(x_0)) = 0$.

**Proof** By Lemma 5 we have $F(x_k) \leq F(x_0)$ for all $k \geq 0$. Since $\mathcal{L}_f(x_0)$ is assumed bounded, then the sequence $(x_k)_{k \geq 0}$ is also bounded. This implies that the set $\Omega(x_0)$ is also bounded. Closeness of $\Omega(x_0)$ also follows observing that $\Omega(x_0)$ can be viewed as an intersection of closed sets, i.e., $\Omega(x_0) = \cap_{j \geq 0} \cup_{l \geq j} \{x_{k_l}\}$. Hence $\Omega(x_0)$ is a compact set. Further, let us proof that $F$ is constant on $\Omega(x_0)$. From Lemma 6 we have:

$$\sum_{k=0}^{K} \|d_k\|^2 < \infty.$$ 

This implies that $\|d_k\| \to 0$ as $k \to \infty$. Hence, by Lemma 6 we have:

$$\lim_{j \to \infty} \|\nabla F(x_{k_j})\| = 0. \quad (26)$$

Moreover from Lemma 5 we have that $F(x_k)_{k \geq 0}$ is monotonically decreasing and since $F$ is assumed bounded from below by $F^* > -\infty$, it converges, let us say to $F_* > -\infty$, i.e. $F(x_k) \to F_*$ as $k \to \infty$, and $F_* > F^*$. On the other hand, let $\bar{x}$ be a limit point of $(x_{k_j})_{j \geq 0}$, i.e. $\bar{x} \in \Omega(x_0)$. This means that there is a subsequence $(x_{k_j})_{j \geq 0}$ of $(x_{k_j})_{j \geq 0}$ such that $x_k \to \bar{x}$ as $k \to \infty$. Since $f$ and $\psi$ are continuous, it follows that $\bar{F}(x_{k_j}) \to F(\bar{x}).$ This implies that $F(\bar{x}) = F_*$. Finally, to prove that $\nabla F(\Omega(x_0)) = 0$, one can note that when $k \to \infty$, we have $x_k \to \bar{x}$ and $\nabla F(x_k) \to \nabla F(\bar{x})$ and by (26), $\|\nabla F(x_k)\| \to 0$. \qed
Next lemma shows convergence rates for a sequence satisfying a certain recurrence.

**Lemma 9** Let $\zeta > -1$, $c > 0$ and $\{\Delta_k\}_{k \geq 0}$ be a sequence of positive numbers satisfying the following recurrence:

$$\Delta_k - \Delta_{k+1} \geq c \Delta_k^{\zeta+1} \quad \forall k \geq 0. \quad (27)$$

Then, we have:

(i) For $c = 1$ and $\zeta > 0$ the sequence $\Delta_k \to 0$ with sublinear rate:

$$\Delta_k \leq \left( \frac{\Delta_0}{(\zeta + 1) \Delta_k^\zeta} \right) \left( \frac{1}{\zeta^k} \right). \quad (28)$$

(ii) For $c \in (0, 1)$ and $\zeta = 0$ the sequence $\Delta_k \to 0$ with linear rate:

$$\Delta_k \leq (1 - c)^k \Delta_0. \quad (29)$$

(iii) For $c > 0$ and $\zeta \in (-1, 0)$ the sequence $\Delta_k \to 0$ with superlinear rate:

$$\Delta_{k+1} \leq \left( \frac{1}{1 + c \Delta_{k+1}} \right) \Delta_k. \quad (30)$$

*Proof* Consider $c = 1$ and $\zeta > 0$. Multiplying (27) by $\Delta_k^{-(\zeta+1)}$ we get:

$$1 \leq \left( \Delta_k^{-\zeta} - \Delta_{k+1}^{-\zeta} \right) = \left( 1 - \frac{\Delta_{k+1}}{\Delta_k} \right) \Delta_k^{-\zeta}. \quad (31)$$

Let us show that the function $g(y) = y^{-\zeta} + \zeta y - (1 + \zeta)$ satisfies $g(y) \geq 0$ for all $y \in (0, 1]$ and $\zeta > 0$. Indeed, since:

$$g'(y) = -\zeta y^{-(\zeta+1)} + \zeta \leq 0 \quad \forall y \in (0, 1],$$

it follows that $g(y)$ is decreasing on $(0, 1]$. Moreover, $g(1) = 0$ and also

$$\lim_{y \searrow 0} g(y) = \lim_{y \searrow 0} \left( \frac{1}{y^\zeta} + \zeta y - (1 - \zeta) \right) = +\infty.$$

