(Dated: May 14, 2021)

We investigate the delocalization of quantum information in the nonequilibrium dynamics of the XY spin chain with asymptotically decaying interactions $\sim 1/r^\alpha$. As a figure of merit, we employ the tripartite mutual information (TMI), whose sign indicates if quantum information is predominantly shared globally. Interestingly, the sign of the TMI distinguishes regimes of the exponent $\alpha$ that are known for different behaviour of information propagation. While an effective causal region bounds the propagation of information, if interactions decay sufficiently fast, this information is mainly delocalized, which leads to the necessity of global measurements. Furthermore, the results indicate that mutual information is monogamous for all possible partitionings in this case, implying that quantum entanglement is the dominant correlation. If interactions decay sufficiently slow, though information can propagate (quasi-)instantaneously, it is mainly accessible by local measurements at early times. Furthermore, it takes some finite time until correlations start to become monogamous, which suggests that apart from entanglement, other nonmonogamous correlations are sizeable at early times. Our findings give new insights into the dynamics, and structure of quantum information in many-body systems with long-range interactions, and might get verified on state-of-the-art experimental platforms.

I. INTRODUCTION

Entanglement, a key resource in quantum information processing [1], is believed to give precious insights into exciting physical phenomena in a variety of fields [2]. Driven by recent progress on experimental platforms such as trapped ions [3], ultracold atoms in optical lattices [4, 5], and Rydberg atoms [6, 7], quantum many-body systems out of equilibrium gained a lot of attention lately [8]. How quantum information propagates, and distributes over the degrees of freedom of a many-body system is fundamental for a plethora of subjects, ranging from the simulability of these systems on classical computers [9], to the AdS/CFT correspondence [10].

A few decades ago, Lieb and Robinson [11] proved the emergence of a causal region, or lightcone, in nonrelativistic systems with sufficiently local interactions. That is to say: there exists a finite speed at which correlations and, therefore, information can propagate through the system. In consequence, correlations among remote regions get exponentially suppressed until some time that is proportional to their distance, $t \sim r$. Today’s experimental platforms offer vast possibilities to explore the physics of quantum lattice models with increasing accuracy and system size. In some cases, the systems’ constituents couple through long-range forces, which can result in interactions proportional to a powerlaw $\sim 1/r^\alpha$. If the exponent $\alpha$ is small, interactions are not sufficiently local anymore. As these platforms aim to serve as reliable quantum simulators [12] in the future, this led to a renewed theoretical interest in many-body systems with long-range interactions.

It is particularly intriguing that the notion of causality does not necessarily apply to long-range interacting systems, and information propagation can differ substantially [13–15]. While the causal region continuously alters with decreasing $\alpha$, it even can be absent if the exponent of the powerlaw decay is smaller than the systems’ dimension, $\alpha < D$. Thus, information can propagate (quasi-)instantaneously between remote regions. Counterintuitively, this regime was further associated with slower growth of bipartite entanglement [13–16]. The exponent of the powerlaw decay, therefore, strongly affects the nonequilibrium properties of a many-body system, and subsequent works aimed to improve the understanding of information propagation in long-range interacting systems [17–20]. Here, we want to shed more light on the particular structure of quantum information. Especially, we investigate how the exponent $\alpha$ determines if quantum information is delocalized, i.e., if information is rather shared globally than among individual subsystems.

This work is structured as follows. In Sec. [1] we introduce the quantities we use to probe the correlation structure of a many-body system, namely the Von Neumann entropy, the mutual information, and the tripartite mutual information (TMI). The TMI accounts for the delocalization of quantum information. Thereafter, in Sec. [II] we investigate the TMI in the nonequilibrium dynamics of the long-range XY spin chain. At first, we provide analytical arguments that quantum information does not delocalize in the 1-excitation subspace, which can be understood by the limited amount of entanglement that emerges. Subsequently, we numerically investigate the dynamics in the largest subspace of the model. In this case, we deduce regimes for the exponent $\alpha$ which exhibit different structure of quantum informa-
tion at early times. How one can test our findings in the laboratory is briefly touched in Sec. [V] Finally, in Sec. [V] we discuss our results, pose some open questions, and talk about future directions.

