Kagome superconductors with T_C up to 7K have been discovered over 40 years. Recently, unconventional chiral charge order has been reported in kagome superconductor KV₃Sb₅, with an ordering temperature of one order of magnitude higher than the T_C. However, the chirality of the charge order has not been reported in the cousin kagome superconductor CsV₃Sb₅, and the electronic nature of the chirality remains elusive. In this letter, we report the observation of electronic chiral charge order in CsV₃Sb₅ via scanning tunneling microscopy (STM). We observe a 2×2 charge modulation and a 1×4 superlattice in both topographic data and tunneling spectroscopy. 2×2 charge modulation is highly anticipated as a charge order by fundamental kagome lattice models at van Hove filling, and is shown to exhibit intrinsic chirality. We find that the 1×4 superlattices forms various small domain walls, and can be a surface effect as supported by our first-principles calculations. Crucially, we find that the amplitude of the energy gap opened by the charge order exhibits real space modulations, and features 2×2 wave vectors with chirality, highlighting the electronic nature of the chiral charge order. STM study at 0.4K reveals a superconducting energy gap with a gap size 2Δ =0.85meV, which estimates a moderate superconductivity coupling strength with $2\Delta/k_BT_C=3.9$. When further applying a c-axis magnetic field, vortex core bound states are observed within this gap, indicative of cleanlimit superconductivity.

Owing to the unusual lattice geometry, spins on kagome lattices can be geometrically frustrated and form a quantum spin liquid [1,2]. Similarly, a fundamental tight-binding model of kagome lattice considering the nearest neighboring hoping will produce an intriguing electronic band structure containing Dirac cones, flat band, and van Hove singularities. Thus, materials containing kagome lattices are an exciting platform to explore the quantum level interplay between geometry, correlation, and topology. For instance, certain kagome magnets are found to exhibit electronic nematicity, giant spin-orbit tunability, and topological Chern quantum phases [3-16]. Kagome superconductors with competing orders have been identified for over 40 years [17-19], such as LaRu₃Si₂ with T_C of 7K and a fundamental kagome band structure [20]. Recently, another layered kagome superconductor AV₃Sb₅ (A = K, Rb, Cs) was discovered with T_C up to 2.5K for A=Cs [21-23], providing new research avenues, particularly for transport and STM studies [21-33].

High-quality single crystals of CsV_3Sb_5 were grown by a self-flux method with Cs-Sb binary eutectic mixture ($Cs_{0.4}Sb_{0.6}$) as the flux [21]. We found that the molar ratio of $Cs_{0.4}Sb_{0.6}$: $CsV_3Sb_5=15:1$ is the best condition for obtaining large crystals with high quality. In order to obtain high-quality crystals, it is necessary to perform surface treatment of raw materials in a hydrogen atmosphere [34,35]. Our crystals have shiny surfaces with a hexagonal shape, and the typical size of crystals is about $3\times4\times0.5$ mm³, as shown in the left inset of Figure 1(b). The

crystal structure was analyzed via X-ray diffraction using a θ -2 θ scan. The magnetic susceptibility and magnetization were measured in a physical property measurement system magnetometer in vibrating-sample measurement mode. The transport property measurements were carried out in a five-contact configuration so that the longitudinal and Hall resistivity can be taken simultaneously. STM data were obtained with a Pt/Ir tip at 4.2K and 0.4K. The topographic data were obtained in a constant current mode with bias voltage V=50mV and current I=0.05nA. Spectroscopic data were obtained with V=50mV and I=0.5nA V=50mV at 4.2K, and V=5mV and I=0.1nA at 0.4K.

