We study the quantum conditional entropy production, which quantifies the irreversibly conditioned on the coupling memory of the system. We prove that the quantum unconditional entropy production is less than the conditional one, where the latter has contribution from the informational nonequilibriumness. The mismatch, defined as the quantum dissipative information, pinpoints the distributive correlation established between the environment and the memory. Although the quantum unconditional entropy production can be zero, the conditional one is in general not, which is beyond the thermal equilibrium. Positive quantum dissipative information characterizes a potential work waste. We also prove the quantum fluctuation theorems related to the conditional entropy production, based on different two-point measurement schemes. The dissipative information itself also follows the quantum fluctuation theorem. We present examples based on the qubit collisional model and the qubit Maxwell’s demon.

Introduction – Thermodynamics and quantum mechanics as two fundamental theories describing physics of vast different scales are merging into one known as quantum thermodynamics [1, 2]. The concept of entropy production, as the key quantity in the second law of thermodynamics, has also been established in quantum thermodynamics [3]. The irreversibility of any processes is reinterpreted as the information loss related to the environments [4]. The stochastic version of the second law of thermodynamics, known as the fluctuation theorem [5–7], is also extended to the quantum level, commonly founded on the two-point measurement scheme [8–10].

Suppose that the system couples to a quantum memory. The entropy of the system, denoted by the von-Neumann entropy $S_S$, can be reduced if the information on the memory is known. In other words, entropy and correlation is reversely related [11]. The entropy of system (S) conditioned on the memory (M) is quantified by the conditional entropy $S_{S\mid M}$ [12]. We have $S_{S\mid M} \leq S_S$ with equal sign if the system and the memory are uncorrelated. Negative conditional entropy suggests the entanglement resources beyond classical cases [13, 14].

Conceptually different with the conditional entropy, the conditional entropy production quantifies the irreversibility of the dynamics, depending on which information is acquired, or defined as lost, in the given process. Irreversibility can be subjective, which is the motivation for the study of the conditional entropy production or the conditional thermodynamic laws. For example, if the state of the environment is known (by the measurements) after the system-environment interaction, information acquired by the measurements makes the process less irreversible [15, 16].

We study the conditional entropy production in terms of the coupling memory, also known as the Maxwell’s demon [17–23]. When the system couples to the environments, the memory also establishes the correlation with the environment, without interacting with the environment directly. Such distributive correlation [24, 25], missed in previous studies on the quantum Maxwell’s demon, contributes to an additional information loss, which is a lower bound of the conditional entropy production.

In this Letter, we prove that the conditional entropy production of the system (conditioned on the memory) is equal or larger than the unconditional entropy production. We call the positive mismatch between the two as the dissipative information. Work can be extracted from the correlation between the system and the memory [26–28]. Dissipative information characterizes the waste of such correlation work. We also establish the fluctuation theorems associated with the conditional entropy production, based on different two-point measurement schemes. Surprisingly, the dissipative information itself also follows the fluctuation theorem at the semi-classical level, which is beyond the fluctuation theorem on the thermodynamic quantities, such as the heat [29] and the entropy productions [30]. We give examples based on the qubit collisional model [3] and talk about the universal positive dissipative information of the qubit Maxwell’s demon.

Conditional entropy production – Consider a quantum system (S) interacting with the reservoir (R), also called environment in this Letter. Their interaction is characterized by a unitary evolution $U_{SR}$. Initially, we have $\rho_S \otimes \rho_R^i$. The final state is

$$\rho_{SR} = U_{SR}(\rho_S \otimes \rho_R^i)U_{SR}^\dagger.$$  

(1)

The irreversibility of the evolution is justified by tracing out the environment. The unconditional entropy produc-
the environment \( \Delta \Phi \) of the system is \([3]\)
\[
\Sigma_S(t_i : t_f) = \Delta S_S(t_i : t_f) + \Delta \Phi_R(t_i : t_f),
\]
with the entropy change of the system \( \Delta S_S(t_i : t_f) = S_S(t_f) - S_S(t_i) \) as well as the entropy flux \( \Delta \Phi_R(t_i : t_f) \) from the system to the environment. We assume that the initial state of the environment is thermal \( \rho^i_R = e^{-\beta H_R} / Z_R \) with the temperature \( \beta = 1/T \) and the Hamiltonian of the environment \( H_R \). Boltzmann constant is set to 1.

The entropy flux is related to the heat flux \( \Delta \Phi_R(t_i : t_f) = \beta Q_R(t_i : t_f) \), where the heat is defined as the energy change of the environment \( Q_R(t_i : t_f) = \text{Tr}[(\rho^i_R - \rho^f_R) H_R] \).

Local reversible evolutions, such as \( U_{SR} = U_S \otimes \mathbb{I}_R \), give \( \Sigma_S = 0 \). Correlating with the environment is identified as the irreversibility of system’s dynamics \([4]\).

Suppose that the system \( S \) is initially correlated to the quantum memory \( M \). See Fig. 1. We study the conditional entropy production, which characterizes the irreversibility of the dynamics based on the view of the memory, rather than the system itself. We define the conditional entropy production of the system conditioned on the memory as
\[
\Sigma_{SM}(t_i : t_f) = \Delta S_{SM}(t_i : t_f) + \Delta \Phi_{SM}(t_i : t_f),
\]
with the conditional entropy change \( \Delta S_{SM}(t_i : t_f) = S_{SM}(t_f) - S_{SM}(t_i) \) and the conditional flux \( \Delta \Phi_{SM}(t_i : t_f) \).

Conditional entropy is formulated as \( S_{SM} = S_M - S_S \), quantifying the uncertainty remained in the system given by the information of the memory. We argue that the conditional entropy flux equals to the unconditional entropy flux \( \Delta \Phi_{SM}(t_i : t_f) = \Delta \Phi_S(t_i : t_f) \), since the heat flux, or the energy change of the environment, does not depend on the memory. Similar argument has been applied to the conditional entropy production conditioned on the measurement results of the environments \([16]\).