II. ENTROPY AND CORRELATION MEASURES

Let us establish what quantities we henceforth use to probe the correlation structure of a quantum many-body system. To capture correlations as a property of the quantum state itself, we are mainly concerned with operator-independent quantities. We shall, therefore, introduce the fundamental quantity in this regard: the Von Neumann entropy. Given a quantum system \( \Omega \) that is described by a pure state \( \rho = |\Psi\rangle \langle \Psi| \), associated with some finite-dimensional Hilbert space \( \mathcal{H} \), the Von Neumann entropy for a subsystem \( A \subset \Omega \) is defined as

\[
S_A = - \text{Tr} [\rho_A \log (\rho_A)] = - \sum_{\lambda \in \sigma(\rho_A)} \lambda \log (\lambda) .
\]

In Eq. (1), \( \rho_A = \text{Tr}_{\bar{A}} (|\Psi\rangle \langle \Psi|) \) is the reduced state associated with \( A \), \( \sigma(\rho_A) \) denotes the spectrum of \( \rho_A \), and \( \bar{A} = \Omega \setminus A \) is the complement of \( A \). The logarithm is taken to base 2, if not mentioned otherwise.

Since the overall system \( \Omega \) has zero entropy, a nonvanishing entropy for subsystem \( A \) indicates that we lose information about the state of \( A \) if we neglect its environment \( \bar{A} \). Hence, Eq. (1) is a natural measure of entanglement between subsystem \( A \) and its environment \( \bar{A} \), see Fig 1(a). The entropy is in general bounded by

\[
0 \leq S_A \leq \log [\min (d_A, d_{\bar{A}})] ,
\]

where \( d_A \) is the dimension of the Hilbert space associated with \( A \). The right equality in (2) holds iff \( A \) is maximally entangled with \( \bar{A} \), while the left equality holds iff the systems’ state is separable with respect to the bipartition \( \{ A, \bar{A} \} \), i.e., \( |\Psi\rangle = |\Psi\rangle_A \otimes |\Psi\rangle_{\bar{A}} \).

The Von Neumann entropy is frequently applied to probe nonequilibrium many-body physics. If we consider a one dimensional spin chain, the time-dependent growth of the half-chain entropy gives rise to the build up of bipartite entanglement in the system. While sufficiently local Hamiltonians, i.e., large values of the exponent \( \alpha \), are associated with a linear entropy growth, this growth is only logarithmic for very long-range interactions [14].

The quasi-particle contribution, that is responsible for the linear growth [21], is increasingly suppressed by collective excitations with decreasing \( \alpha \) leading to a slowdown of entanglement production [16]. Later on, we will see that the particular structure of quantum information is widely different in these scenarios.

For many occasions, though, it is of particular interest how two subsystems \( A \) and \( B \) are correlated to each other, where \( A \cup B \subset \Omega \) and \( A \cap B = \emptyset \). For instance, two distant spins that are part of a larger spin chain.

Based on the Von Neumann Entropy, one can define the mutual information

\[
I_{A:B} = S_A + S_B - S_{AB} ,
\]

where \( AB := A \cup B \). One might be tempted to think that equation (3) is a measure of entanglement between \( A \) and \( B \), however, the mutual information contains both, classical and quantum correlations, and is considered as a measure of total correlation between the two subsystems [22], see Fig 1(b). The mutual information is strictly non-negative, \( I_{A:B} \geq 0 \), where the equality holds iff \( A \) and \( B \) are uncorrelated, \( \rho_{AB} = \rho_A \otimes \rho_B \). Furthermore, it is nonincreasing under reduction, i.e., \( I_{A:BC} \geq I_{A:B} \).

