(Dated: 26 February 2022)

In this work we computationally study the effect of microstructure on saturation magnetostriction of Terfenol-D ($\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$) by means of Finite Element Method. The model is based on the equilibrium magnetoelastic strain tensor at magnetic saturation, and shows that the crystal orientation might play a more significant role on saturation magnetostriction than the morphology of the grains. We also calculate the dependence of saturation magnetostriction on the dispersion angle of the distribution of grains in the oriented growth crystal directions $\langle 011 \rangle$ and $\langle 111 \rangle$, finding that not highly oriented grain distributions reduce saturation magnetostriction significantly. This result evinces the importance of high-quality control of grain orientation in the synthesis of grain-aligned polycrystalline Terfenol-D, and provides a quantitative estimation for the range of acceptable values for the dispersion angle of the distribution of the oriented grains.

I. INTRODUCTION

Terfenol-D ($\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$) is a compound with Laves phase C15 structure type (face centered cubic) that exhibits a giant magnetostriction along $\langle 111 \rangle$ crystallographic direction ($\lambda_{111} = 1.6 \times 10^{-3}$) under moderate magnetic fields (< 2 kOe) at room temperature¹. Presently, this material is commercially used in many types of sensors and actuators² with different forms like monolithic rods¹, particle-aligned polymer matrix composites³⁻⁵, and thin films⁶. While single-crystal magnetostrictive alloys are easier to understand and characterize, polycrystals are more suitable for macroscale applications due to lower production cost and faster production rate. The elastic and magnetoelastic properties of polycrystals can be significantly influenced by many factors, such as crystal orientation, orientation degree, microstructure, volume fraction, grain boundaries, grain morphology and crystal defects. For instance, the low magnetostriction along the crystallographic direction $\langle 100 \rangle$ ($\lambda_{100} = 9 \times 10^{-5}$) of Terfenol-D reduces the saturation magnetostriction up to $\lambda_s \approx 1 \times 10^{-3}$ in polycrystalline samples with randomly oriented grains².

The orientation of the grains in some specific crystallographic directions can significantly modify the elastic and magnetoelastic properties of polycrystalline Terfenol-D^{7,8}. A typical configuration in monolithic Terfenol-D is to align the crystal axis $\langle 112 \rangle$ along the rod axis^{1,2,9}. Other possible growth directions have also been studied like $\langle 110 \rangle$ and $\langle 111 \rangle$ ¹⁰⁻¹⁴. For instance, Wang et al. investigated Terfenol-D polycrystals with $\langle 110 \rangle$ axial alignment finding good magnetostrictive properties under low magnetic fields¹¹. Grain-aligned Terfenol-D in growth direction $\langle 110 \rangle$ and $\langle 112 \rangle$ can be made with different directional solidification techniques, such as Bridgman method, Czochralski method, and zone melting method¹⁵, while in growth direction $\langle 111 \rangle$ Terfenol-D has been successfully prepared using a seeding technique¹⁰. The grain's morphology and orientation of the samples, as well as resulting magnetoelastic properties, are very sensitive to synthesis conditions such as cooling rate,

crystal growth velocity, magnetic field, temperature of melt, chemical composition and temperature gradient^{12,15-18}. Different grain's morphology has been reported in Terfenol-D like plate-shaped¹², round-shaped, polygons¹⁸ and column-shaped¹⁵, but the influence and role of these geometries on saturation magnetostriction are still unclear. In Terfenol-D composites it was found that shape anisotropy induced by the morphology of the grains could be responsible for the grain orientation in a magnetic field⁵. On the other hand, a statistical distribution of the grain orientation around a preferred growth direction is likely to take place in systems with many aligned grains. This property might be described by the dispersion angle of the crystal orientation distribution around a preferred growth direction. For instance, highly oriented grains in $\langle 110 \rangle$ with dispersion angle of only 3° has been achieved using a temperature gradient directional solidification technique¹². The influence of this dispersion angle on saturation magnetostriction has not been quantified in much detail yet. This correlation could provide some hints about the range of acceptable values for the quality of the grain orientation in the synthesis of grain-aligned polycrystalline Terfenol-D. We point out that small deviations from a perfect alignment might induce significant changes on saturation magnetostriction due to the large difference between the magnetostriction in the crystallographic directions $\langle 111 \rangle$ and $\langle 100 \rangle$ ($\lambda_{111} \gg \lambda_{100}$). Here, we try to estimate these effects on saturation magnetostriction computationally.

