(Dated: 14 May 2021)

We characterized a double torsion pendulum system, including measurements of the photon-spin-induced torque. Our experimental strategy was similar to that used in Beth’s experiment, which was performed in 1936 to measure photon-spin-induced torque using forced oscillation caused by polarization modulation of light incident on a suspended object. Through simple passive isolation of the suspended object from external vibration noise, the achieved torque sensitivity was $2 \times 10^{-17}$ N m in a measurement time of $10^4$ s, which is close to the thermal noise limit and one order smaller than the minimum torque measured in Beth’s experiment. The observed spin-induced torque exerted on the light-absorbing optics is consistent with the angular momentum transfer of $\hbar$ per photon.

I. INTRODUCTION

The torsion pendulum, or torsion balance, is a sensitive device used to detect weak forces. It was used in the experiments of Cavendish and Coulomb, conducted in the 18th century to measure gravitational and electrostatic constants. The torsion pendulum is still one of the most sensitive measurement methods in modern physics and engineering, with applications ranging from low-frequency gravitational wave detection to studies of the mechanical properties of materials.

The torsion pendulum has been used to detect small mechanical torques exerted on macroscopic objects from quantum mechanical spins. The first experiment was performed in 1915 by Einstein and de Haas, who demonstrated that the mechanical rotation of a ferromagnetic material is caused by flipping of its magnetization or internal atomic spins. The second experiment, by Beth, was carried out in 1936 and demonstrated that flipping the photon spin from $+\hbar$ to $-\hbar$ ($\hbar$: Planck’s constant divided by $2\pi$) induced the rotation of a transmitting half-wave plate. The results of both experiments are understood in terms of angular momentum conservation of the system of atomic or photonic spins, and the rotation of the macroscopic object. Spin-induced torque has received renewed attention in recent spintronics and optomechanics studies. Angular momentum transmission due to a spin wave has been mechanically detected with a yttrium ion garnet cantilever. Gigahertz rotation of optically levitated nanoparticles has been demonstrated via spin transfer arising from circularly polarized trapping light.

In our previous report, we discussed the development of a torsion pendulum to study spin transfer from an optically spin-polarized atomic gas to a solid gas container through atom-surface interactions. The experiment was similar to that of Beth, in which an object suspended with a thin wire was irradiated from the bottom with circularly polarized light. Beth’s experiment has been described in many textbooks. However, to our knowledge, the careful and patient measurements conducted therein have not been replicated using the original forced oscillation method, partly due to experimental difficulties including radiation pressure torque and the so-called radiometer effects, as well as the multiple steps involved in deriving the torque from the measured amplitude of the forced oscillation, as pointed out in Ref. In Ref, the authors directly measured photon-spin-induced torque on the order of $10^{-12}$ N m from the acceleration of a suspended half-wave plate with a high-power infrared laser.

In this study, we analyzed our developed pendulum system, including measurement of the photon-spin-induced torque. Our experimental strategy was similar to that applied in Beth’s ex-
experiment, that is, forced torsional oscillation induced by periodic application of external torque at the resonance frequency of the pendulum. The main differences between our system and that of Beth’s study are the use of a double pendulum, in which the first pendulum works as a vibration isolator, and a higher operating frequency of 0.1 Hz relative to 0.002 Hz in Beth’s experiment. Through this simple passive isolation from external vibration noise, the torque sensitivity was $2 \times 10^{-17}$ N m (in $10^4$ -s measurement time), which is close to the thermal noise limit and one order smaller than the minimum torque measured in Beth’s experiment. The observed spin-induced torque exerted on the light-absorbing optics is consistent with the angular momentum transfer of $\hbar$ in the direction of light propagation per photon for left-circularly polarized light.

This paper is organized as follows. We first explain the experimental apparatus, with special attention given to the design of the double pendulum in Sec. II. In Sec. III, we describe the experimental procedure, including a forced torsional oscillation approach and a lock-in data analysis method. We then present our experimental results in Sec. IV, in which estimation of the torque sensitivity and measurement of photon-spin-induced torque are discussed. The paper is concluded in Sec. V.

II. EXPERIMENTAL APPARATUS

The experimental apparatus, shown in Fig. I, is a slightly modified version of our previously reported one. The double torsion pendulum, discussed in detail below, was suspended in a vacuum chamber fixed on an optical table. The pressure inside was $1 \times 10^{-5}$ Pa, which was lower than the radiation pressure exerted on a suspended object by a typical torque laser beam used in the experiment ($1 \times 10^{-4}$ Pa the laser intensity of $3 \times 10^4$ W/m²). Thus, the radiometer effect from the background gas was negligible.