In nonequilibrium many-body physics, for example, Eq. (3) can quantify how correlations among two spatial regions emerge during the dynamics induced by the systems Hamiltonian. Alternatively, we can evaluate connected correlators like

\[
\langle O_A O_B \rangle - \langle O_A \rangle \langle O_B \rangle ,
\]

where \( O_A, O_B \) are hermitian operators associated with some physical observable supported on \( A \), and \( B \) respectively. In contrast to the mutual information (3), Eq. (4) quantifies correlations with respect to the chosen operators rather than the many-body state itself. Nevertheless, both quantities capture the aforementioned different regimes of information propagation in quantum many-body systems with long-range interactions.

Even though the Von Neumann entropy (1), the mutual information (3), or connected correlators (4) offer vast insights into a quantum many-body system, they all quantify some type of correlation between two parties, i.e., bipartite correlations. However, correlations can emerge among various parties, and it is far from trivial.
to grasp and quantify this multipartite correlations. In particular, multipartite entanglement has evolved to be a field of research on its own over the last decades [23].

To probe correlations beyond the bipartite regime, we consider the tripartite mutual information [24] (TMI)

\[
I_{A:B:C} = I_{A:B} + I_{A:C} - I_{A:B:C},
\]

where \( A, B, \) and \( C \) are three disjoint subsystems of \( \Omega \). The TMI was introduced in [25] as topological entanglement entropy, where the authors used it to characterize multipartite entanglement in groundstates of topologically ordered two-dimensional systems. In the case of an overall pure state, the TMI [5] is symmetric under permutations of \( A, B, C, \) and \( D \), where \( D \) refers to the complement of \( ABC \). Moreover, \( I_{A:B:C} = 0 \), if the systems state is separable with respect to any partitioning of these subsystems, for instance: \( |\Psi\rangle = |\Psi\rangle_{AB} \otimes |\Psi\rangle_{CD} \). Thus, if Eq. [5] acquires a finite value, the systems’ state is at least fourpartite entangled.

From an informational standpoint, the TMI [5] quantifies how quantum information distributes among the subsystems \( A, B, \) and \( C \). Unlike mutual information, the TMI has no definite sign. While \( I_{A:B:C} > 0 \) indicates that more quantum information is shared among individual subsystems, information is rather shared globally if \( I_{A:B:C} < 0 \). Furthermore, if the TMI has a large magnitude and a positive sign, local measurements on \( B \) and \( C \) are sufficient to extract most of the information shared with \( A \). In the case of a negative sign, however, joint global measurements on \( BC \) are required. In the latter case, quantum information is said to be delocalized with respect to the three subsystems, see Fig. 1(c).

Moreover note that, if \( I_{A:B:C} \leq 0 \), mutual information is monogamous, i.e.,

\[
I_{A:B:C} \geq I_{A:B} + I_{A:C}.
\]

Monogamy, a common notion in quantum information theory, is known to apply to quantum entanglement [28]. Therefore, entanglement is not a shareable resource, implying that strong entanglement between \( A \) and \( B \) limits the amount of entanglement between \( A \) and \( C \). This is formalized by inequalities of the form \( E_{A:B:C} \geq E_{A:B} + E_{A:C} \), where \( E \) is some measure of entanglement. Since mutual information is a measure of total correlation, it is not monogamous in general. However, delocalization of quantum information among \( A, B, \) and \( C \) also implies the validity of the monogamy condition [5]. If the latter holds for arbitrary partitionings, one might argue that entanglement is the dominant correlation in the system [27, 28].

Recently, the TMI is applied to probe nonequilibrium physics, either in the context of unitary quantum channels [24, 29] or quantum many-body dynamics [30, 32]. In the next section, we will examine how the exponent of the powerlaw decay affects the distribution of quantum information in the nonequilibrium dynamics of a quantum spin chain. Especially, we identify regimes that are associated with a negative value of the TMI and, therefore, the delocalization of quantum information.