Therefore, $g(y) \geq 0$ for all $y \in (0, 1]$ and $\zeta > 0$. Since $\frac{\Delta_{k+1}}{\Delta_k} \in (0, 1]$, we get:

$$\left( \frac{\Delta_{k+1}}{\Delta_k} \right)^{-\zeta} + \zeta \left( \frac{\Delta_{k+1}}{\Delta_k} \right) - 1 - \zeta \geq 0,$$

or equivalently

$$\frac{1}{\zeta} \left[ \left( \frac{\Delta_{k+1}}{\Delta_k} \right)^{-\zeta} - 1 \right] \geq \left( 1 - \frac{\Delta_{k+1}}{\Delta_k} \right).$$
Combining the last inequality with \( (31) \), we obtain:

\[
1 \leq \frac{\Delta_{k+1}^{-\zeta}}{\zeta} \left[ \left( \frac{\Delta_{k+1}}{\Delta_k} \right)^{-\zeta} - 1 \right] = \frac{\Delta_{k+1}^{-\zeta} - \Delta_k^{-\zeta}}{\zeta}.
\]

Summing this relation, we get:

\[
k\alpha \leq \sum_{i=0}^{k-1} \left( \Delta_{i+1}^{-\zeta} - \Delta_i^{-\zeta} \right) = \Delta_k^{-\zeta} - \Delta_0^{-\zeta},
\]
and by arranging the terms we finally obtain:

\[
\Delta_k \leq \frac{\Delta_0^{-\zeta}}{\zeta k \Delta_0^{-\zeta} + 1},
\]

thus proving \( (28) \).

If \( \zeta = 0 \) and \( c \in (0, 1) \), we get:

\[
\Delta_{k+1} \leq (1 - c) \Delta_k,
\]
thus proving \( (29) \).

Finally, for \( c > 0 \) and \( -1 < \zeta < 0 \), we have \( \Delta_{k+1} \leq \Delta_k \) and consequently \( (27) \) leads to the following recurrence:

\[
\Delta_k - \Delta_{k+1} \geq c \Delta_k^{\zeta+1} \quad \forall k \geq 0.
\]

Rearranging the terms we get:

\[
\Delta_{k+1} \left( 1 + c \Delta_k^{\zeta} \right) \leq \Delta_k \iff \Delta_{k+1} \leq \left( \frac{1}{1 + c \Delta_k^{\zeta+1}} \right) \Delta_k,
\]

which yields \( (30) \). Note that \( \Delta_{k+1} \to \infty \), provided that \( \zeta < 0 \). These prove our statements.

For simplicity of the exposition, let us define the following constants:

\[
\gamma_1 = \begin{cases} C_1 q^{-\zeta} & \text{if } F \text{ satisfy KL property,} \\ C_2 q^{-\zeta} & \text{if } F \text{ is uniformly convex.} \end{cases} \quad (32)
\]

\[
\gamma_2 = \begin{cases} 1 - C_1 q^{-1} & \text{if } F \text{ satisfy KL property for } q = 2, \\ 1 - 2 C_2 & \text{if } F \text{ is uniformly convex for } q = 2. \end{cases} \quad (33)
\]

and

\[
C_1 = \frac{2 - q}{q} \quad \text{and} \quad C_2 = (1 - \beta)(1 - \delta). \quad (34)
\]
Theorem 2 Let Assumptions 4 and 5 hold. Additionally, assume that the sublevel set \( L_f(x_0) \) is bounded and \( F \) satisfies the KL property (7) on \( \Omega(x_0) \) (in particular, \( F \) is uniformly convex). Then, for any number of iterations \( K \) satisfying
\[
K > \frac{1}{(1 - \beta)(1 - \delta)} - 1,
\]
the sequence \((x_k)_{k \geq 0}\) generated by algorithm SCPG has with high-probability the followings rates in function values:

(i) If \( q \in (1, 2) \), we have the following sublinear rate:
\[
\mathbb{P} \left[ F(x_K) - F_* \leq \frac{F(x_0) - F_*}{\left(1 + (C_1(C_2(K + 1) - 1))\gamma_1(F(x_{k_0}) - F_*)\right)^{q/2}} \right] \geq 1 - e^{-\frac{\Delta_f^2}{\alpha^2(1 - \delta)(K + 1)}},
\]
where \( k_0 \) is the first well-aligned iteration.

(ii) If \( q = 2 \), we have the following linear rate:
\[
\mathbb{P} \left[ F(x_K) - F_* \leq \gamma_2(C_2(K + 1) - 1)(F(x_0) - F_*) \right] \geq 1 - e^{-\frac{\Delta_f^2}{\alpha^2(1 - \delta)(K + 1)}}. \tag{35}
\]

(iii) If \( q > 2 \), the probability of algorithm SCPG to have at least \((1 - \beta)(1 - \delta)(K + 1)\) well-aligned iterations is high for any \( K > 0 \) and for this well-aligned iterations, \( A_K = \{k_0, \ldots, k_J\} \), we have the following superlinear rate, i.e.:
\[
F(x_{k_j}) - F_* \leq \left(\frac{1}{1 + C\sigma_q^2(F(x_{k_j}) - F_*)^{q-1}}\right) F(x_{k_{j-1}}) - F_* \tag{36}
\]