Terfenol-D exhibits a complex nonlinear stress-strain relationship¹⁹, where its Young's modulus depends on the stress and magnetic field strongly. In general, one needs advanced nonlinear constitutive models to describe all magnetostrictive features of this material^{20,21}. In this work, we restrict our study only to the magnetic saturated state of Terfenol-D, which allows us to greatly simplify the Finite Element Method (FEM) model through the use of the theoretical equilibrium magnetoelastic strain tensor at saturation²².

FIG. 1. Transformation of the magnetoelastic strain tensor (ϵ) when an active rotation of the crystal is performed with Euler angles (ϕ, θ, ψ) in Bunge convention.

II. METHODOLOGY

A. Theoretical equations

To compute saturation magnetostriction, we use the equilibrium magnetoelastic strain tensor that can be analytically

derived from the minimization of both the elastic (E_{el}) and magnetoelastic (E_{me}) energies with respect to strain ϵ ^{22,23}

$$\frac{\partial(E_{el} + E_{me})}{\partial \epsilon_{ij}} = 0, \quad i, j = x, y, z \quad (1)$$

For a cubic single crystal (point groups $432, \bar{4}3m, m\bar{3}m$) equilibrium magnetoelastic strain tensor reads^{22,23}

$$\epsilon(\alpha) = \begin{pmatrix} \lambda^\alpha + \frac{3}{2}\lambda_{001}(\alpha_{100}^2 - \frac{1}{3}) & \frac{3}{2}\lambda_{111}\alpha_{100}\alpha_{010} & \frac{3}{2}\lambda_{111}\alpha_{100}\alpha_{001} \\ \frac{3}{2}\lambda_{111}\alpha_{100}\alpha_{010} & \lambda^\alpha + \frac{3}{2}\lambda_{001}(\alpha_{010}^2 - \frac{1}{3}) & \frac{3}{2}\lambda_{111}\alpha_{010}\alpha_{001} \\ \frac{3}{2}\lambda_{111}\alpha_{100}\alpha_{001} & \frac{3}{2}\lambda_{111}\alpha_{010}\alpha_{001} & \lambda^\alpha + \frac{3}{2}\lambda_{001}(\alpha_{001}^2 - \frac{1}{3}) \end{pmatrix}, \quad (2)$$

where λ^α describes the isotropic magnetostriction, while λ_{001} and λ_{111} are the anisotropic magnetostrictive coefficients that give the fractional length change along the $\langle 001 \rangle$ and $\langle 111 \rangle$ crystallographic directions when a demagnetized material is magnetized in these directions, respectively. The vector $\alpha = (\alpha_{100}, \alpha_{010}, \alpha_{001})$ gives the reduced magnetization (saturated magnetic state) with respect to the crystal axes, that is, the quantities α_{100} , α_{010} and α_{001} denote the components of the reduced magnetization along the crystallographic directions $\langle 001 \rangle$, $\langle 010 \rangle$ and $\langle 001 \rangle$, respectively.

