Living systems operate far from thermal equilibrium by converting the chemical potential of ATP into mechanical work to achieve growth, replication or locomotion. Given time series observations of intra-, inter- or multicellular processes, a key challenge is to detect non-equilibrium behavior and quantify the rate of free energy consumption. Obtaining reliable bounds on energy consumption and entropy production directly from experimental data remains difficult in practice as many degrees of freedom typically are hidden to the observer, so that the accessible coarse-grained dynamics may not obviously violate detailed balance. Here, we introduce a novel method for bounding the entropy production of physical and living systems which uses only the waiting time statistics of hidden Markov processes and hence can be directly applied to experimental data. By determining a universal limiting curve, we infer entropy production bounds from experimental data for gene regulatory networks, mammalian behavioral dynamics and numerous other biological processes. Further considering the asymptotic limit of increasingly precise biological timers, we estimate the necessary entropic cost of heartbeat regulation in humans, dogs and mice.

Living systems break time reversal symmetry \cite{1,2}. Growth \cite{3}, self-replication \cite{2} and locomotion \cite{4} are all irreversible processes, violating the principle of detailed balance, which states that every forward microstate trajectory is just as likely to occur as its time reversed counterpart \cite{1,5–7}. Irreversibility places thermodynamic constraints on sensing \cite{8,9}, reproduction \cite{2}, and signaling \cite{10}, and trade-offs arise between the rate of free energy consumption and precision, speed, or accuracy of performing some function \cite{8,11}. To accurately quantify these constraints, it is important to be able to bound the rate at which free energy is consumed, or equivalently the rate of entropy production \cite{5,12,13}. However, most experimental measurements can only observe a small number of degrees of freedom \cite{13,14}, making such inference challenging. In particular, many systems are only accessible at the coarsest possible level of two states, such as a gene switching \cite{15}, or a molecule docking and undocking to a sensor \cite{9,16}. In these cases, commonly used inference tools cannot be applied, due to the absence of observable coarse-grained currents \cite{17–20}, and as the forward and reverse trajectories need not be asymmetric \cite{21–24}, even if the underlying system operates far from equilibrium.

Here, we introduce a broadly applicable method that makes it possible to estimate the entropy production rate of a coarse-grained two-state dynamics by measuring the variance of time spent in a state. This is achieved by first finding a canonical formulation and then solving a numerical optimization problem to obtain a universal limiting curve, above which the entropy production rates of all systems with the observed waiting time statistics must lie. We illustrate that this method outperforms the thermodynamic uncertainty relation (TUR) \cite{9,17,19,25} on synthetic test data, and demonstrate its practical usefulness in applications to experimental data for a gene regulatory network \cite{15}, the behavioral dynamics of cows \cite{26}, and several other biological processes (Table S1 \cite{27}). Furthermore, by considering a stochastic timer \cite{28–31} in the limit of increasing precision, we derive an asymptotic formula relating the waiting time variance and the entropy production rate. This analytical result can be used to bound the entropy production required to maintain precise biophysical timing process, which we illustrate for data from experimental measurements \cite{32,33} of heartbeats of humans, dogs and mice.

We start from the standard assumption \cite{5} that meso-scale systems in contact with a heat bath can be described by a Markovian stochastic dynamics on a finite set of discrete states \{1, \ldots, \Ne\}. Transitions from state \(i\) to \(j\) occur at rate \(W_{ij}\), so a probability distribution over the states, \(p_i(t)\), evolves according to

\[
\frac{d}{dt} p_i = \sum_j p_j W_{ji},
\]

with \(W_{ii} = -\sum_{j\neq i} W_{ij}\) \cite{5}. Under the mild assumption that the system is irreducible, meaning there exists a path with non-zero probability between every pair of states, Eq. (1) has a unique stationary state \(\pi = (\pi_i)\), satisfying \(0 = \pi W\), and which every initial probability distribution tends to \cite{34}. Suppose we observe a single trajectory with initial condition currently in state \(i\), it will have a probability \(W_{ij} dt\) of transitioning to state \(j\) in the interval \([t, t+dt]\), and upon arriving at state \(j\), the time, \(T\), it stays there will be exponentially distributed, with \(P(t < T < t + dt) = -W_{jj} \exp(W_{jj} t) dt\). The rate of entropy production at steady state \(\pi\) is \cite{19},

\[
\sigma = k_B \sum_{i<j} (\pi_i W_{ij} - \pi_j W_{ji}) \log \left(\frac{\pi_i W_{ij}}{\pi_j W_{ji}}\right),
\]

which for isothermal systems, when multiplied by the heat bath temperature, is the rate of free energy required to maintain the state away from equilibrium. The system
is in thermal equilibrium when the entropy production rate vanishes, which is exactly when detailed balance is satisfied, \( \pi_i W_{ij} = \pi_j W_{ji} \), for all \( i, j \).