Proof Denote the set of indexes corresponding to well-aligned iterations by \( A_K = \{k_0, \ldots, k_J\} \). From Lemma 6 using relation (21), it follows that:
\[
\frac{\eta_{\min}}{2} \|d_{k_j}\|^2 \leq F(x_{k_j}) - F(x_{k_{j+1}}).
\]
By Lemma 8 and relation (21), we obtain:
\[
C \|\nabla F(x_{k_j})\|^2 \leq \frac{\alpha \eta_{\min}}{4(H^2_{f,\psi_{k_j}} + H^2_{\psi,\psi_{k_j}})} \|\nabla F(x_{k_j})\|^2 \leq \frac{\eta_{\min}}{2} \|d_{k_j}\|^2 \leq \frac{\sigma_d^2}{C}(F(x_{k_j}) - F(x_{k_{j+1}})).
\]
Combining the inequality above with the KL property (7), we get:
\[
(F(x_{k_j}) - F_*)^{\frac{q}{2}} \leq \sigma_d^{\frac{q}{2}} \|\nabla F(x_{k_j})\|^2 \leq \left(\frac{\sigma_d^2}{C}\right)^{\frac{q}{2}}(F(x_{k_j}) - F(x_{k_{j+1}})). \tag{37}
\]
If the function $F$ is uniformly convex, we obtain:

$$
(F(x_k) - F_*)^\frac{2}{q} \leq \left( \frac{1}{q\sigma_q^{q-1}} \right)^{\frac{2}{q}} \|\nabla F(x_k)\|^2
$$

$$
\leq \frac{C}{\sigma_q^{q-1}} \left( F(x_k) - F(x_{k+1}) \right). 
$$

Since $(F(x_k))_{k \geq 0}$ is a decreasing sequence (see Lemma 5), we have $F(x_{k+1}) \leq F(x_k)$ and by (37) and KL we get the recurrence:

$$
(F(x_k) - F_*) - (F(x_{k+1}) - F_*) \geq C\sigma_q^{\frac{2}{q}} (F(x_k) - F_*)^\frac{2}{q}, 
$$

(39)

while by (38) and uniform convexity we get the recurrence:

$$
(F(x_k) - F_*) - (F(x_{k+1}) - F_*) \geq C\sigma_q^{\frac{2(q-1)}{q}} (F(x_k) - F_*)^\frac{2}{q}. 
$$

(40)

First, consider that $q \in (1, 2)$. Multiplying both sides of the inequality (39) and (40) by $\left( C\sigma_q^{\frac{2}{q}} \right) \frac{q}{2}$ and $\left( C\sigma_q^{\frac{2(q-1)}{q}} \right) \frac{q}{2}$, respectively, we obtain:

$$
\Delta_k - \Delta_{k+1} \geq (\Delta_k)^\frac{q}{2},
$$

(41)

with $\Delta_k = \gamma_1^{\frac{q}{2}} (F(x_k) - F_*)$ and $\gamma_1$ defined in (32). Considering the first inequality in (26) for $\zeta = \frac{2-q}{q} > 0$, we get:

$$
\Delta_k \leq \frac{\Delta_0}{(\zeta J \Delta_0 + 1)^{\frac{q}{2}}},
$$

$$
\iff \gamma_1^{\frac{q}{2}} (F(x_k) - F_*) \leq \frac{\gamma_1^{\frac{q}{2}} (F(x_k) - F_*)}{\left( J \left( \frac{2-q}{q} \right) \gamma_1 (F(x_k) - F_*)^{2-q} + 1 \right)^{\frac{1}{2-q}}}
$$

$$
\iff F(x_k) - F_* \leq \frac{F(x_k) - F_*}{\left( J \left( \frac{2-q}{q} \right) \gamma_1 (F(x_k) - F_*)^{2-q} + 1 \right)^{\frac{1}{2-q}}}
$$

Using again that $(F(x_k))_{k \geq 0}$ is decreasing and $|A_K| = J + 1$, we obtain:

$$
F(x_K) - F_* \leq (F(x_k) - F_*) \left( \frac{|A_K| - 1}{q} \gamma_1 (F(x_k) - F_*)^{\frac{2-q}{2-q}} + 1 \right)^{\frac{1}{2-q}}.
$$

If we denote

$$
D = \gamma_1 (F(x_k) - F_*)^{\frac{2-q}{2-q}},
$$

then
we get
\[ F(x_K) - F_* \leq \frac{F(x_{k_0}) - F_*}{\left(1 + \frac{(2-q)|A_K|}{q}D\right)^{\alpha q}}. \]

By Lemma 7, we have for all \( \beta \in (0, 1) \):
\[ P[|A_K| - 1 \geq (1 - \beta)(1 - \delta)(K + 1) - 1] \geq 1 - e^{-\frac{\beta^2}{2}(1 - \delta)(K+1)}. \] (42)