The form of the magnetoelastic strain tensor in Eq.2 corresponds to a cubic crystal with crystallographic axes $\langle 100 \rangle$, $\langle 010 \rangle$ and $\langle 001 \rangle$ along the Cartesian X, Y and Z axes, respectively. If we perform an active rotation of the crystal with Euler angles (ϕ, θ, ψ) in Bunge convention $Z-X'-Z''$, then the magnetoelastic strain tensor is transformed as²⁴

$$\epsilon'''(\alpha) = N(\psi)N'(\theta)N(\phi)\epsilon(\alpha)\tilde{N}(\phi)\tilde{N}'(\theta)\tilde{N}(\psi), \quad (3)$$

where

$$N(\phi) = \begin{pmatrix} \cos(\phi) & -\sin(\phi) & 0 \\ \sin(\phi) & \cos(\phi) & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad (4)$$

$$N'(\theta) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos(\theta) & -\sin(\theta) \\ 0 & \sin(\theta) & \cos(\theta) \end{pmatrix}.$$

The matrices \tilde{N} and \tilde{N}' are the transpose of matrices N and

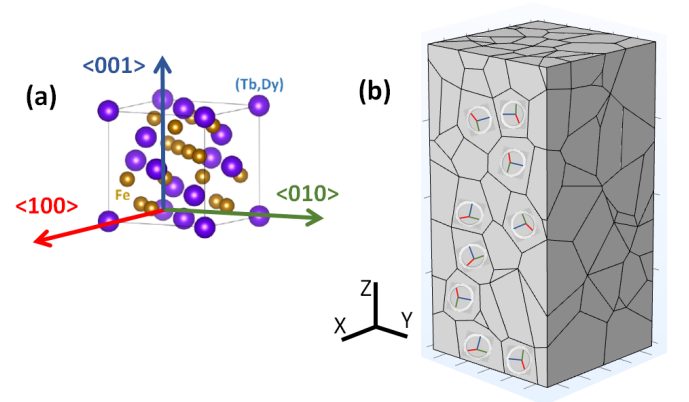

FIG. 2. (a) Unit cell of Terfenol-D with Laves phase C15 structure. (b) Polycrystalline model of Terfenol-D where the crystallographic axes of some grains are depicted.

N' , respectively. In Fig. 1 we illustrate this transformation, while Fig.2 shows how the crystallographic axes of the unit cell of Terfenol-D is related to the coordinates (XYZ) of the polycrystalline model. If in a rotated grain inside the polycrystalline model we set the reduced magnetization $\mathbf{m} = (m_x, m_y, m_z)$ with respect to the Cartesian axes X, Y and Z , then the reduced magnetization with respect to the crystal-

lographic axes of this grain is given by

$$\alpha = N(-\phi)N'(-\theta)N(-\psi)\mathbf{m}. \quad (5)$$

This conversion formula is useful for the evaluation of magnetoelastic strain tensor of each rotated grain in a polycrystalline materials since the magnetization of all grains is saturated to a particular direction with respect to the Cartesian coordinates X, Y and Z of the whole material, see Fig.3.

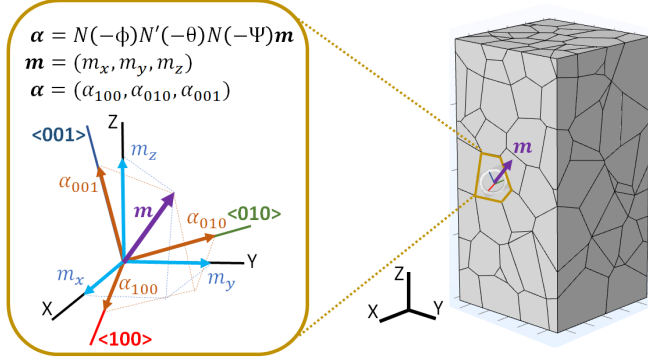

FIG. 3. Diagram showing the components of the reduced magnetization vector (\mathbf{m}) for a particular grain inside the polycrystalline material. The components of the reduced magnetization are shown in the global polycrystalline material's coordinates XYZ (m_x, m_y, m_z) and rotated crystallographic axes ($\alpha_{100}, \alpha_{010}, \alpha_{001}$). The grain is actively rotated with Euler angles (ϕ, θ, ψ) in Bunge convention, as depicted in Fig.1.