Besides the positivity of both the unconditional and conditional entropy productions, we can show that

**Theorem 1** \( \Sigma_{SM}(t_i : t_f) \geq \Sigma_S(t_i : t_f) \geq 0 \).

The proof is presented in the Supplementary Material. Although the memory stores the information on the system, system-environment evolution corrupts the correlation between the system and the memory. In other words, the memory is less related to the state of the system after its evolution with the environment.

To see the difference between the unconditional and conditional entropy productions, we define their mismatch as
\[
\Sigma_I(t_i : t_f) = \Sigma_{SM}(t_i : t_f) - \Sigma_S(t_i : t_f),
\]
called as the dissipative information, where the classical case has been studied in \([31]\). Based on Theorem 1, we know

**Corollary 2** \( \Sigma_I(t_i : t_f) \geq 0 \).

Qualitatively, the dissipative information characterizes the correlation drop between the system and the memory: \( \Sigma_I(t_i : t_f) = -\Delta I_{SM}(t_i : t_f) \), where \( \Delta I_{SM}(t_i : t_f) = I_{SM}(t_f) - I_{SM}(t_i) \) is the mutual information change between the system and the memory. The mutual information is the amount of correlation between the two parties defined as \( I_{SM} = S_S + S_M - S_{SM} \). Therefore the positivity of the dissipative information, or the Theorem 1, is guaranteed by the monotonicity of the quantum mutual information \([32]\), or equivalently the strong subadditivity of the von Neumann entropy \([33]\).

On one hand, the unconditional entropy production is the lower bound of the conditional entropy production:
\[
\Sigma_{SM}(t_i : t_f) \geq \Sigma_I(t_i : t_f),
\]
The equal sign happens when the environments only couples the subspace of the system, while only the complementary subspace couples to the memory \([34]\). One the other hand, the lower bound which is expressed in terms of the dissipative information
\[
\Sigma_{SM}(t_i : t_f) \geq \Sigma_I(t_i : t_f),
\]
is reached when the system and the environment is a global fixed point of the evolution \( U_{SR} \). In other words, the system is at the thermal equilibrium with the environment while the dissipative information is still nonzero.

Another way to understand the dissipative information is through the mutual information between the memory and the reservoir, given by

**Theorem 3** \( \Sigma_I(t_i : t_f) = I_{M|R|S}(t_f) \).

Here \( I_{M|R|S} \) is the conditional mutual information between the environment and the memory (conditioned on the system), defined as \( I_{M|R|S} = S_R + S_M - S_S - S_{MSR} \). Nonzero dissipative information means that the memory and the environment establish a correlation through the system, called the distributive correlation \([24, 25]\). Since the information related to the environments is considered as lost, the conditional mutual information \( I_{M|R|S}(t_f) \) can be regarded as part of the entropy production. Previous studies have revealed that the conditional mutual information \( I_{M|R|S} \) bounds the fidelity to reconstruct
combined system (system plus memory) from the system alone [35, 36]. Our results fill the gap between the reconstructability and the irreversibility. Lower fidelity to reconstruct the initial state implies the more irreversible of the evolution.

**Work and heat bounds** – Consider the evolution $U_{SR}$ as some work extraction protocols, such as proposed in [37]. The maximal amount work extractable from the system is bound by the nonequilibrium free energy change $\Delta F_{S}(t_{i} : t_{t}) = F_{S}(t_{t}) - F_{S}(t_{i})$ with $F_{S} = \text{Tr}(H_{S}\rho_{S}) - T S_{S}$ and the Hamiltonian of the system $H_{S}$ [38]. The ordinary work and heat bounds are given by the unconditional entropy production. Specifically, the work done on the system satisfies $W_{\text{ext}}(t_{i} : t_{t}) \geq \Delta F_{S}(t_{i} : t_{t})$. The associated heat is bounded by $\beta Q_{S}(t_{i} : t_{t}) \leq \Delta S_{S}(t_{i} : t_{t})$ where $Q_{S}$ is the heat flow from the environment to the system: $Q_{S} = -Q_{R}$. Note that extracting the work means $W_{\text{ext}} < 0$ and $Q_{S} > 0$.

The conditional entropy production bounds the work in terms of the conditional free energy change $W_{\text{ext}}(t_{i} : t_{t}) \geq \Delta F_{S|M}(t_{i} : t_{t})$. Here $\Delta F_{S|M}$ is the conditional free energy change and $F_{S|M} = \text{Tr}(H_{S}\rho_{S}) - T S_{S|M}$. The conditional free energy is equal to the maximal extractable work from the system given the information of the memory. In other words, more work can be extracted from the correlation between the system and the memory if the correlation is accessible [26, 28].

However, we can see that the work bound $W_{\text{ext}}(t_{i} : t_{t}) \geq \Delta F_{S|M}(t_{i} : t_{t})$ is not tight compared to $W_{\text{ext}}(t_{i} : t_{t}) \geq \Delta F_{S}(t_{i} : t_{t})$, since

$$W_{\text{ext}}(t_{i} : t_{t}) \geq \Delta F_{S|M}(t_{i} : t_{t}) + T \Sigma_{t_{i}}(t_{i} : t_{t}) \geq \Delta F_{S|M}(t_{i} : t_{t}), \quad (7)$$

where $\Sigma_{t_{i}}(t_{i} : t_{t}) \geq 0$ according to Corollary 2. The corresponding heat bound is

$$\beta Q_{S}(t_{i} : t_{t}) \leq \Delta S_{S|M}(t_{i} : t_{t}) - \Sigma_{t_{i}}(t_{i} : t_{t}). \quad (8)$$

Since the working protocol $U_{SR}$ only locally interacts with the system, the information stored in the memory is not applied. While the correlation between the system and the memory is corrupted proportional to $\Sigma_{t_{i}}(t_{i} : t_{t})$, the amount of correlation work $T \Sigma_{t_{i}}(t_{i} : t_{t})$ is wasted. The “wasted” work is stored as correlation between the memory and the environment, suggested by Theorem 3. According to the protocol in [27], such correlation can be converted to the work if the environment is accessible.