### III. DELocalization of QUantum INFORMATION

To study how quantum information distributes over the degrees of freedom of a many-body system, we consider a one-dimensional chain of pairwise interacting spins (qubits) described by the XY-Hamiltonian

\[
\mathcal{H} = \sum_{m<n} J_{mn} (X_m X_n + Y_m Y_n). 
\]

Here, \( X_m \) and \( Y_m \) denote the standard Pauli X- and Y-operators, acting on the lattice site \( m \). We further choose the eigenbasis of the Pauli Z-operator as the local basis for each spin, \( Z_m |0_m\rangle = - |0_m\rangle \), and \( Z_m |1_m\rangle = |1_m\rangle \). The interaction strength \( J_{mn} \) between two spins is given by a powerlaw

\[
J_{mn} = \frac{J_0}{|m-n|^{\alpha}},
\]

where \( J_0 \) is the nearest-neighbour interaction strength, and the exponent \( \alpha \geq 0 \) determines its spatial decay. Note that, if \( \alpha \to \infty \), this results in nearest-neighbour interactions overall. Since the Hamiltonian [7] conserves the number of excitations, i.e., \( |\mathcal{H}, \sum_m Z_m \rangle = 0 \), the Hilbert space decomposes into a direct sum of invariant subspaces \( \mathcal{H} = \bigoplus_k \mathcal{S}_k \), where each subspace \( \mathcal{S}_k \) is associated with a particular number \( k \) of excitations.

In what follows, we explore the delocalization of quantum information, measured by the TMI [5], in the nonequilibrium dynamics induced by the Hamiltonian [7]. Initially, the system is in a product state \( |\Psi_0\rangle \) that is not an eigenstate of its Hamiltonian. We are, hence, interested in the nonequilibrium dynamics of the many-body state

\[
|\Psi_t\rangle = e^{-i\mathcal{H}t} |\Psi_0\rangle,
\]

where \( \hbar = 1 \). This scenario is well suited to be performed on current experimental platforms. In the following section, we will describe in more detail how one can test our findings in the laboratory.

We first consider an initial state with just one localized excitation, for instance, at lattice site \( i \): \( |\Psi_0\rangle = |0\ldots 1_{i-1} 0_{i} 1_{i+1} \ldots 0\rangle \). The symmetry of the Hamiltonian then confines the dynamics of the system to the 1-excitation subspace \( \mathcal{S}_1 \). Thus, at any time the state of the system [9] can be written as

\[
|\Psi_t\rangle = \sum_m c_m |m\rangle,
\]

where the \( c_m \) are time-dependent coefficients, \( |m\rangle = |0\ldots 1_{m-1} 0_{m} 1_{m+1} \ldots 0\rangle \), and \( c_m = \delta_{mi} \) at \( t = 0 \). During the
nonequilibrium dynamics, the initially localized excitation coherently disperses and correlations between different regions of the system emerge.

Hereinafter, we shall compute the entropy $S_A$ of some subsystem $A$ that consists of a set of lattice sites. If we take the state $|0\rangle$ and trace out all sites that are not associated with $A$, we obtain

$$
\rho_A = \sum_{m,n\in A} c_m^* c_n |m_A\rangle \langle n_A| + \sum_{m\notin A} |c_m|^2 |0_A\rangle \langle 0_A|,
$$

where $|m_A\rangle$ is the state of $A$ with excitation at site $m$ and $|0_A\rangle = \bigotimes_{m\in A} |0_m\rangle$ is the state with all sites that belong to $A$ in the zero state. If we define $p_A := \sum_{m\in A} |c_m|^2$ and

$$
|1_A\rangle := (p_A)^{-1/2} \sum_{m\in A} c_m |m_A\rangle,
$$

we can diagonalize Eq. (11) in accordance with

$$
\rho_A = p_A |1_A\rangle \langle 1_A| + (1-p_A) |0_A\rangle \langle 0_A|.
$$

The entropy of $A$ is then given by the binary entropy

$$
H(p_A) = -p_A \log(p_A) - (1-p_A) \log(1-p_A) \leq 1,
$$

and is, thus, tighter bounded than if $A$ contains more then one lattice site. The amount of entanglement between the subsystem $A$ and its environment is therefore restricted to one 'e-bit' independent of the size of $A$.