Once the equilibrium strain tensor of each rotated grain with saturation magnetization in the direction \mathbf{m} is computed through Eq. 3 combined with Eq.5, we can calculate the final deformation that takes place from the demagnetized state to the magnetic saturated state. The deformation is given by the displacement vector $\mathbf{u}(\mathbf{r}) = \mathbf{r}' - \mathbf{r}$ that gives the displacement from a point at the initial position \mathbf{r} (at the demagnetized state) to its final position \mathbf{r}' (at the magnetic saturated state). For small deformations, the displacement vector is calculated by solving²⁵

$$\varepsilon_{ij}'''(\alpha) = \frac{1}{2} \left(\frac{\partial u_i}{\partial r_j} + \frac{\partial u_j}{\partial r_i} \right), \quad i, j = x, y, z \quad (6)$$

where ε_{ij}''' is the transformed strain tensor (Eq. 3) of each rotated grain.

B. Numerical methods

In practice, we first compute α for each grain via Eq.5 by using the given Euler angles of each grain and the selected direction to saturate the magnetization of all grains \mathbf{m} . Next, we use the given Euler angles and calculated vector α of each grain to compute the equilibrium strain tensor ε''' via Eq. 3. Lastly, the deformation is obtained by solving Eq.6. This procedure is done by means of FEM techniques as implemented in the software COMSOL²⁶ interfaced with MATLAB²⁷. In

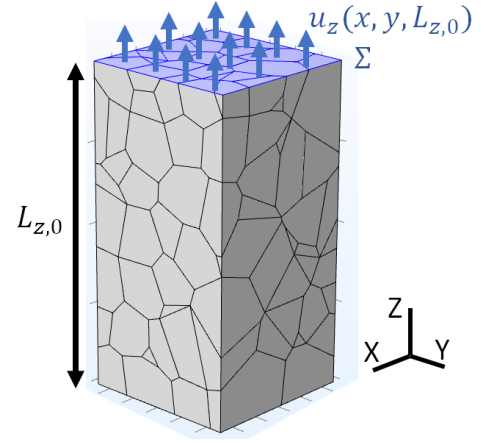

FIG. 4. Scheme showing the calculation of the change in length along the z-axis for the polycrystalline model of Terfenol-D.

the simulations we used a tetrahedral mesh and the direct method PARDISO to solve the linear systems of equations with default settings of COMSOL (version 5.6). The generation of the polycrystalline models and nearly uniform sampling of crystal orientations (Euler angles, active rotation in Bunge convention) are performed with software Neper^{28,29}. Once the deformation of the system is calculated, the change in length ΔL_z in the z-axis direction is calculated as the spatial average of the z-component of the displacement vector (u_z) on the top of boundary Σ

$$\langle \Delta L_z \rangle = \langle L_z - L_{z,0} \rangle = \frac{\int_{\Sigma} u_z(x, y, L_{z,0}) dx dy}{\int_{\Sigma} dx dy}, \quad (7)$$

where $L_{0,z}$ is the initial length in the z-axis direction in the demagnetized state (before deformation takes place). A fixed constraint is imposed at the bottom boundary $u_z(x, y, 0) = 0$ for reference purposes, see Fig.4. Eq.7 is numerically computed with the analysis tools implemented in COMSOL²⁶. Next, magnetostriction is calculated as the relative length change $\lambda = \langle \Delta L_z \rangle / L_{z,0}$. For the magnetostrictive coefficients of Terfenol-D we use its room temperature values $\lambda_{001} = 90 \times 10^{-6}$, $\lambda_{111} = 1600 \times 10^{-6}$ and $\lambda^{\alpha} = 0^{2,30}$.

III. RESULTS

A. Influence of grain morphology

To study the influence of grain morphology on elastic and magnetoelastic properties, we consider a material made of Terfenol-D with a rectangular geometry ($L_{x,0} = L_{y,0} = 10\mu\text{m}$ and $L_{z,0} = 20\mu\text{m}$) and 3 types of microstructure: (i) voronoi, (ii) columnar and (iii) multilayer, see Fig.5. For the voronoi and columnar microstructures we include 200 grains with uniformly-distributed orientations in 3D space²⁹, and we study two cases for each microstructure using a different seed in their generation with software Neper²⁸. For the multilayer microstructure we include 50 layers with the same width

FIG. 5. Polycrystalline models considered in this work to study the influence of grain morphology on saturated magnetostriction.