**Fluctuation theorems of conditional entropy production** – Fluctuation theorems generalize the thermodynamic laws into the stochastic level, which is also a powerful tool to study arbitrary nonequilibrium processes in an equality. The trajectories of the quantum processes are specified by the measurements at the beginning and the end (the two-point measurement scheme) [8–10]. The backaction from measurements is minimized if measurements are performed at the eigenbasis of the system or the environments. Quantum correlations can also be preserved if the global measurements, on the joint state of the system and the memory, are applied [39, 40].

In our study, both classical and quantum correlations between the system and the memory are included in the conditional entropy production defined in Eq. (3). Firstly, we consider the fluctuation theorem founded on the measurement on the eigenbasis of the joint state SM. The stochastic conditional entropy production is given by

$$\sigma_{S|M} = \Delta S_{S|M} + \beta q_{R}, \quad (9)$$

where $\Delta S_{S} = -\ln P_{w} - (-\ln P_{a})$ and the stochastic heat $q_{R}$ is $E_{R}(r') - E_{R}(r')$. The conditional probability is $P_{n|a} = P_{n}/P_{a}$, given by the spectral decompositions $\rho_{SM} = \sum_{a} P_{n|a} |a\rangle \langle a|$. The prime notation is for the final state. The energy $E_{R}(r')$ of the environment obeys the thermal distribution with the index $r'$. If the memory is ignored, the stochastic entropy production of the system is

$$\sigma_{S} = \Delta S_{S} + \beta q_{R}, \quad (10)$$

The average with subscript “$q$” is taken over all possible forward trajectories based on the two-point measurement on the system-memory global state. The detailed proof sees the Supplementary Material. Note that the quantum correlation between the system and the memory is included in the above fluctuation theorem. Taking the average gives $\Sigma_{S|M} = \langle \sigma_{S|M} \rangle_{q}$. The derivation sees the Supplementary Material. Applying the Jensen’s inequality gives $\langle \sigma_{S|M} \rangle_{q} \geq 0$.

At the semi-classical cases, the two-point measurements are performed at the local basis of the system and the memory respectively. Then the stochastic conditional entropy production becomes $\sigma_{S|M} = \Delta S_{S|M} + \beta q_{R}$ with $\Delta S_{S|M} = -\ln P_{w} - (-\ln P_{a})$. The conditional probability is specified by $P_{n|a} = P_{n}/P_{a}$, similar for the final state. Then we have the fluctuation theorem:

**Theorem 4** $\langle e^{-\sigma_{S|M}} \rangle_{q} = \langle e^{-\sigma_{S} - \sigma_{V}} \rangle_{q} = 1.$

The average with subscript “$q$” is taken over all possible forward trajectories based on the two-point measurement on the system-memory global state. The detailed proof sees the Supplementary Material. Note that the quantum correlation between the system and the memory is included in the above fluctuation theorem. Taking the average gives $\Sigma_{S|M} = \langle \sigma_{S|M} \rangle_{q}$. The derivation sees the Supplementary Material. Applying the Jensen’s inequality gives $\langle \sigma_{S|M} \rangle_{q} \geq 0$.

The average with subscript “$q$” is taken over all possible forward trajectories based on the two-point measurement on the system-memory global state. Taking the average gives $\Sigma_{S|M} = \langle \sigma_{S|M} \rangle_{q}$. The derivation sees the Supplementary Material. Applying the Jensen’s inequality gives $\langle \sigma_{S|M} \rangle_{q} \geq 0$.
The average with the subscript “c” is taken over the trajectories based on the two-point measurement on the local basis. Note that the stochastic unconditional entropy production in Eq. (10) is defined by the local state trajectories, which gives \( \Sigma_q = \langle \sigma_q \rangle_c \).

More interestingly, the dissipative information, at the semi-classical level \( \delta I = \delta_{SM} - \sigma_S \), also follows the fluctuation theorem:

**Theorem 6** \( \langle e^{-\delta I} \rangle_c = 1 \).

The inequality \( \langle \delta I \rangle_c \geq 0 \) states the strong subadditive of the Shannon entropy. The detailed proof sees the Supplementary Material. Note that the average gives the memory at the initial time. The dissipative information gives the semi-classical level dissipative conditional entropy production, \( \delta E = \delta_{SM} - \sigma_q \), which is also the maximum quantum relative entropy of coherence \( \Delta J = J(t_f) - J(t_i) \) [42], wiped out by the local eigenstate measurement on the initial and final state.

**Examples on the qubit model** — Suppose that both the system and the memory are one qubit. Their initial states are thermal, given by \( \rho_{SM} = e^{-\beta H_{SM}} / Z_{SM} \) with the Hamiltonian \( H_{SM} = E^i_{SM} |1\rangle_S \langle 1 |_{SM} \). We assume \( E^i = E^i_S = E^i_M \) for simplicity. Their correlations can be categorized as classical or quantum. One example of classical correlation is \( \rho_{SM}^{\text{cl}} = p|00\rangle_{SM} \langle 00 | + (1 - p)|11\rangle_{SM} \langle 11 | \) with \( p = (1 + e^{-\beta E^i})^{-1} \). One example of quantum correlation, given by \( \rho_{SM}^{\text{qm}} = |\psi_{SM}\rangle \langle \psi_{SM}| \) with \( |\psi_{SM}\rangle = \sqrt{p}|00\rangle_{SM} + \sqrt{1 - p}|11\rangle_{SM} \), characterizes the maximal quantum correlation between the system and the memory. Quantum correlation gives rise to the negative conditional entropy \( \Sigma_{\text{SM}}^q = -S(\rho_{SM}^{\text{qm}}) \) [13, 14].