Hence, if \( K > \frac{1}{(1 - \beta)(1 - \delta)} - 1 \), we get:
\[ P[|A_K| - 1 \leq \frac{1}{(1 - \beta)(1 - \delta)(K + 1) - 1}] \geq 1 - e^{-\frac{\beta^2}{2}(1 - \delta)(K+1)}. \] (43)

This yields:
\[ P \left[ F(x_K) - F_* \leq \frac{F(x_{k_0}) - F_*}{\left(1 + (C_1 C_2(K + 1) - 1)D\right)^{\alpha q}} \right] \geq 1 - e^{-\frac{\beta^2}{2}(1 - \delta)(K+1)}, \]

and since \( F(x_{k_0}) \leq F(x_0) \), the first statement of the theorem follows.

Second, if \( q = 2 \), by (29) and (39), we have:
\[ F(x_{k+1}) - F_* \leq (1 - 2 C\sigma_2)^J (F(x_{k_0}) - F_*). \]

Moreover, by (29) and (40), we get
\[ F(x_{k+1}) - F(x^*) \leq (1 - 2 C\sigma_2)^J (F(x_{k_0}) - F(x^*)). \]

Using the fact that \( (F(x_k))_{k \geq 0} \) is decreasing and \( |A_K| = J + 1 \), we obtain:
\[ F(x_K) - F_* \leq \gamma_2 |A_K|^{-1} (F(x_0) - F_*). \] (44)

with \( \gamma_2 \) defined in (33). If \( K > \frac{1}{(1 - \beta)(1 - \delta)} - 1 \) by (42), we get:
\[ P \left[ |A_K|^{-1} \leq \gamma_2 (1 - \beta)(1 - \delta)(K+1) - 1 \right] \geq 1 - e^{-\frac{\beta^2}{2}(1 - \delta)(K+1)}. \]

Using this probability bound in (44), our statement (35) follows.

Finally, if \( q > 2 \), using \( F(x_{k+1}) \leq F(x_k) \), by (41), we obtain:
\[ \Delta_{k+1} \geq \Delta_{k+1}^2. \]

Using \( \zeta = \frac{2}{q} - 1 \in (-1, 0) \), then we get (30), which yields (36). \( \square \)
Let us define $\Delta k_0 = F(x_{k_0}) - F^*$, where $k_0$ is the first well-aligned iteration. First let us analyze the convergence rate when the function $F$ satisfy KL property. Define $\text{cond}_q = \sigma_q^2 (H_{f,\max}^2 + H_{\psi,\max}^2)_{\eta_{\min}^{-1}}$. Then, we notice that the dependence on $N$ of the convergence rates from Theorem 2 for algorithm SCPG in the optimality given by the function values are of the following orders:

For $q \in (1, 2)$ and orthogonal matrices:

$$O \left( \frac{1}{(1 + kN^{-1}\text{cond}_q^{-1}(\Delta k_0)_{\frac{1}{q}})^{\frac{2}{q}} + 2} \right),$$

while for Johnson-Lindenstrauss matrices is of order:

$$O \left( \frac{1}{(1 + k\text{cond}_q^{-1}(\Delta k_0)_{\frac{1}{q}})^{\frac{2}{q}} + 2} \right),$$

For $q = 2$ and orthogonal matrices:

$$O \left( \left( 1 - \frac{1}{N\text{cond}_2} \right)^k \right),$$

while for Johnson-Lindenstrauss matrices is of order:

$$O \left( \left( 1 - \frac{1}{\text{cond}_2} \right)^k \right).$$

One can easily notice that all previous rates depend at most linearly on the number of blocks $N = n/p$.

### 5 Convergence analysis: convex case

In this section we assume that the composite objective function $F = f + \psi$ is convex. Note that we do not need to impose convexity on $f$ and $\psi$ separately. Denote the set of optimal solutions of (1) by $X^*$ and let $x^*$ be an element of this set. Define also:

$$R = R(x_0) = \max_y \min_{x^* \in X^*} \{ \| y - x^* \| : F(y) \leq F(x_0) \},$$

which is a measure of the size of the sublevel set of $F$ in $x_0$.

**Theorem 3** If Assumptions 1 and 2 hold, the sublevel set $L_f(x_0)$ is bounded and additionally $F$ is convex, then for any number of iterations $K$ satisfying

$$K > \frac{1}{(1 - \beta)(1 - \delta)} - 1,$$

the sequence $(x_k)_{k \geq 0}$ generated by algorithm SCPG has with high-probability the following sublinear rate in function values:

$$P \left[ F(x_K) - F(x^*) \leq \frac{1}{C} \left( \frac{R^2}{(1 - \beta)(1 - \delta)(K + 1)} - 1 \right) \right] \geq 1 - e^{-N^2(1-\delta)(K+1)}. \quad (45)$$
Proof By Lemma 6, for \( k \in \mathcal{A}_K \), we have that
\[
\|d_k\|^2 \geq \frac{\alpha}{2(H_{f,\max}^2 + H_{\psi,\max}^2)}\|\nabla F(x_k)\|^2.
\]
Since \( \mathcal{A}_K = \{k_0, \ldots, k_J\} \). Combining the inequality above and Lemma 5 with the relation (21), we get:
\[
F(x_{k_j}) - F(x_{k_{j+1}}) \geq \frac{\eta_{\min}}{2}\|d_{k_j}\|^2 \geq C\|\nabla F(x_{k_j})\|^2. \tag{46}
\]
On the other hand, since \( F \) is convex, we have:
\[
F(x^*) - F(x_{k_j}) \geq \langle \nabla F(x_{k_j}), x^* - x_{k_j+1} \rangle \geq -\|\nabla F(x_{k_j})\|\|x_{k_j+1} - x^*\| \geq -\|\nabla F(x_{k_j})\|R.
\]
Hence
\[
\|\nabla F(x_{k_j})\| \geq \frac{F(x_{k_j}) - F(x^*)}{R}. \tag{47}
\]
By (46) and (47), we obtain:
\[
(F(x_{k_j}) - F(x^*)) - (F(x_{k_{j+1}}) - F(x^*)) \geq C\left(\frac{F(x_{k_j}) - F(x^*)}{R^2}\right)^2.
\]
Since \( (F(x_k))_{k \geq 0} \) is a decreasing sequence (see Lemma 5), we have \( F(x_{k_{j+1}}) \leq F(x_{k_j}) \) and thus:
\[
(F(x_{k_j}) - F(x^*)) - (F(x_{k_{j+1}}) - F(x^*)) \geq C\left(\frac{F(x_{k_j}) - F(x^*)}{R^2}\right)^2.
\]
Multiplying both sides by \( C/R^2 \), we further get:
\[
\frac{C\left(\frac{F(x_{k_j}) - F(x^*)}{R^2}\right)}{R^2} = \Delta_{k_j}.
\]
We denote:
\[
\frac{C\left(\frac{F(x_{k_j}) - F(x^*)}{R^2}\right)}{R^2} = \Delta_{k_j}.
\]
Then, we obtain the following recurrence:
\[
\Delta_{k_j} - \Delta_{k_{j+1}} \geq \left(\Delta_{k_j}\right)^2.
\]
From Lemma 9, eq. 28, we obtain:
\[
\Delta_{k_j} \leq \frac{1}{J},
\]
or equivalently
\[
\frac{C\left(\frac{F(x_{k_j}) - F(x^*)}{R^2}\right)}{R^2} \leq \frac{1}{|\mathcal{A}_K| - 1} \iff F(x_{k_j}) - F(x^*) \leq \frac{1}{C\left(\frac{R^2}{|\mathcal{A}_K| - 1}\right)}.
\]
Using again the fact that \((F(x_k))_{k \geq 0}\) is decreasing, we get:

\[
F(x_K) - F(x^*) \leq \frac{1}{C} \left( \frac{R^2}{|A_K| - 1} \right).
\] (48)

Recall that from Lemma 7, we have:

\[
P \left[ \frac{1}{|A_K| - 1} \leq \frac{1}{(1 - \beta)(1 - \delta)(K + 1) - 1} \right] \geq 1 - e^{-\frac{C^2}{2m^2(1 - \delta)(K + 1)}}.
\]

for all \(\beta \in (0, 1)\). If \(K > \frac{1}{(1 - \beta)(1 - \delta)} - 1\), then \((1 - \beta)(1 - \delta)(K + 1) - 1 > 0\) and from (48) our convergence rate follows.

We notice that the dependence on \(N\) of the convergence rate from Theorem 3 for algorithm SCPG in the optimality given by the function values is for orthogonal matrices of order:

\[
O \left( N \cdot \left( \frac{H_{\max}^2 + H_{\max}^2 \eta_{\min}}{k} \right)^{-1} \right),
\]

while for Johnson-Lindenstrauss matrices of order:

\[
O \left( \frac{H_{\max}^2 + H_{\max}^2 \eta_{\min}^1}{k} \right).
\]

One can easily notice that all our convergence bounds from this paper depend at most linearly on the number of blocks \(N = n/p\). Recall that the existing works on coordinate descent for separable \(\psi\) have rates that depend also linearly on such \(N\) [3, 11, 10, 26, 20, 28], while for nonseparable \(\psi\) the dependence on \(N\) in the rates is much higher in papers such as [22, 23, 30].