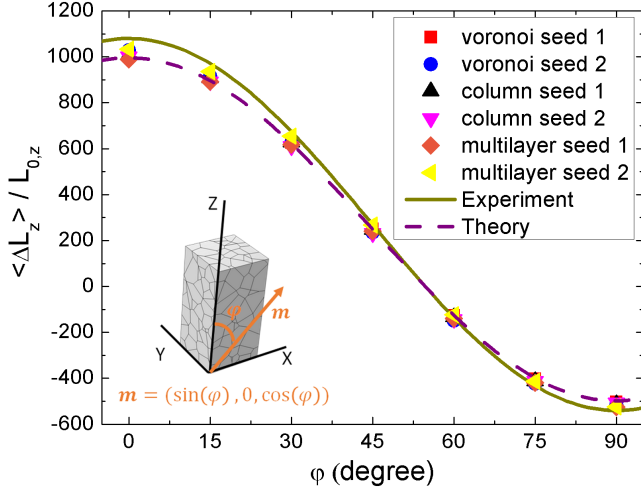

FIG. 6. Relative length change along z-axis direction versus the angle φ between the magnetization direction of all grains $\mathbf{m} = (\sin\varphi, 0, \cos\varphi)$ and z-axis direction $\beta' = (0, 0, 1)$. Symbols represent FEM simulations for different types of grain morphology and uniformly-distributed crystal orientations in 3D space. Solid and dash lines stand for Eq.8 using the experimental and theoretical value for λ_S , respectively.

TABLE I. Isotropic magnetostrictive coefficient (λ_S) calculated with FEM simulations for different types of microstructure with uniformly-distributed crystal orientations in 3D space. The theoretical and experimental values are also shown for comparison. The theoretical value for λ_S is obtained via Eq.9.

Experiment	1080 ^a

^aRef.²

($0.4\mu\text{m}$), and we study two cases using the same morphology but with different uniformly-distributed crystal orientations of the layers. Following the methodology explained in Section II B, we computed the relative length change along z-axis direction versus the angle φ between the saturated magnetization direction of all grains $\mathbf{m} = (\sin\varphi, 0, \cos\varphi)$ and z-axis direction, see Fig.6. We find that the FEM results for all models follow the relation^{2,31}

$$\frac{\Delta L}{L_0} \bigg|_{\beta'}^{\mathbf{m}} = \frac{3}{2} \lambda_S \left[(\mathbf{m} \cdot \beta')^2 - \frac{1}{3} \right], \quad (8)$$

where λ_S is the isotropic magnetostrictive coefficient of the polycrystalline material, and the vector $\beta' = (\beta'_x, \beta'_y, \beta'_z)$ is a unit vector that describes the measuring length direction in the global Cartesian coordinates XYZ of the polycrystalline material. For instance, since here we are computing the relative length change along z-axis direction, then we have $\beta' = (0, 0, 1)$. In the theory of magnetostriction for polycrystalline materials, a widely used approximation is to assume that the stress distribution is uniform through the material. In this case the isotropic magnetostrictive coefficient reads^{2,23,31–33}