CsV₃Sb₅ crystallizes in the hexagonal P6/mmm space group, consists of V-Sb slabs that are intercalated by cesium cation, as illustrated in Fig. 1(a). The most notable feature in this compound is that the vanadium sublattice forms a 2D kagome net. X-ray diffraction pattern displays sharp (00l) reflection peaks, as shown in Fig. 1(b). The full width at half maximum (FWHM) of (004) peak is only 0.07°, as shown in the right inset of Fig. 1(b). Both resistivity data [Fig. 1(c)] and susceptibility data [Fig. 1(d)] show two phase transitions. The 90K transition corresponds to the development of a charge order, and the 2.5K transition corresponds to the development of superconductivity. Below the charge order transition temperature, previous studies reveal the possibility of anomalous Hall effect [24,25]. Similar to these studies, at 5K, both the magnetization data [Fig. 1(f)] and the Hall resistivity data [Fig. 1(e)] as a function of the magnetic field applied along the c-axis show a double kink feature. By further subtracting a linear background as the ordinary Hall response, this unusual Hall response would resemble an anomalous Hall effect, as shown in the inset of Fig. 1(e). Our low-field magnetization loop data in the inset of Fig. 1(f) also confirms the absence of magnetic hysteresis. The observation of anomalous Hall effect and increasing magnetization below charge ordering temperature with decreasing temperature implies the highly unconventional nature of the charge order.

In this material, the V and Sb layers have a stronger chemical bonding, and the material tends to cleave between Cs and Sb layers. The Sb surface is most interesting, as it is strongly bonded to the V kagome lattice. Previous STM studies have resolved Sb honeycomb surfaces in AV₃Sb₅, and studied the charge order and surface superlattices [20-26]. We study CsV₃Sb₅ with STM at 4.2K. Through cryogenic cleaving, we have also obtained large Sb surfaces in CsV₃Sb₅ as shown in Fig. 2(a). Similar to KV₃Sb₅ [28], we observe a soft charge order gap opening from -23meV to +35meV [Fig. 2(b)]. The Fourier transform of the topography confirms the 2×2 charge order as marked by the shaded red region in Fig. 2(c), which is ubiquitous for all AV₃Sb₅ compounds. In defect-free areas of KV₃Sb₅ and RbV₃Sb₅, the 2×2 charge order is found to display a chirality [28,29], where its three vector peaks have different intensities. We thus perform a spectroscopic map in a defect-free area [Fig. 1(d)] for CsV₃Sb₅ to check the existence of the chirality. The energy-resolved intensity of three 2×2 vector peaks is displayed in Fig. 2(e), where we observe clear intensity differences. The observed anisotropy can be due to a chiral charge order as observed and discussed in certain transition-metal dichalcogenides and high-temperature superconductors [36,37]. The chirality can be defined as the counting direction (clockwise or anticlockwise) from the lowest to the highest pair of vector peaks. By

contrast, near a defect-rich region [Fig. 2(f)], we find that there is almost no chirality for the charge order [Fig. 2(g)], which suggests the existence of extrinsic effects. In both cases, the intensity of Q_1 is strongest, and along this direction, there are additional 1×4 superlattice vector peaks in the q-space data [Fig. 2(c)]. This observation suggests an interplay between the 1×4 superlattice and 2×2 charge order.

The 1×4 superlattice is not observed on the Sb surface in KV₃Sb₅ [28], certain Sb surface in CsV₃Sb₅ [30], and the K/Cs/Rb surfaces in AV₃Sb₅. We also find many domains of the 1×4 superlattice, including 120-degree domains [Fig. 3(a)] and phase shift domains [Fig. 3(b)]. The domain size can be very small (less than 10nm), which will not be energy favorable if it is bulk in nature. In addition, bulk X-ray measurements have detected the 2×2 charge order but have not yet observed the 1×4 superlattice [21,28]. Therefore, these pieces of experimental evidence taken together suggest that the 1×4 superlattice effect is likely to be fragile and of surface origin. For another example, it is known that the 1×2 superlattice observed by STM in BaFe₂As₂ is a polar surface effect [38], and there can be various small domain walls of the 1×2 superlattices, as similarly observed here. To explore the surface origin possibility, we perform first-principles calculations. The geometry optimizations of surface atoms were performed in the framework of density-functional theory with the projector augmented wave method and the PBE exchangecorrelation functional [39], which are implemented in the Vienna Ab into Simulation Package [40]. We built two types of 1×4 supercells slabs, repeating the primitive cell in two different directions: parallel (Type-A) and vertical (Type-B) to the a-axis. After fully relaxed surface atoms, we found only the Type-B slab is stabilized into the 1×4 supercell, which is consistent with our experimental measurements. Our calculations show that 1×4 supercells are due to the in-plane shifting of V atoms relative to surface Sb atoms, as indicated by the black arrows in Fig. 3(c).