The angle of the suspended object (“optics holder”) was monitored using an optical lever method with a probe laser and a position-sensitive detector located 0.35 m away from the torsional axis. Light from the torque laser, with a wavelength of 852 nm, was incident on the object from the bottom. The light polarization was controlled with a set of waveplates, such as a liquid crystal variable retarder (LCVR) or a motorized rotatable quarter-wave plate, to periodically flip the polarization of the torque laser.

Compared to Beth’s experiment, which used a quartz fiber 0.25 m in length, the optics holder to be rotated was suspended with a short tungsten (W) wire approximately 5 mm in length and
10 µm in diameter. We refer to this portion of our double pendulum as the second pendulum. The short wire resulted in a higher torsional resonance frequency of 0.1 Hz, compared to 0.002 Hz in Beth’s experiment, enabling better isolation from external vibration noise, as discussed below. It also provided shorter measurement times, which minimized spurious effects of drifting. The optics holder accommodated half-inch optics, on which torque was exerted from the torque laser beam; a mirror reflected the torque laser beam when it transmitted the optics. A cubic mirror was attached to the top of the optics holder for the optical lever. The inertia momentum of the optics holder was estimated to be \((9.4 \pm 0.9) \times 10^{-8}\) kg m\(^2\).

The optics holder suspended with the short wire was attached to another torsion pendulum (the
FIG. 2. Damping of the torsional oscillation of the first pendulum with the rotational flange. At 0 s, the automatic feedback to the flange angle was activated toward the target angle of 0 mrad.

FIG. 3. Fourier transform spectrum of free torsional oscillation of the pendulum for 10^5-s measurement. Numerical simulations for the double and single pendulums are also shown.

The first pendulum, which consisted of an object (the “wheel”) with a large moment of inertia and a long wire. The inertia momentum of the wheel was estimated to be 7 × 10^{-6} kg m^2, and the W wire was approximately 1 m in length and 10 µm in diameter. The first pendulum had a low resonance frequency of torsional oscillation at 0.0008 Hz and served as a vibration isolator for the second pendulum, as discussed below.

The long wire was attached to a vacuum chamber flange, which was rotatable with an electric motor. This rotatable flange was used to dampen the torsional oscillation of the first pendulum, as shown in Fig. 2. This damping technique was quite useful for readying the system for forced oscillation measurements for the second pendulum, after the apparatus experienced large external perturbations such as earthquakes, which often caused large and slowly damping torsional oscillations of the first pendulum.

Figure 3 shows the Fourier transform spectrum of a free oscillation, recorded for 10^5 s after
damping of the first pendulum oscillation had been completed. The peak at 0.0008 Hz corre-
sponds to the resonant torsional oscillation of the first pendulum. The amplitude decreased as
the frequency increased beyond the resonance frequency. The peak at 0.1 Hz corresponds to the
torsional oscillation of the second pendulum and is the focus of this study. The peak at 0.5 Hz
originated from the simple or conical oscillation of the first pendulum.

To quantitatively examine the effect of vibration isolation with the first pendulum, we numeri-
cally solved the coupled equations that describe the torsional motions of the two pendulums with
application of Gaussian noise to the fixed end of the first pendulum wire; the freedom of mo-
tion in the simulation was the rotation of the first and second pendulums around the fixed wire
axis. With appropriate experimental parameters, as shown in Fig. 3, the simulation reproduced the
experimental observations fairly well, particularly the decrease in baseline oscillation amplitude
at higher frequencies than the resonance of the first pendulum. The effect of vibration isolation
can be clearly understood by comparing the measured spectrum with the single pendulum simu-
lation performed on the assumption that the second pendulum was attached directly to the flange
without the first pendulum. However, the peak for the resonant torsional oscillation of the second
pendulum was higher than that expected from the double pendulum simulation. We presumed
that the external vibration noise that induced the vertical and horizontal motions of the wire-fixed
point was coupled to the torsional motion of the second pendulum. The high amplitude of the
measured spectrum at lower frequencies can be attributed to larger external vibration noise at low
frequencies.

III. EXPERIMENTS

We adopted a force oscillation method at the resonance frequency of the second pendulum.
The optical torque was modulated with either the rotatable quarter-wave plate or the LCVR. We
proceeded carefully to minimize vibration and noise effects related to motor operation, mechanical
vibration (of the rotatable waveplate), and laser power fluctuations of the LCVR.