Moreover, given two disjoint subsystems $A$ and $B$, it follows straightforwardly that the entropy of the union $S_{AB}$ is determined by $H(p_A + p_B)$. The TMI (5) then takes the form

$$
H(p_A) + H(p_B) + H(p_C) + H(p_A + p_B + p_C) - H(p_A + p_B) - H(p_A + p_C) - H(p_B + p_C).
$$

According to Eq. (12), the TMI is a function of the variables $p_A$, $p_B$ and $p_C$, where $p_A$ can be interpreted as the probability of finding the excitation if we perform a measurement on $A$. At the boundaries of the parameter space, that is $p_A \vee p_B \vee p_C = 0$, and $p_A + p_B + p_C = 1$, Eq. (12) vanishes, implying $I_{A:B:C} = 0$. Furthermore, one can find a maximum of Eq. (12) at $p_A = p_B = p_C = 1/4$. Due to the concavity of entropy, we can then conclude that $I_{A:B:C} \geq 0$ for all positive partitions.

Thus, in this particular scenario, quantum information does not delocalize among spatial regions in general. This further implies that mutual information is either exactly extensive or nonmonogamous. Since the symmetry of the Hamiltonian strongly constrains the amount of entanglement that can emerge, this entanglement can not dominate correlations overall. We should note though, that this is an exception, as our numerical calculations show that the TMI has no definite sign if the dynamics is confined to the $k$-excitation subspace, where $k > 1$. This result is in agreement with [30], where only for a few initial states with low effective dimension, a negative value for the TMI could not be observed. This emphasizes that delocalization of quantum information, and monogamy of mutual information require a more complex correlation structure than just entanglement. For instance, it follows from the derivation above that generalized W states [33], which belong to one class of multipartite entanglement, will never lead to a negative TMI.

For a more sophisticated picture, we consider an initial state that leads to richer dynamics. This state is chosen to be a Néel ordered state $|\Psi_0\rangle = |0101\ldots\rangle$. In line with the groundstate of the model, this state is an element of the largest subspace $\mathcal{S}_{[N/2]}$. In that case, an analytical treatment is rather difficult, and we therefore resort to numerical calculations. In the spirit of the half-chain Von Neumann entropy, we divide the system into four connected regions $A,B,C,D$ of equal size, to probe delocalization of quantum information in general. In particular, we solve the Schrödinger equation numerically and evaluate the TMI (5) for this partitioning at every time step.

In Fig. 2, the TMI is displayed in the $(\alpha,t)$-plane for a system of $N = 16$ spins. For larger exponents, i.e. $\alpha \geq 1$, the TMI vanishes at early times and then attains a negative value. As this regime is associated with a finite speed of propagation [13], correlations between distant regions get exponentially suppressed at early times. The systems’ state is, therefore, in good approximation still separable with respect to the subsystems $A, B, C$, leading to a vanishing TMI at early times. Once the subsystems start to exchange information, this information is delocalized, which follows from the negative value of the TMI. Oppositely, for $\alpha \lesssim 1$, quantum information does not delocalize at early times. The data moreover suggests that quantum information in general delocalizes for longer times except for very small exponents, $\alpha \rightarrow 0$. In Fig. 3, the TMI is shown for a system of $N = 20$ spins, and particular values of the exponent $\alpha$. One can recognize that the positive peak of the TMI at early times is suppressed with increasing $\alpha$. Though quantum information does not delocalize for $\alpha \leq 1$ at early times, the TMI decreases to a larger negative value for smaller exponents at longer times. Note that we observe similar behaviour for other choices of the partitioning. These results demonstrate that the exponent of the powerlaw decay shapes the distribution of quantum information. Interestingly, regimes that are associated with a strongly altered, or absent causal region, i.e. $\alpha \lesssim 1$, do not delocalize quantum information at early times.