We consider a quasistatic isothermal process [37], where the system is doing work while absorbing heat from the environment. The environment is the qubit reservoir at temperature \( \beta \). At each step, the system quenches the Hamiltonian by a value \( \delta E \), then interacts with the \( n \)-th qubit from the environment via the XY interaction \( U_{SR_n} = e^{-i \sigma_n \delta \sigma_n} / Z_{SR_n} \). Here \( \sigma_n(\phi) \) are Pauli matrices. Such interaction has been experimentally realized in the nuclear spin systems [43, 44]. Note that the system stays in the thermodynamic state with the same temperature \( \beta \) after each step. Such a condition puts constraints on the energy levels of the qubits from the environments. For more information about the setup see the Supplementary Material.

The quasistatic limit \( \delta E \to 0 \) leads to \( \Sigma_q \to 0 \). See numerical results with small values of \( \delta E \) in Fig. 2. However, the conditional entropy production is not zero \( \Sigma_{\text{SM}}^q > \Sigma_{\text{SM}} > \Sigma_q \), which reflects the informational nonequilibriumness. The superscript \( q \) or \( q \) suggests the classical or quantum correlation between the system and the memory at the initial time. The dissipative information with quantum correlation is larger than the classical one \( \Sigma_{\text{SM}}^q > \Sigma_{\text{SM}}^c \), since both the quantum and the classical correlation are dissipating during the process. As the system and the memory are decoupled after the process, the dissipative information reaches the maximum \( \Sigma_{\text{SM}}^q = 2\Sigma_{\text{SM}}^q = 2S(\rho_{SM}^{\text{qm}}) \), which is also the maximum quantum and classical correlations established between the memory and the environment respectively.

At quasistatic level, the work done on the system is \( W_{\text{ext}} = T \ln[(1 + e^{-\beta E^i})/(1 + e^{-\beta E^f})] \), where the final Hamiltonian of the system is \( H^f = E^f |1\rangle_S \langle 1 | \). The work and heat saturates the bounds \( \Delta F_S \) and \( \Delta S_S \) respectively. However, the change of conditional free energy, as well as the change of conditional entropy, suggest the work waste according to the inequalities (7) and (8). See Fig. 2 for the numerical results.

In the qubit Maxwell’s demon protocol [19], the demon (memory) firstly establishes the correlation with the system via the operation \( U_{MS} \). Then the demon performs the feedback control operation to decrease the entropy of the system. The feedback control can be the measurement type or the unitary type. The measurement-type demon performs the control operations \( U^{(k)} \) on the system, based on the (eigenbasis) measurement results \( k = 0, 1 \) of the memory. The unitary-type demon controls the system via the two-qubit controlled operation. See Fig. 3. The difference between these two types are the type of remaining correlations between the system.
and the memory. In Supplementary Material we show that there is remaining quantum correlation between the system and the memory for any non-optimal unitary feedback control operation. The non-optimal measurement-type feedback control operations suggest the remaining classical correlations between the system and the memory.

Suppose that the system and the memory has the classical correlation $\rho_{SM}^{ic}(\varepsilon_c) = \rho_{SM}^{ic} - \varepsilon_c p(1-p)(\sigma_3^c \otimes \sigma_3^M)$ or the quantum correlation $\rho_{SM}^{iq}(\varepsilon_q) = \rho_{SM}^{iq} - \varepsilon_q \sqrt{p(1-p)}(|0\rangle_{SM}|11\rangle_{SM} + |1\rangle_{SM}|00\rangle_{SM})$, with the noise parameters $\varepsilon_c, \varepsilon_q \in [0, 1]$. Note that $\rho_{SM}^{ic}(1) = \rho_{SM}^c \otimes \rho_{SM}^M$ and $\rho_{SM}^{iq}(1) = \rho_{SM}^{iq}$. We can see that the dissipative information vanishes at $\varepsilon_c = 1$, which gives rises to $\Delta S_{SM} = 0$ and $\Sigma S_{SM} = \Sigma c$. The quantum part of the dissipative information vanishes at $\varepsilon_q = 1$ while the dissipative information itself is nonzero because $\Sigma c > 0$. See Fig. 3. In our examples, any nonzero correlation between the system and the memory leads to the nonzero dissipative information during the work extraction protocol.

**Conclusion** — In summary, we show that the quantum system, coupled with a memory, interacting with the thermal environment, has the conditional entropy production which is always larger than the unconditional one. The mismatch between the unconditional and conditional entropy productions, defined as the dissipative information, is shown to be the mutual information change between the system and the memory, or equivalently the conditional mutual information between the memory and the environment. The dissipative information provides a thermodynamic interpretation of the conditional mutual information [35, 36]. Positive dissipative information suggests the waste of correlation work [26–28]. In addition, we establish the quantum fluctuation theorems of the conditional entropy production based on different two-point measurement schemes [39, 40]. We also find the quantum fluctuation theorem of the dissipative information based on the local two-point measurements. Our study reveals the entropy production given by the informational nonequilibriumness, which enriches the understandings of informational thermodynamics [38].

Supplemental Material: Conditional Entropy Production and Quantum Fluctuation Theorem of Dissipative Information

A. POSITIVITY OF CONDITIONAL ENTROPY PRODUCTION AND DISSIPATIVE INFORMATION

Theorem 1 states the relationship between the unconditional and conditional entropy productions. Theorem 3 states that the dissipative information can be traced to the conditional mutual information between the memory and the environment. We prove the two theorems in the following.