$$\lambda_S = \frac{2}{5} \lambda_{001} + \frac{3}{5} \lambda_{111}. \quad (9)$$

This result is analogous to the Reuss approximation used in the elastic theory of polycrystals to obtain a lower bound of Young's modulus^{23,34–36}. In Table I we present the results for λ_S calculated with FEM simulations for different types of microstructure with uniformly-distributed crystal orientations in 3D space. These values are obtained by fitting the data shown in Fig.6 to Eq.8. The theoretical and experimental values are also shown for comparison in Table I. The theoretical value is obtained via Eq.9 with the anisotropic magnetostrictive coefficients used in the model ($\lambda_{001} = 90 \times 10^{-6}$ and $\lambda_{111} = 1600 \times 10^{-6}$). We see that Eq.9 gives a reasonable lower bound for λ_S ($\lambda_S = 996 \times 10^{-6}$) that is close to the experimental value² $\lambda_S = 1080 \times 10^{-6}$. We observe that all simulated microstructures lead to very similar values for λ_S . The observed small difference in λ_S could be more related to the different random orientation distribution of each model rather than the morphology. This fact is clearly seen for the multilayer models since the same grain morphology is used in

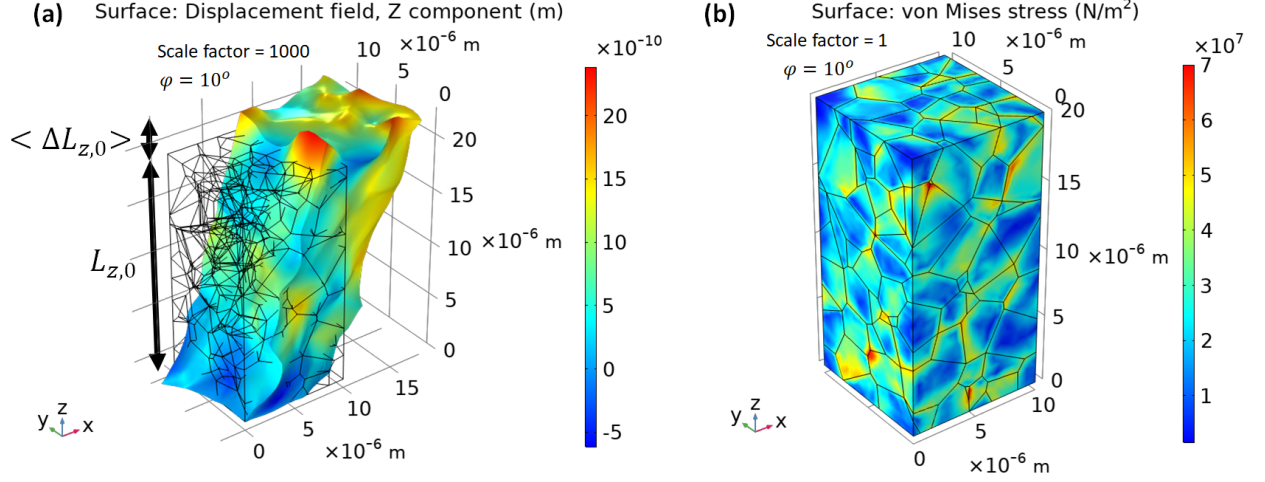

FIG. 7. Calculated magnetostrictive response for the voronoi microstructure (seed 1) with uniformly-distributed crystal orientations in 3D space when magnetization of all grains is saturated along $\mathbf{m} = (\sin\phi, 0, \cos\phi)$ with $\phi = 10^\circ$. Surface color shows (a) the z-component of the displacement vector u_z and (b) von Mises stress. A scale factor 1000 is applied to (a) in order to facilitate the visualization of the deformation.

the two simulated cases. A more detailed view of the magnetostrictive deformation for the voronoi microstructure (seed 1) is depicted in the Fig.7. In this figure, we also plotted the von Mises stress that can be used to analyze possible failures of the material under mechanical stress. We see that the highest values of von Mises stress (~ 0.07 GPa) are found close to some specific grain boundaries.