Special precautions were required against torque caused by radiation pressure. The radiation
pressure $P_{\text{rad}}$ for light-absorbing optics can be expressed as

$$P_{\text{rad}} = \frac{I_{\text{light}}}{c},$$

(1)

where $I_{\text{light}}$ and $c$ are the intensity and speed of light, respectively. The torque exerted on the optics
by the radiation pressure of the torque laser beam incident on the rotational axis of the optics is
on the order of $\alpha P_{\text{rad}} a^3$, where $a$ is the radius of the torque laser beam. The factor $\alpha$ reflects the effects of imperfect incidence of the torque laser, including deviation and incline from the rotation axis. The torque induced by photon spin transfer has a magnitude on the order of $P_{\text{rad}} a^2 \lambda$, where $\lambda$ is the wavelength of the torque laser. When we measure optical torque in polarization modulation mode, the ratio of modulation of the radiation pressure torque to that of the spin-induced torque is on the order of $(a/\lambda) \alpha \beta \sim 10^3 \alpha \beta$, where $\beta$ is a factor representing the modulation of the radiation pressure torque. A plausible reason for this modulation is variation in the laser power. Careful adjustment of the optical system was required to make the factor $\alpha \beta$ less than $10^{-3}$, such that the spin-induced torque dominated the radiation pressure torque.

The forced oscillation data were analyzed via a lock-in method to derive the oscillation amplitude and phase delay with respect to the reference signal, which was synchronized with the modulation of the torque laser polarization, or to derive the in-phase and quadrature components of the oscillation. The torque modulation $N$ was derived from the amplitude $A$ of the forced oscillation at resonance, using the following formula:

$$ N = \frac{\pi k A}{4 Q} = \frac{\pi I \omega_R^2 A}{4 Q}, $$

where $k$ is the torsion constant, $I$ is the inertia momentum, $\omega_R$ is the resonance angular frequency, and $Q$ is the Q-factor of the resonance. The factor $\pi/4$ accounts for the square wave modulation of the torque.

IV. RESULTS

A. Characterization of the pendulum

Because the optics holder was able to accommodate various types of half-inch optics, we examined several optics. One of the optics examined was a half-inch version of a depolarizer (DPP25-B; Thorlabs Inc., Newton, NJ, USA); more specifically, this was a microretarder array of 25-µm-wide strips with spatially varying retardation and fast-axis orientation. This particular optic converts a linearly polarized light beam into a pseudo-randomly polarized beam. We found that the depolarizer experienced a greater than expected (from the spin angular momentum transfer of $\hbar$ per photon) modulation of optical torque, associated with a pair of orthogonal, linearly polarized light waves at specific angles. We have not pursued the reason for the large optical torque, but suspect
FIG. 4. Temporal evolution of the amplitude and phase delay of the second pendulum oscillation caused by modulation of the linear polarization planes of the torque laser at 0.11028 Hz for the depolarizer.

FIG. 5. Resonance spectrum of the second pendulum, with the depolarizer irradiated with orthogonal linearly polarized light waves. Each error bar represents the standard deviation for each 10$^4$-s measurement.

that diffraction is responsible.\textsuperscript{15} We took advantage of the large optical torque modulation exerted on the depolarizer (by the orthogonal linearly polarized light waves) to characterize the pendulum.

Figure 4 shows the typical temporal evolution of the amplitude of the torsional oscillation of the second pendulum. At 0 s, the polarization plane of the linearly polarized light with a power of 290 mW began to switch between two orthogonal polarization planes at 0.11028 Hz; the amplitude increased to become a steady amplitude with a time constant of 500 s. The phase delay was about $\pi/2$, indicating that the modulation frequency was close to resonance. We calculated the average and standard deviation values for this steady-state period (after $\sim$2000 s in Fig. 4).

Figure 5 shows the squared amplitude and phase delay of the oscillation as a function of modulation frequency. Resonance dependence on the frequency can be clearly seen. The Lorentzian fitting gave a peak amplitude of 25.8$\pm$0.4 $\mu$rad, a resonance frequency of 0.110317$\pm$0.000007 Hz, and a full width at half maximum value of $(6.4\pm0.2) \times 10^{-4}$ Hz; thus, the Q-factor was 173$\pm$5.
A change in oscillation phase delay from zero to $\pi$ through $\pi/2$ at resonance was observed.

From the observed resonance spectrum shown in Fig. 5, we derived the torque modulation exerted on the depolarizer as $(5.3 \pm 0.5) \times 10^{-15}$ N m. This is about 40 times larger than expected from the spin transfer of $\hbar$ per photon.