6 Simulations

One of our motivations for analyzing coordinate descent schemes for composite problems with nonseparable terms came from the need of having fast algorithms for solving the subproblem in the cubic Newton method [25], which is supported by global efficiency estimates for general classes of optimization problems. Recall that in the cubic Newton method at each iteration one needs to minimize an objective function of the form:

\[
\min_x F(x) := \frac{1}{2} \langle Ax, x \rangle + \langle b, x \rangle + \frac{M}{6} \|x\|^3,
\] (49)

where \(A \in \mathbb{R}^{n \times n}, b \in \mathbb{R}^n\) and \(M > 0\) are given. As discussed in Section 2, the function \(\psi(x) = \frac{M}{6} \|x\|^3\) is uniformly convex with \(\sigma_3 = \frac{M}{6}\), but it is nonseparable. Moreover, in this case \(f(x) = \langle b, x \rangle + \frac{1}{2} \langle Ax, x \rangle\) is smooth. Hence, this problem fits into our general model (11) and we can use algorithm SCPG to solve it. In this section we discuss some implementation details for the subproblem of SCPG when solving the quadratic minimization with cubic regularization and perform detailed numerical simulations.
6.1 Implementation details

Note that at each iteration of SCPG for problem \([\text{49}]\) we need to solve a subproblem of the form:

\[
\min_{d \in \mathbb{R}^p} \langle U^T \nabla f(x), d \rangle + \frac{H_{f,U}}{2} \|d\|^2 + \frac{M}{6} \|x + Ud\|^3.
\]

Note that \(\psi\) is differentiable and \(\nabla \psi(x) = \frac{M}{2} \|x\|_x\). Hence, from the optimality condition of this subproblem, we obtain:

\[
U^T \nabla f(x) + H_{f,U} d^* + M \|x + Ud^*\|_U U^T(x + Ud^*) = 0. \tag{50}
\]

Considering the case where the matrix \(U\) has orthonormal columns, we get:

\[
U^T \nabla f(x) + \left( H_{f,U} + \frac{M}{2} \|x + Ud^*\|_U \right) d^* + M \|x + Ud^*\|_U U^T x = 0,
\]

which yields an expression for the solution

\[
d^* = -\frac{2U^T \nabla f(x) + M \|x + Ud^*\|_U U^T x}{2H_{f,U} + M \|x + Ud^*\|_U} \tag{51}.
\]

Note that, if we can compute efficiently \(\|x + Ud^*\|\), we can also get \(d^*\) easily. We show below that \(\|x + Ud^*\|\) can be obtained from the roots of a quartic equation. Multiplying the first optimality condition \([\text{50}]\) by \(U\) and adding

\[
\left( H_{f,U} + \frac{M}{2} \|x + Ud^*\|_U \right) (x + Ud^*) = -UU^T \nabla f(x) + H_{f,U} x
\]

we obtain

\[
\left( H_{f,U} + \frac{M}{2} \|x + Ud^*\|_U \right) (x + Ud^*) = -UU^T \nabla f(x) + H_{f,U} x + M \|x + Ud^*\|(x - UU^T x).
\]

Taking the norm on both sides and denote \(\mu = \|x + Ud^*\|\), we obtain:

\[
\left( H_{f,U} + \frac{M}{2} \mu \right) \mu = \|H_{f,U} x + \frac{M}{2} \mu(x - UU^T x) - UU^T \nabla f(x)\|.
\]

Now consider for simplicity the particular form of \(U\):

\[
U = \begin{bmatrix} I_p & \mathbf{0}_{(n-p) \times p} \\ \mathbf{0}_{(n-p) \times p} & \mathbf{0}_{(n-p) \times (n-p)} \end{bmatrix},
\]

where \(I_p \in \mathbb{R}^{p \times p}\) is the identity matrix and \(\mathbf{0}_{(n-p) \times p} \in \mathbb{R}^{(n-p) \times p}\) is the zero matrix. In this case we have:

\[
UU^T = \begin{bmatrix} I_p & \mathbf{0}_{p \times (n-p)} \\ \mathbf{0}_{(n-p) \times p} & \mathbf{0}_{(n-p) \times (n-p)} \end{bmatrix}.
\]
This leads to: $U U^T x = \begin{bmatrix} x_p \\ 0_{n-p} \end{bmatrix}$, where $0_{n-p} \in \mathbb{R}^{n-p}$ is the null vector. Therefore, the equality (6.1) becomes:

$$\left( H_{f,U} + \frac{M}{2} \mu \right) \mu = \left\| H_{f,U} x_p - (U U^T \nabla f(x))_p \right\|.$$

Taking the square in both sides, we obtain

$$\left( H_{f,U} + \frac{M}{2} \mu \right) \mu^2 = \left\| H_{f,U} x_p - (U U^T \nabla f(x))_p \right\|^2 + \left( H_{f,U} + \frac{M}{2} \mu \right)^2 \left\| x_{n-p} \right\|^2$$

$$\Leftrightarrow \left( H_{f,U}^2 + H_{f,U} M \mu + \frac{M^2}{4} \mu^2 \right) \mu^2$$

$$= \left\| H_{f,U} x_p - (U U^T \nabla f(x))_p \right\|^2 + \left( H_{f,U}^2 + H_{f,U} M \mu + \frac{M^2}{4} \mu^2 \right) \left\| x_{n-p} \right\|^2$$