B. Influence of grain orientation

Elastic and magnetoelastic properties of polycrystalline materials can be tuned by orienting the growth of all grains along a specific crystallographic direction^{7,11–13}. In this section, we computationally explore how this effect influences the saturated magnetostriction for Terfenol-D. For this analysis we consider the same voronoi microstructure (seed 1) than in Section III A, but now the crystallographic direction $\langle 011 \rangle$ or $\langle 111 \rangle$ of all grains will be uniformly oriented to the z-axis with a dispersion angle δ . The magnetization of all grains is saturated along the z-axis $\mathbf{m} = (0, 0, 1)$. The uniform distribution of the crystallographic direction $\langle 011 \rangle$ along the z-axis with a dispersion angle δ is achieved by setting the Euler angles to rotate each grain as³⁷

$$\begin{aligned} |\arccos(2v-1)| &< \delta, \\ \phi &= 0, \\ \theta &= \frac{\pi}{4} - |\arccos(2v-1)|, \\ \psi &= 2\pi u, \end{aligned} \quad (10)$$

where v and u are random real numbers between 0 and 1. In Fig.8 we show the generated uniform distribution of crystallographic axis $\langle 011 \rangle$ along the z-axis direction with dispersion angle $\delta = 5^\circ, 20^\circ, 45^\circ$. Similarly, the uniform distribution of the crystallographic direction $\langle 111 \rangle$ along the

z-axis with a dispersion angle δ is achieved by setting the Euler angles to rotate each grain as³⁷

$$\begin{aligned} |\arccos(2v-1)| &< \delta, \\ \phi &= \frac{\pi}{4}, \\ \theta &= \pi - \arctan\left(\frac{1}{\sqrt{2}}\right) - |\arccos(2v-1)|, \\ \psi &= 2\pi u. \end{aligned} \quad (11)$$

In Fig. 9 we present the relative length change along the z-axis as a function of the dispersion angle δ for the FEM models with uniform distribution of crystallographic axes $\langle 011 \rangle$ and $\langle 111 \rangle$ along the z-axis direction. We observe that the dispersion angle has a very strong effect on the saturation magnetostriction of Terfenol-D which is favored by the fact $\lambda_{111} \gg \lambda_{100}$. As a result, a broad range of values of saturation magnetostriction can be achieved by tuning the dispersion angle. For instance, we see that orientation distributions in the crystallographic axis $\langle 111 \rangle$ with dispersion angle δ lower than 35° exhibit larger magnetostriction than an uniform distribution of the crystal orientations in the all 3D space. For this case, we verify that in the limit $\delta \rightarrow 0$ the relative length change leads to $\lambda_{111} = 1600 \times 10^{-6}$, as it should be. Interestingly, for small dispersion angles up to $\delta \approx 10^\circ$ the saturation magnetostriction changes less than 5% with respect to the perfectly aligned case ($\delta = 0^\circ$). Hence, $\delta \approx 10^\circ$ could be considered as a possible acceptable upper limit for the dispersion angle to achieve high saturation magnetostriction in grain-aligned polycrystalline Terfenol-D.

IV. CONCLUSIONS

In summary, our computational analysis of the effect of microstructure on saturation magnetostriction for Terfenol-D

FIG. 8. Uniformly distribution of crystallographic axis $\langle 011 \rangle$ along the z-axis direction with dispersion angle $\delta = 5^\circ, 20^\circ, 45^\circ$.

FIG. 9. Computed relative length change along the z-axis as a function of the dispersion angle δ for the FEM models with uniformly distribution of crystallographic axes $\langle 011 \rangle$ and $\langle 111 \rangle$ along the z-axis direction. The magnetization of all grains is saturated along the z-axis $\mathbf{m} = (0, 0, 1)$. Horizontal dash line stands for the result given by the FEM model using a uniformly distribution of the crystal orientations in all 3D space.

shows that crystal orientation distribution could play a more important role than grain morphology. We also quantified the effect of the dispersion angle of the grains on saturation magnetostriction, finding that it influences this property strongly. We estimated that small dispersion angles up to 10° might be sufficient to achieve high saturation magnetostriction in the oriented growth crystal directions $\langle 011 \rangle$ and $\langle 111 \rangle$ of polycrystalline Terfenol-D. This result shows the need for a precise control of grain orientation distribution in the synthesis of grain-aligned polycrystalline Terfenol-D.