To get more insight into the early-time dynamics, we calculate the minimal/maximal TMI out of all possible partitionings for a smaller system of $N = 12$ spins, and the time interval $J_0 t \in [0,1/2]$. In Fig. 4, the result of this calculation is shown for $\alpha = 0.2$, and $\alpha = 3.0$ respectively. We observe that for $\alpha = 3.0$ the maximal TMI stays near zero while the minimal TMI monotonically decreases until saturation. In addition, the largest value of
the maximal TMI in the overall time interval decays exponentially as a function of $\alpha$ as it can be seen in the left inset of Fig. 4. This suggests that mutual information is monogamous overall in the nearest neighbour limit, that is, the monogamy condition holds for all possible partitionings. As previously mentioned, this indicates that entanglement is the dominant correlation in this regime. On the contrary, for $\alpha = 0.2$ the minimal TMI is positive and growing at early times. Hence, there is not a single partitioning $A, B, C$ that fulfills the monogamy condition until the minimal TMI changes its sign. We further investigate this behaviour in right inset of Fig. 4 where the time $\tau$ it takes until the minimal TMI acquires a negative sign is displayed in dependence of the exponent $\alpha$. Surprisingly, one can observe that this time is finite for $\alpha \leq 0.5$ and vanishes for $\alpha > 0.5$. Thus, for $\alpha \leq 0.5$, correlations are nonmonogamous in general for $t < \tau$, which signifies that entanglement is not the dominant correlation at early times.

Our interpretation of these results is as follows. In the nearest neighbour limit, $\alpha \rightarrow \infty$, the XY model can be mapped onto a model of free fermions via a Jordan-Wigner transformation, and subsequent diagonalization in quasi-momentum space, i.e.,

$$\mathcal{H} = \sum_k \epsilon_k \eta_k^\dagger \eta_k,$$

where $\eta_k^{(1)}$ annihilates (creates) a fermionic quasi-particle with quasi-momentum $k$. The systems’ dynamics is then understood by the propagation of quasi-particles, entangling different regions of the system as their propagate. Information that is initially localized in some region is spread by these quasi-particles which move at different velocities. Thus, this information will disperse, leading to a negative TMI. With decreasing $\alpha$, the Hamiltonian becomes more symmetric, and collective excitations more dominant, which constrains the effective Hilbert space of the dynamics at early times. In the limiting case $\alpha = 0$, where all excitations are of collective nature, the Hamiltonian is fully permutation symmetric. Since these collective excitations spread redundant information, we observe a positive TMI at early times. Note that in the nearest neighbour limit, $\alpha \rightarrow \infty$, the XY model can be mapped onto a model of free fermions via a Jordan-Wigner transformation, and subsequent diagonalization in quasi-momentum space, i.e.,

$$\mathcal{H} = \sum_k \epsilon_k \eta_k^\dagger \eta_k,$$

where $\eta_k^{(1)}$ annihilates (creates) a fermionic quasi-particle with quasi-momentum $k$. The systems’ dynamics is then understood by the propagation of quasi-particles, entangling different regions of the system as their propagate. Information that is initially localized in some region is spread by these quasi-particles which move at different velocities. Thus, this information will disperse, leading to a negative TMI. With decreasing $\alpha$, the Hamiltonian becomes more symmetric, and collective excitations more dominant, which constrains the effective Hilbert space of the dynamics at early times. In the limiting case $\alpha = 0$, where all excitations are of collective nature, the Hamiltonian is fully permutation symmetric. Since these collective excitations spread redundant information, we observe a postive TMI at early times. Note that in the nearest neighbour limit, $\alpha \rightarrow \infty$, the XY model can be mapped onto a model of free fermions via a Jordan-Wigner transformation, and subsequent diagonalization in quasi-momentum space, i.e.,