Proof of Theorem 1: As shown in [S1], the positivity of unconditional entropy production, $\Sigma_S \geq 0$, is guaranteed by the positivity of relative entropy. The mismatch between the unconditional and conditional entropy productions equals to

$$\Sigma_{S|M}(t_i : t_f) - \Sigma_S(t_i : t_f) = \Delta S_{S|M}(t_i : t_f) - \Delta S(t_i : t_f)$$

$$= \Delta S_{SM}(t_i : t_f) - \Delta S_{M}(t_i : t_f) - \Delta S(t_i : t_f)$$

$$= -\Delta I_{S:M}(t_i : t_f), \quad (S1)$$

which is the negative of mutual information change between the system and the memory. Because there is no correlation between the memory and the environment, therefore we can rewrite the initial mutual information between the system and the memory as

$$I_{S:M}(t_i) = I_{SR:M}(t_i). \quad (S2)$$

Moreover, the unitary evolution $U_{SR}$ preserves the mutual information between SR and M, namely

$$I_{SR:M}(t_i) = I_{SR:M}(t_f). \quad (S3)$$

Then we can rewrite Eq. (S1) as

$$\Sigma_{S|M}(t_i : t_f) - \Sigma_S(t_i : t_f) = I_{SR:M}(t_f) - I_{S:M}(t_f) \geq 0. \quad (S4)$$

The last inequality is from the monotonicity of the quantum mutual information [S2].

Proof of Theorem 3: The conditional mutual information $I_{M:R|S}(t_i)$ has the form

$$I_{M:R|S}(t_i) = S_{SR}(t_i) + S_{SM}(t_i) - S_S(t_i) - S_{MSR}(t_i)$$

$$= I_{SR:M}(t_i) - I_{S:M}(t_i). \quad (S5)$$

Then according to Eq. (S4), we have

$$I(t_i : t_f) = I_{M:R|S}(t_i). \quad (S6)$$

B. FLUCTUATION THEOREMS OF THE CONDITIONAL ENTROPY PRODUCTION

In this section, we present proof on the fluctuation theorems given in the main text, where Theorem 4 is based on the global trajectories of the system and the memory while Theorems 5 and 6 are founded on the local state measurements. The advantage for the global trajectories is to preserve the quantum correlation between the system and the memory [S3, S4]. At the local trajectory level, the dissipative information itself also follows the fluctuation theorem.

The forward global trajectory of the evolution is given by

$$P_F[\gamma_{MSR}^q] = |\langle n', r'|U_{SR}|n, r\rangle|^2 P_n P_r, \quad (S7)$$
where $P_n$ is the probability of the initial state $\rho^S_{\text{SM}}$ at the eigenbasis $|n\rangle$, and $P_{r(r')} = e^{-\beta E_{r,r'}}/Z_R$. State $|n'\rangle$ is the eigenbasis of the final state $\rho^R_{\text{SM}}$. Note that the trajectory is based on the project measurements on the joint system-memory state at the initial and final time. The variables $\gamma_{\text{MSR}}^q = \{n, r, n', r'\}$ specify the global trajectory including the quantum correlation. The memory state does not change during the evolution $U_{\text{SR}}$.

The backward global trajectory given by the evolution $U_{\text{SR}}^\dagger$ has the form

$$P_B[\gamma^q_{\text{MSR}}] = |\langle n, r | U_{\text{SR}}^\dagger | n', r' \rangle|^2 \tilde{P}_{n'} \tilde{P}_{r'},$$

(S8)

where the initial state of the backward evolution is set as $\rho^S_S \otimes \rho^R_R$, known as the reference state. Specifically, we have $\tilde{P}_n, \tilde{P}_r = \langle n', r' | \rho^S_{\text{SM}} \otimes \rho^R_{\text{SM}} | n', r' \rangle$.

We can simply verify the normalization of both forward and backward global trajectories

$$\sum_{\gamma^q_{\text{MSR}}} P_F[\gamma^q_{\text{MSR}}] = \sum_{\gamma^q_{\text{MSR}}} P_B[\gamma^q_{\text{MSR}}] = 1.$$  

(S9)

Equipped with forward and backward global trajectories, we can prove Theorem 4.

**Proof of Theorem 4:** The stochastic conditional entropy production can be written by the forward and backward trajectories

$$\sigma_{S|M} = \Delta s_{S|M} + \beta q_R$$

$$= \ln \left( \frac{P_n P_r}{P_{n'} P_{r'}} \right) - \ln \left( \frac{\tilde{P}_{n'} \tilde{P}_{r'}}{P_{n'} P_{r'}} \right)$$

$$= \ln \left( \frac{P_F[\gamma^q_{\text{MSR}}]}{P_b[n, r] } \right) - \ln \left( \frac{P_B[\gamma^q_{\text{MSR}}]}{P_b[n, r] } \right).$$

(S10)

The stochastic conditional entropy production can also be rewritten as

$$\sigma_{S|M} = \ln \left( \frac{P_n}{P_{n'}} \right) + \ln \left( \frac{P_r}{P_{r'}} \right)$$

$$= \ln \left( \frac{P_n}{P_{n'}} \right) + \ln \left( \frac{P_{n'}}{P_{r'}} \right) + \ln \left( \frac{P_r}{P_{n'}} \right) - \ln \left( \frac{\tilde{P}_{n'} \tilde{P}_{r'}}{P_{n'} P_{r'}} \right)$$

$$= \sigma_S + \sigma_I.$$  

(S11)