Previous first-principles calculation [28,41] in AV₃Sb₅ has also confirmed that the 2×2 charge order is a bulk effect and is consistent with a hexamer and trimer formation [28] (or termed as inverse star of David formation [41]) in the V kagome lattice. The chirality feature of the charge order, however, is beyond the current first-principles calculation. Prior to any theoretical discussion of the origin of chirality, it is crucial to explore whether the chirality is of electronic nature. An issue in the differential conductance mapping presented in Fig. 2 is that it cannot distinguish the electronic contribution from the structural contribution, as the tunneling junction setup can often have a dependence on structure features. However, it is generally believed that the energy gap of the charge order is of electronic origin. We therefore systematically measure the energy gap of the charge order at each spatial point and map out the spatial distribution of the charge order gap value as shown in Fig. 4(a), which reveals a striking spatial modulation of the energy gap value. The Fourier transform of the gap map in Fig. 4(b) shows the 2×2 vector peaks with clear anisotropy, thus similarly defining a chirality in the electronic charge order. We have further checked this phenomenon in the cousin kagome superconductor RbV₃Sb₅ in Figs. 4(c) and (d), and observed similar chirality of the electronic charge order. In Fig. 4 (e), we show typical linecut dI/dV spectrums along the line draw in Fig. 4(c), further illustrating the charge order gap modulation in real-space.

The observation of electronic chiral charge order is unprecedented in the studying of quantum materials, and can be highly related to the electronic nature of kagome lattice at van Hove filling as in AV₃Sb₅ [42-46]. In contrast to the honeycomb lattice, the kagome lattice has three sublattices, and the kagome lattice at van Hove filling exhibits unequal predominant sublattice occupancy [42]. With extended Coulomb interactions considered, this sublattice interference mechanism will produce a chiral charge order with relative angular momentum [44]. Phenomenologically, a chiral charge order parameter has also been proposed to interact with the underlying topological band structure of this material to produce a large intrinsic anomalous Hall effect [28,43,44,45], which is consistent with the transport data. Another anomalous feature of the chiral charge order is that it can carry orbital currents [28,43,44,46], analogous to the fundamental Haldane model [47] and Varma model [48]. A tantalizing visualization of the orbital magnetism is recently reported by muon spin spectroscopy, and a spontaneous internal magnetic field is observed just below the charge ordering temperature [49].

Finally, we explore the superconducting tunneling spectrum at 0.4K, well below the superconducting transition temperature. Consistent with previous reports [30,32,33], the tunneling spectrums show an energy gap with a gap size 2Δ =0.85meV determined by the coherence peak-to-peak distance [Fig. 5(a)(b)]. Accordingly, we obtain the superconductivity coupling strength $2\Delta/k_BT_c$ =3.9, which is slightly larger than the standard BCS value and suggests the electron pairing is close to a moderate coupling. By applying a 50mT magnetic field along the c-axis, we observe a zero-energy vortex core state [Fig. 5(c)(d)]. The formation of a clear vortex core bound state implies that the superconducting state is in the clean-limit, where the electron mean free path is much longer than the superconducting coherent length. One notable observation in the superconducting state is that the gap is shallow, and the measured gap is filled with substantial states. The origin of the in-gap states deserves future attention with lower temperature and higher energy resolution measurements. If such states are intrinsic and robust, then it is worthy of discussing further their relationship with the tantalizing broken-symmetry [32][49] of the superconducting state.