Thus, we obtain the following fourth equation:

$$\frac{M^2}{4} \mu^4 + H_{f,U} M \mu^3 + \left( H_{f,U}^2 - \frac{M^2}{4} \left\| x_{n-p} \right\|^2 \right) \mu^2 - H_{f,U} M \left\| x_{n-p} \right\|^2 \mu = 0. \quad (52)$$

It is well known that for the fourth order univariate equation its roots can be computed in closed form [10]. Note that in the equations (51) and (52), we need to compute $A_{pn} x + b_p$, the computational cost of this operation is $O(pn)$. Hence the cost of solving our subproblem is $O(pn)$. Recall that, for $U$ orthogonal we can consider $p \sim \sqrt{n}$. In this case the cost of solving the subproblem becomes $O(n^2)$.

6.2 Numerical simulations

In this section we compare algorithm SCPG with the methods proposed in [8] and [27] for the same problem (49). Note that, since SCPG recovers Algorithm (4.8) in [27], we can also apply that method in the nonconvex case. Recall that the update rule in [8] is given by:

$$x_{k+1} = (I - \eta A - \frac{M}{2} \eta \|x_k\| I)x_k - \eta b,$$

with $0 < \eta \leq \frac{1}{4 \|A\| + 2MR}$ and $R = \frac{\|A\|}{M} + \sqrt{\frac{\|A\|^2}{M^2} + \frac{2\|b\|}{M}}$ Moreover, the update rule in [27] is given by:

$$x_{k+1} = \frac{2}{2H + M\mu}(H x_k - A x_k - b),$$
with $\|A\| \leq H$ and $\mu \geq 0$ given by the solution of the equation

$$M \frac{\mu^2}{2} + H \mu - \|Hx_k - Ax_k - b\| = 0.$$ 

In our implementations we used the parameters $\eta = \frac{1}{4\|A\| + 2MR}$ and $H = \|A\|$. Moreover, in SCPG method we used $H_{f,U_k} = \|U_k^T AU_k\|$. Following [8], the starting point in our implementations is:

$$x_0 = -r \frac{b}{\|b\|}, \text{ with } r = \frac{b^T Ab}{M\|b\|^2} + \sqrt{\left(\frac{b^T Ab}{M\|b\|^2}\right)^2 + \frac{2\|b\|}{M}}.$$ 

In the simulations we compare the number of full iterations for each method in order to achieve:

$$\|\nabla F(x_k)\| \leq 10^{-2}.$$ 

We generate $b \in \mathbb{R}^n$ from a standard normal distribution $\mathcal{N}(0, 1)$. We consider the cases when the function $f$ is convex ($A = B^T B$, with $B \in \mathbb{R}^{m \times n}$) and when $f$ is nonconvex ($A = C^T + C$, with $C \in \mathbb{R}^{n \times n}$). Both, $B$ and $C$ are sparse matrices generated from a standard normal distribution $\mathcal{N}(0, 1)$. The results are given in Tables 1 and 2. From the tables we notice that our method has superior performance in terms of full number of iterations compared to the algorithms from [8] and [27], in particular SCPG is $5 - 10$ times faster than the method in [8] (which was designed to solve exactly the problem [19]).

7 Conclusions

In this paper we have designed stochastic coordinate proximal gradient methods for composite optimization problems having the objective function formed as a sum of two terms, one smooth and the second possibly nonconvex and nonseparable. We have provided probabilistic worst-case complexity analysis for our stochastic coordinate descent method in convex and nonconvex settings, in particular we have proved high-probability bounds on the number of iterations before a given optimality is achieved. To the best of our knowledge, this work is the first proposing a pure stochastic coordinate descent algorithm which is supported by global efficiency estimates for general classes of nonseparable composite optimization problems. The preliminary numerical results have also confirmed the efficiency of our algorithm. It will be interesting to investigate whether this type of method can be applied to also solve composite problems with $\psi$ nonsmooth.

Appendix

Proof of Lemma 1. From mean value theorem we have:

\[ f(x + Uh) - f(x) = \int_0^1 \langle \nabla f(x + tUh), Uh \rangle dt. \]

If the function \( f \) satisfies (2), then it follows:

\[ |f(x + Uh) - f(x) - \langle \nabla f(x), Uh \rangle| = \left| \int_0^1 \langle \nabla f(x + tUh) - \nabla f(x), Uh \rangle dt \right| \]

\[ \leq \int_0^1 |(U^T (\nabla f(x + tUh) - \nabla f(x)), h)| dt \]

\[ \leq \int_0^1 \|U^T (\nabla f(x + tUh) - \nabla f(x))\| \|h\| dt \]

\[ \leq \int_0^1 L_U \|th\| \|h\| dt = L_U \|h\|^2 \int_0^1 t dt = \frac{L_U}{2} \|h\|^2. \]