Then we have

$$\langle e^{-\sigma_{S|M}} \rangle_q = \langle e^{-(\sigma_S + \sigma_I)} \rangle_q = \sum_{\gamma^q_{\text{MSR}}} P_F[\gamma^q_{\text{MSR}}] \frac{P_B[\gamma^q_{\text{MSR}}]}{P_F[\gamma^q_{\text{MSR}}]} = \sum_{\gamma^q_{\text{MSR}}} P_B[\gamma^q_{\text{MSR}}] = 1.$$  

(S12)

The average of stochastic conditional entropy production $\sigma_{S|M}$ gives

$$\langle \sigma_{S|M} \rangle_q = \sum_{\gamma^q_{\text{MSR}}} |\langle n', r' | U_{\text{SR}} | n, r \rangle|^2 P_n P_r \left( \ln \left( \frac{P_n P_r}{\tilde{P}_{n'} \tilde{P}_{r'}} \right) \right)$$

$$= \sum_{n,r} P_n P_r \ln \langle \langle n, r | U_{\text{SR}} | n', r' \rangle \rangle - \sum_{n', r'} \langle \langle n', r' | \rho^S_{\text{MSR}} | n', r' \rangle \rangle \ln \left( \frac{\tilde{P}_{n'} \tilde{P}_{r'}}{P_{n'} P_{r'}} \right)$$

$$= \sum_n P_n \ln P_n + \sum_r P_r \ln P_r - \sum_{n'} \tilde{P}_{n'} \ln \tilde{P}_{n'} - \sum_{r'} \tilde{P}_{r'} \ln \tilde{P}_{r'}$$

$$= \text{Tr} (\rho^S_{\text{SM}} \ln \rho^S_{\text{SM}}) + \text{Tr} (\rho^R_{\text{SM}} \ln \rho^R_{\text{SM}}) - \text{Tr} (\rho^S_{\text{SM}} \ln \rho^R_{\text{SM}}) - \text{Tr} (\rho^R_{\text{SM}} \ln \rho^S_{\text{SM}})$$

$$= \sigma_S(t_i) - \sigma_S(t_i) + \beta \sigma_R(t_i) - \beta \sigma_R(t_i)$$

$$= \sigma_{S|M}(t_i) - \sigma_{S|M}(t_i) + \beta Q_R(t_i : t_i)$$

$$= \Sigma_{S|M}(t_i : t_i).$$

(S13)
Note that we have assumed the thermal state $\rho_R^t$, which gives $\ln \rho_R^t = -\beta H_R - \ln Z_R$.

If the two-point measurements are performed at the local basis of system, memory and environment, we can define the forward local trajectory

$$P_F[\gamma_{\text{MSR}}^c] = |\langle a', r'|U_{\text{SR}}|a, r\rangle|^2 P_{ab} P_r,$$

(S14)

with the initial probability $P_{ab} = \langle a, b|\rho_{AB}|a, b\rangle$. Here $\gamma_{\text{MSR}}^c = \{a, b, r, a', r'\}$ denotes the measurement results. In general, $P_{ab} \neq P_a P_b$ due to the classical correlation between the system and the memory. The backaction of the measurements is to wipe out the quantum correlation of the initial state. The left correlation is classical, characterized by the probability $P_{ab}$. Similar backaction of the final state measurement exists. If we only look at the trajectory of the system and the environment, then trajectory can be obtained by marginalizing the variables of the memory, which gives

$$P_F[\gamma_{\text{SR}}^c] = \sum_b P_F[\gamma_{\text{MSR}}] = |\langle a', r'|U_{\text{SR}}|a, r\rangle|^2 P_a P_r,$$

(S15)

with $\gamma_{\text{SR}}^c = \{a, r, a', r'\}$. The measurements on the system and the memory commute which guarantees the marginal rules of the trajectory.

The backward process is given by the time-reverse evolution $U_{\text{SR}}^\dagger$. The initial state of the backward process is the same reference state as the backward global trajectory. Then the backward local trajectory is

$$P_B[\gamma_{\text{MSR}}^c] = |\langle a, r|U_{\text{SR}}^\dagger|a', r'\rangle|^2 \tilde{P}_{a'b}\tilde{P}_{r'},$$

(S16)

with the probabilities $\tilde{P}_{a'b} = \langle a', b|\rho_{SR}^t|a', b\rangle$. The corresponding backward trajectory of SR can be obtained by marginalizing the variables of the memory, namely $P_B[\gamma_{\text{SR}}^c] = \sum_b P_B[\gamma_{\text{MSR}}^c]$. Also the above trajectories follow the normalization condition

$$\sum_{\gamma_{\text{MSR}}} P_F[\gamma_{\text{MSR}}] = \sum_{\gamma_{\text{MSR}}} P_B[\gamma_{\text{MSR}}] = \sum_{\gamma_{\text{SR}}} P_F[\gamma_{\text{SR}}] = \sum_{\gamma_{\text{SR}}} P_B[\gamma_{\text{SR}}] = 1.\ (S17)$$

Equipped with forward and backward local trajectories, we can prove Theorems 5 and 6.