We estimated the minimum torque detectable with the current apparatus. We obtained 10 sets of $10^4$-s free torsional oscillation data for the pendulum, and applied lock-in analysis to them with imaginary reference signals at the resonance frequency. Figure 6 shows the obtained quadrature components of the oscillation. The 10 measurements resulted in an average quadrature component of 0.11 $\mu$rad and a standard deviation of 0.11 $\mu$rad. We therefore estimated that the noise level of the amplitude detection was 0.1 $\mu$rad, which corresponded to a torque of $2 \times 10^{-17}$ N m in $10^4$ s.

The thermal noise limit of the torque $N_{\text{ther}}$ can be estimated using the following formula,

$$N_{\text{ther}} = \frac{\pi}{4} \sqrt{\frac{4k_B T \omega R \Delta t}{Q}},$$

where $k_B$ is Boltzmann’s constant, $T$ is temperature, and $\Delta t$ is the measurement time. The estimated thermal noise limit was $2 \times 10^{-17}$ N m, which is close to the experimentally estimated value.

B. Measurement of spin-induced torque: revisiting Beth’s experiment

The minimum detectable torque was estimated to be $2 \times 10^{-17}$ N m, which corresponds to the torque induced by spin transfer from light with a power of 40 mW and wavelength of 852 nm, if we assume each photon transfers an angular momentum of $\hbar$ to the optics. We measured this spin-induced torque using a neutral density (ND) filter (NE560B-B; Thorlabs Inc.) as a light absorber.

FIG. 6. Quadrature components of the free torsional oscillation. Each error bar represents the standard deviation for each $10^4$-s measurement.
The absorption of the torque light by the ND filter was over 99.9%. The spatial mode of the laser beam was filtered to be TEM$_{00}$ with a single-mode fiber. The laser power incident on the ND filter was 130 mW. The polarization of the torque laser was modulated between left- and right-circular polarizations using the LCVR.

Figure 7 shows the quadrature component of the induced torsional oscillation as a function of the modulation frequency. The Lorentzian fitting gave a peak amplitude of $0.75 \pm 0.29 \mu$rad at the resonance frequency of $0.08981 \pm 0.00005$ Hz, and a full width at half maximum value of $(3.4 \pm 1.9) \times 10^{-4}$ Hz. The Q-factor was derived as $270 \pm 150$. Note that due to the exchange of suspended objects, including W wires, these values were slightly different from those of the depolarizer. As a result, the measured torque modulation was $(7 \pm 4) \times 10^{-17}$ N m, consistent with the $6 \times 10^{-17}$ N m derived from the assumption that one photon transfers $\hbar$ angular momentum to the ND filter.

We also confirmed that the observed oscillation phase was consistent with the expected rotation direction; specifically, left-circularly polarized light carries $+\hbar$ angular momentum along the direction of propagation$^{10,14}$ and exerts a positive torque on the ND filter.

To confirm that the observed torque originated from photon spin, rather than from other effects such as radiation pressure torque, we measured the light polarization dependence. At a fixed modulation frequency, we changed the polarization modulation by rotating the LCVR axis from a pair of counterrotating circular polarizations to a pair of counterrotating elliptical polarizations. Figure 8 shows the measured torque as a function of the spin component along the light propagation direction. The spin component of 0 $\hbar$ corresponds to nominally unmodulated linear polarization,
whereas the spin component of $1\,\hbar$ corresponds to circular polarizations, with elliptical polarizations between the two extremes. The observed torque is reasonably proportional to the photon spin component of the propagation direction.

We also modulated the power of the torque laser without changing the polarization, to estimate the torque modulation originating from the radiation pressure; specifically, a 14\% change in power induced a torque modulation of $1 \times 10^{-16}$ N m. The power modulation associated with the polarization change with the LCVR was 2\% at most; thus, this could not be the main reason for the observed torque modulation. Taken together, we concluded that the observed torque was induced by photon spin transfer.

V. CONCLUSIONS

In this paper, we describe the characterization of our developed double torsion pendulum system using optical torque with a forced oscillation method similar to Beth’s experiment. In the double pendulum approach, the first pendulum operates as a vibration isolator. With this simple passive isolation from external vibration noise, the torque sensitivity reached $2 \times 10^{-17}$ N m in $10^4$-s measurement time, which is close to the thermal noise limit and one order smaller than the minimum torque measured in Beth’s experiment. We evaluated the photon-spin-induced torque using a ND filter as a light absorber. The observed torque was consistent with the torque expected from the angular momentum transfer of $\hbar$ (or $-\hbar$) per photon in left- (or right-) circularly polarized light. Our demonstration can be regarded as a recapitulation of Beth’s experiment.

Finally, the developed double pendulum could be used in future detailed studies of spin transfer.
from gases to solids.