\( \square \)

Proof of Lemma 2. For any \( x \in \mathbb{R}^n \) and \( h \in \mathbb{R}^p \), we have:

\[ U^T \int_0^1 y dt = \int_0^1 U^T y dt \quad \forall y \in \mathbb{R}^n. \]

Therefore, we have:

\[ U^T (\nabla f(x + Uh) - \nabla f(x)) = \int_0^1 U^T \nabla^2 f(x + tUh) Uh dt. \]

If (4) is satisfied, we get:

\[ \|U^T (\nabla f(x + Uh) - \nabla f(x))\| = \left\| \int_0^1 U^T \nabla^2 f(x + tUh) Uh dt \right\| \]

\[ \leq \int_0^1 \|U^T \nabla^2 f(x + tUh) Uh\| dt \leq \int_0^1 \|U^T \nabla^2 f(x + tUh) U\| \|h\| dt \]

\[ \leq \int_0^1 L_U \|h\| dt = L_U \|h\|. \]

On the other hand, if (2) is satisfied, then for any \( x \in \mathbb{R}^n \), \( h \in \mathbb{R}^p \) and \( \alpha > 0 \), we have:

\[ \left\| \int_0^\alpha U^T \nabla^2 f(x + tUh) Uh dt \right\| = \|U^T (\nabla f(x + \alpha Uh) - \nabla f(x))\| \leq \alpha L_U \|h\|. \]

This implies that:

\[ \left\| \frac{1}{\alpha} \int_0^\alpha U^T \nabla^2 f(x + tUh) U dt \frac{h}{\|h\|} \right\| \leq L_U. \]
Taking $\alpha \to 0$, we get:

$$\left\| U^T \mathcal{W} f(x) U \right\|_h \leq L_U.$$ 

From this and the definition of matrix norm $\|A\| = \max_{\|h\| = 1} \|Ah\|$, we get \( \Box \). 

**Proof of inequality** \( \mathcal{U} \): $px + \log(1 - p + pe^{-x}) \leq \frac{x^2p}{2}$ for all $p \in [0, 1]$ and $x \geq 0$. Indeed, let us denote $\zeta(x) = px + \log(1 - p + pe^{-x})$ and $\eta(x) = \frac{px^2}{2}$. We have $\zeta(0) = \eta(0) = 0$ and also the relation:

$$\zeta'(x) = p - \frac{pe^{-x}}{1 - p + pe^{-x}}, \quad \eta'(x) = px.$$ 

Hence $\zeta'(0) = \eta'(0) = 0$. Moreover, $\eta''(x) = p$ and the relation:

$$\zeta''(x) = \frac{(1 - p)pe^{-x}}{(1 - p + pe^{-x})^2}. \quad (53)$$

We further have:

$$0 \leq \left( (1 - p) - e^{-x} \right)^2 \iff 0 \leq (1 - p)^2 - 2(1 - p)e^{-x} + (e^{-x})^2,$$

$$\iff 4(1 - p)e^{-x} \leq (1 - p)^2 + 2(1 - p)e^{-x} + (e^{-x})^2 = (1 - p + e^{-x})^2,$$

$$\iff 2\sqrt{(1 - p)e^{-x}} \leq 1 - p + e^{-x},$$

$$\iff 2\sqrt{(1 - p)e^{-x}} - (1 - p)e^{-x} \leq 1 - p + pe^{-x}.$$ 

Using this in \( 53 \), we obtain:

$$\zeta''(x) \leq \frac{(1 - p)pe^{-x}}{(2\sqrt{(1 - p)e^{-x}} - (1 - p)e^{-x})^2}.$$ 

Since $x \geq 0$ and $0 \leq p \leq 1$, we have $(1 - p)e^{-x} \geq 0$ and thus:

$$\sqrt{(1 - p)e^{-x}} \leq (1 - p)e^{-x} \iff \frac{1}{(1 - p)e^{-x}} \geq \frac{1}{\sqrt{(1 - p)e^{-x}}}.$$ 

Finally, we get:

$$\zeta''(x) \leq \frac{p(1 - p)e^{-x}}{(2\sqrt{(1 - p)e^{-x}} - \sqrt{(1 - p)e^{-x}})^2}$$

$$= \frac{p(1 - p)e^{-x}}{\left( \sqrt{(1 - p)e^{-x}} \right)^2} = p = \eta''(x).$$ 

Since $\eta''(x) - \zeta''(x) \geq 0$ for all $x \geq 0$, it follows that the function $h(x) = \eta(x) - \zeta(x)$ is convex in the set $\mathcal{B} = \{x : x \geq 0\}$. Moreover, since $h'(0) = 0$, then 0 is a minimizer of $h$ over $\mathcal{B}$. Since $h(0) = 0$, we have $0 \leq h(x)$ for $x \in \mathcal{B}$. Hence, $\zeta(x) \leq \eta(x)$.