**Proof of Theorem 5:** The stochastic conditional entropy production based on the local two-point measurement can be rewritten as

$$\bar{\sigma}_{S|M} = \Delta s_{S|M} + \beta q_{SR}\nabla$$

$$= \ln \left( \frac{P_{ab} P_r}{P_b} \right) - \ln \left( \frac{\tilde{P}_{a'b}\tilde{P}_{r'}}{P_b} \right)$$

$$= \ln \left( \frac{P_F[\gamma_{\text{MSR}}]}{P_b} \right) - \ln \left( \frac{P_B[\gamma_{\text{MSR}}]}{P_b} \right).\ (S18)$$

Similarly, we have

$$\sigma_S = \ln \left( P_F[\gamma_{\text{SR}}] \right) - \ln \left( P_B[\gamma_{\text{SR}}] \right).\ (S19)$$

Then we have the integral fluctuation relations

$$\langle e^{-\bar{\sigma}_{S|M}} \rangle_c = \sum_{\gamma_{\text{MSR}}} P_F[\gamma_{\text{MSR}}] P_B[\gamma_{\text{MSR}}] = \sum_{\gamma_{\text{MSR}}} P_B[\gamma_{\text{MSR}}] = 1;\ (S20)$$

$$\langle e^{-\bar{\sigma}} \rangle_c = \sum_{\gamma_{\text{SR}}} \sum_b P_F[\gamma_{\text{SR}}] P_B[\gamma_{\text{SR}}] = \sum_{\gamma_{\text{SR}}} P_F[\gamma_{\text{SR}}] P_B[\gamma_{\text{SR}}] = \sum_{\gamma_{\text{SR}}} P_B[\gamma_{\text{SR}}] = 1.\ (S21)$$

□
Proof of Theorem 6: The stochastic dissipative information can be rewritten as
\[ \dot{\sigma}_1 = \dot{\sigma}_{\text{SM}} - \sigma_S \]
\[ = \ln \left( \frac{P_F[\gamma_{\text{MSR}}]}{P_F[\gamma_{\text{SR}}]} \right) - \ln \left( \frac{P_B[\gamma_{\text{MSR}}]}{P_B[\gamma_{\text{SR}}]} \right). \]
Then we have
\[ \langle e^{-\dot{\sigma}_1} \rangle_c = \sum_{\gamma_{\text{MSR}}} P_F[\gamma_{\text{MSR}}] \frac{P_F[\gamma_{\text{SR}}]}{P_F[\gamma_{\text{MSR}}]} \frac{P_B[\gamma_{\text{MSR}}]}{P_B[\gamma_{\text{SR}}]} = \sum_{\gamma_{\text{SR}}} P_F[\gamma_{\text{SR}}] = 1. \]
(S23)

Similar with Eq. (S13), the average of \( \sigma_S \) gives \( \Sigma_S = \langle \sigma_S \rangle_c \). The average of \( \dot{\sigma}_{\text{SM}} \) in terms of the local trajectory gives
\[ \langle \dot{\sigma}_{\text{SM}} \rangle_c = S(\rho_{\text{SM}}^f) - S(\rho_{\text{SM}}^i) + \beta Q_R(t_i : t_f), \]
with the dephased state
\[ \tilde{\rho}_{\text{SM}}^i = \sum_{a,b} \langle a,b | \langle a,b | \rho_{\text{SM}} | a,b \rangle \rangle, \]
(S25)

similar for the final state \( \tilde{\rho}_{\text{SM}}^f \). Therefore the mismatch between \( \langle \dot{\sigma}_{\text{SM}} \rangle_c \) and \( \langle \sigma_S \rangle_c \) is only the classical correlation between the system and the memory. Specifically, we have
\[ \Sigma_i(t_i : t_f) = \langle \dot{\sigma}_i \rangle_c - \Delta J, \]
(S26)
with \( \Delta J = J(t_f) - J(t_i) \) and \( J(t_i(t_f)) = S(\rho_{\text{SM}}^{i(f)}) - S(\rho_{\text{SM}}^{i(f)}) \). The magnitude of \( J(t_i(t_f)) \) quantifies the coherence of SM at local basis \([S5]\). Note that \( \Delta J \leq 0 \) since the final state is supposed to have less quantum correlation.

The fluctuation theorem of the dissipative information is founded on the semi-classical level, i.e., the quantum correlation is excluded. As pointed out in \([S6, S7]\), the fluctuation relations about the nonclassical correlation should be described by the quasiprobability instead of the probability. The fluctuation theorem of the dissipative information given by the quasiprobability is equivalent to the strong subadditivity inequality, which is beyond the scope of our current paper.

C. EXAMPLE ON THE QUBIT MODEL

We consider the example where both the system and the memory are one qubit. The interaction between the system and the environment is described by the collisional model, where the system interacts one qubit from the environment at each step. The interaction between the qubit system and the qubit environment is described by the unitary evolution
\[ U_{SR_n} = e^{-i g (\sigma_5^x \sigma_5^y - \sigma_5^y \sigma_5^x)} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(2g) & \sin(2g) & 0 \\ 0 & -\sin(2g) & \cos(2g) & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \]
(S27)

with \( n = 1, 2, \cdots, N \) as the index of \( N \) environmental qubits. The quantum operation on the system, given by
\[ E_n(\rho_{\text{SM}}^{(n)}) = T_{R_n} \left( U_{SR_n} (\rho_{\text{SM}}^{(n)} \otimes \rho_{R_n}) U_{SR_n}^\dagger \right) \]
is a thermalization channel, also called generalized amplitude damping channel \([S8]\).

We quench the energy of state \( |1 \rangle_S \) in each step, in order to extract work from the system. Suppose that at step \( n \), the energy of state \( |1 \rangle_S \) is \( E_{\text{S}}^{(n)} \). And the quenched energy is \( E_{\text{S}}^{(n)} - \delta E \). To make sure that the system reaches the thermal equilibrium state at each step, the energy level of the environment is set to be
\[ E_{R_n} = \frac{1}{\beta} \ln \left( \frac{\cos^2(2g) e^{\beta E_{\text{S}}^{(n)}} - \sin^2(2g) e^{\beta E_{\text{S}}^{(n)} - 1}}{\cos^2(2g) e^{\beta E_{\text{S}}^{(n)} - \sin^2(2g) e^{\beta E_{\text{S}}^{(n)}} - e^{\beta E_{\text{S}}^{(n)} + \delta E}}} \right). \]
(S29)
When \( g = \pi/4 \), the operation \( U_{SR_n} \) performs the SWAP-like operation. And the environmental energy reduces to \( E_{R_n} = E_S^{(n)} - \delta E \). Note that \( U_{SR_n} \) is a strict energy conservation operation as \( \delta E \to 0 \).