$$\mathcal{H} = \sum_k \epsilon_k \eta_k^\dagger \eta_k,$$

where $\eta_k^{(1)}$ annihilates (creates) a fermionic quasi-particle with quasi-momentum $k$. The systems’ dynamics is then understood by the propagation of quasi-particles, entangling different regions of the system as their propagate. Information that is initially localized in some region is spread by these quasi-particles which move at different velocities. Thus, this information will disperse, leading to a negative TMI. With decreasing $\alpha$, the Hamiltonian becomes more symmetric, and collective excitations more dominant, which constrains the effective Hilbert space of the dynamics at early times. In the limiting case $\alpha = 0$, where all excitations are of collective nature, the Hamiltonian is fully permutation symmetric. Since these collective excitations spread redundant information, we observe a positive TMI at early times. Note that in the nearest neighbour limit, $\alpha \rightarrow \infty$, the XY model can be mapped onto a model of free fermions via a Jordan-Wigner transformation, and subsequent diagonalization in quasi-momentum space, i.e.,

$$\mathcal{H} = \sum_k \epsilon_k \eta_k^\dagger \eta_k,$$
of all possible partitionings $A, B, C$ that might encourage to further test the limits of these platforms. Whether or not the purity of current trapped ion systems has a finite entropy unlike the entropy of a pure state. Hence, the whole system mixed in a real experiment in contrast to our idealistic environment, the state of the whole system is in general two identical copies of the system.

Renyi entropy [42, 43]. However, this method requires there also exists a method to determine the second order technique that is able to determine the Von Neumann entropy of different subsystems. The straightforward approach to accomplish this is quantum state tomography [38], however, as this technique scales quite disadvantageous with system size, it is only applicable to very small systems. We are not aware of any technique that is able to determine the Von Neumann entropy, and in addition circumstances quantum state tomography. Recently, though, a technique to determine Renyi entropies was introduced [39–41], and numerical tests indicate that Renyi entropies will lead to qualitatively similar results. For cold atoms in optical lattices, there also exists a method to determine the second order Renyi entropy [42, 43]. However, this method requires two identical copies of the system.

Finally, we shall note that due to coupling to the environment, the state of the whole system is in general mixed in a real experiment in contrast to our idealistic assumption of a pure state. Hence, the whole system has a finite entropy unlike the entropy of a pure state. Whether or not the purity of current trapped ion systems is sufficient to observe our findings is an open question, that might encourage to further test the limits of these platforms.

V. DISCUSSION

Our results demonstrate that, besides the speed of information propagation, the exponent of the powerlaw decay starkly influences the distribution of quantum information. In regimes with a clear causal region, i.e. $\alpha \gtrsim 1$, we find that quantum information is mainly delocalized. Furthermore, the data shows that nonmonogamous correlations get exponentially suppressed with increasing $\alpha$, which suggests that correlations are predominantly caused by entanglement in this regime. Intuitively, this is understood via the picture of fermionic quasi-particles that delocalize quantum information as they propagate.

With increasing interaction range, collective excitations become more dominant. Since these excitations spread, to some extent, redundant information, nonmonogamous correlations are more pronounced and quantum information is protected from delocalization at early times. For sufficiently slow decaying interactions, $\alpha \lesssim 0.5$, we find that mutual information is nonmonogamous overall for a finite time $\tau$. Note that for an intial product state, this regime is associated with distant independent propagation of information, i.e., a complete absence of a causal region [15]. Thus, it seems that a strongly altered or absent causal region is accompanied with sizeable nonmonogamous correlations at early times. Entanglement, therefore, needs some finite time to dominate the systems dynamics in this case, which provides an alternative reasoning on the suppressed entropy growth for very long-range interactions.

Despite these exciting results, many questions remain open. Although our results suggests that the structure of quantum information vastly differs in the identified regimes, so far we do not know how beneficial or disadvantageous these structures are with respect to quantum information processing. Moreover, as our calculations were carried out for relatively small system sizes, and a specific model, it is natural to ask how general these findings are. It would be fairly interesting if one could lay out analytical arguments that mutual information is monogamous in systems described by local Hamiltonians, as it is the case for quantum field theories with holographic duals [28]. At last, we want to emphasize that the TMI indeed probes a many-body system beyond the insights given by the Von Neumann entropy, or mutual information. It would be compelling to see what insights this measure can provide regarding nonequilibrium phenomena like thermalization, and many-body localization [8], for example. We hope this work stimulates further efforts in this direction both theoretically, and experimentally.