At each step, the work done on the system (via the quench) equals to

\[
W_{ext}^{(n)} = -\delta E \frac{e^{-\beta(E_S^{(n)} - n\delta E)}}{1 + e^{-\beta(E_S^{(n)} - n\delta E)}}.
\]

(S30)

At the limit \( \delta E \to 0 \), the total work is

\[
W_{ext} = \lim_{\delta E \to 0} \sum_n W_{ext}^{(n)} = T \ln \left( \frac{1 + e^{-\beta E_S^i}}{1 + e^{-\beta E'}} \right),
\]

(S31)

which saturates the free energy change given by

\[
\Delta \mathcal{F}_S = \mathcal{F}_S(t_2) - \mathcal{F}_S(t_1) = T \ln \left( \frac{1 + e^{-\beta E_S^i}}{1 + e^{-\beta E'}} \right).
\]

(S32)

\section*{D. QUANTUM MAXWELL’S DEMON AS THE QUBIT SYSTEM}

We consider the example where both the demon (memory) and the system are one qubit. The demon establishes the correlation with the system via the operation \( U_{MS} \). Then the demon performs the feedback control operation to decrease the entropy of the system.

First, let us consider the unitary-type demon where all the feedback control operations are given by the two-qubit controlled gates:

\[
\Lambda^{(0)} = |0\rangle_M \langle 0| \otimes U_S^{(0)} + |1\rangle_M \langle 1| \otimes \mathbb{I}_S, \quad \Lambda^{(1)} = |0\rangle_M \langle 0| \otimes \mathbb{I}_S + |1\rangle_M \langle 1| \otimes U_S^{(1)}.
\]

(S33)

Suppose that the reduced density matrix of the system is thermal initially at \( t_1 \). After the feedback control operations, the time is at \( t_2 \). To see the optimal operation \( U_{MS}(t_1 : t_2) = \Lambda^{(1)} \circ \Lambda^{(0)} \circ U_{MS} \), we randomly choose the two-qubit gates \( U_{MS}(t_1 : t_2) \) acting on SM, where the random two-qubit gates are given by randomly choosen three non-local parameters of the two-qubit gates [S9]. Note that local unitary evolutions do not change the entropy of the system. When the temperature of the system is \( \beta = 0 \), the initial state of the system is a completely mixed state. Interaction with the memory only decreases the entropy of the system. However, only when the operation \( U_{MS}(t_1 : t_2) \) is a SWAP-like operation, the entropy of the system reduces to zero. In all other cases, there are correlations between the system and the memory after the evolution \( U_{MS}(t_1 : t_2) \). See Fig. 1 for numerical results. When the initial state of the system is not completely mixed, such as \( \beta = 2 \), interaction between the system and the memory can either increase or decrease the entropy of the system. The increased entropy of the system comes from the correlation with the memory. For \( \beta = 2 \), the optimal \( U_{MS}(t_1 : t_2) \) is also the SWAP-like operation which reduces the entropy of system to zero.

Quantum Maxwell’s demon protocol is also studied with the feedback control operation as the measurement on the memory and then the operation is performed on the system conditioned on the measurement results. But we can postpone the measurement at the end of the unitary feedback control operations. In other words, we have

\[ U^{(0)} = |0\rangle_M \langle 0| \otimes U_S^{(0)} + |1\rangle_M \langle 1| \otimes \mathbb{I}_S = U^{(k)} \]

(S34)

with \( k = 0, 1 \) as the measurement results. In order to minimize the backaction of the measurement, we assume that the measurement is performed on the eigenbasis of memory (denoted as \( |k\rangle \)). Measurements performed on the non-eigenbasis may introduce more randomness during the protocol.

The difference between the unitary feedback control operation and the feedback control operation with the measurement is the final correlation between the system and the memory either quantum or classical. Fig. 1 shows that there is remaining correlation between the demon and the memory if the demon does not perform the optimal SWAP-like operation. We can check that for the non-unitary feedback control, there may still have classical correlations left. See Fig. 2. The mutual information \( \tilde{I}_{S:D}(t_2) \) denotes that the memory is dephased, namely

\[
\tilde{I}_{S:M}(t_2) = \mathcal{S}(\rho_S^{(k)}) + \mathcal{S}(\rho_M^{(k)}) - \mathcal{S}(\tilde{\rho}_{SM}^{(k)}).
\]

(S35)
FIG. S1. The entropy change of the system in terms of the final state mutual information (between the system and the memory) and the entropy of the memory, given by the random operations performed on the system and the memory. The memory has the pure initial state. The system is initially at thermal state $\rho_S(t_1) = \exp(-\beta|1\rangle_S\langle 1|)/Z_S$. The system has the initial temperature (a) $\beta = 0$ and (b) $\beta = 2$. The top grey line is the maximum of $\Delta S_S$. The bottom grey line is the threshold that $\Delta S_S = 0$.

FIG. S2. The mutual information between the system and the memory with the random operations. The initial state of system is the thermal state with (a) $\beta = 0$ and (b) $\beta = 2$. The mutual information $\bar{I}_{S:D}(t_2)$, given by Eq. (S35), quantifies the classical correlation. The top grey line is the maximum of $\Delta S_S$. The bottom grey line is the threshold that $\Delta S_S = 0$.

with

$$\rho_{SM}^{t_2} = \sum_k |k\rangle \langle k| \rho_{SM}^{t_2} |k\rangle \langle k|.$$  

(S36)

Here $|k\rangle$ is the eigenbasis of memory. Different with the unitary feedback control operations, the non-optimal feedback control with the measurement can leave the system and the demon uncorrelated. However, it is not guaranteed.