Only a coarse-grained view of the system is typically available in experimental measurements [23, 36], with the observed dynamics taking place on a set of macro-states, where a meta-state \( I \) may contain several underlying states \( i \) (Fig. 1). Here, we focus on the common case where only two complementary macro-states, \( A \) and \( B \), are accessible and the observed trajectory jumps between them (Fig. 1). After observing many such jumps, the distributions \( f_A(t) \) and \( f_B(t) \) of time spent in \( A \) and \( B \), respectively, can be empirically reconstructed (Fig. 1). As the coarse-grained observations are non-Markov [37], there may be additional information in conditional statistics [36], for instance \( \mathbb{P}(t^A \leq t \mid \text{previous } t^B) \), but these will be hard to measure experimentally and we do not consider them here. At first glance, the distributions \( f_A(t) \) and \( f_B(t) \) alone may not appear to contain much information about the underlying system; however, for an equilibrium system both \( f_A(t) \) and \( f_B(t) \) must decay monotonically [35], implying that the schematic example in Fig. 1 reflects an out-of-equilibrium dynamics.

To quantify the extent to which an observed two-state system is out-of-equilibrium, we reformulate the problem of entropy production estimation within an optimization framework, extending the approach introduced in Ref. [36]. Calling the underlying system \( S \), the rate of entropy production is \( \sigma(S) \), and the observed waiting time distributions are \( f_A(t, S) \) and \( f_B(t, S) \). If \( \mathcal{R} \) describes some other underlying system with the same observables, we cannot know which is the true system. However, we can find a lower bound on the entropy production rate by optimizing over all such \( \mathcal{R} \),

\[
\sigma(S) \geq \min_{\mathcal{R}} \{ \sigma(\mathcal{R}) \mid f_A(t, \mathcal{R}) = f_A(t, S), \\
f_B(t, \mathcal{R}) = f_B(t, S) \},
\]

which holds, since \( S \) is contained in the set on the right.

By construction, this is the best possible estimator given the observed distributions \( f_A \) and \( f_B \). Limited experimental measurements may prevent us from being able to precisely measure the full distribution, but we can typically measure the first few moments \( \langle t^n \rangle_A \) and \( \langle t^n \rangle_B \). We therefore introduce the estimators \( \sigma^{(n)}_T \),

\[
\sigma(S) \geq \min_{\mathcal{R}} \{ \sigma(\mathcal{R}) \mid \langle t^k \rangle_{I, \mathcal{R}} = \langle t^k \rangle_{I, S}, \\
\quad \text{for } I = A, B, k = 1, \ldots, n \} \equiv \sigma^{(n)}_T,
\]

where \( \sigma^{(n)}_T \leq \sigma^{(n+1)}_T \), since increasing \( n \) decreases the size of the set over which minimization is performed.

When describing a system, \( \mathcal{R} \), instead of specifying the transition rates, we can alternatively specify the net transition rates, \( n_{ij} = \pi_i W_{ij} \), for \( i \neq j \), provided they satisfy mass conservation at each vertex, \( \sum_j n_{ij} = \sum_j n_{ji} \), and independently specify the stationary state, \( \pi \). With \( n_{ij} \) fixed, modifying \( \pi \) does not affect the entropy production. In particular, suppose that we have found the optimal state, subject to the constraints, then the fraction of time spent in \( A \) is \( q_A = \sum_{i \in A} \pi_i \), and similarly \( q_B = \sum_{i \in B} \pi_i \). A simple rescaling, \( \pi_i \mapsto \pi_i/2q_A \), for \( i \in A \), \( \pi_i \mapsto \pi_i/2q_B \), for \( i \in B \), does not affect the entropy production rate, but makes the fraction of time spent in each state exactly 1/2. The statistics are rescaled as \( \langle t^k \rangle_I \mapsto (1/2q_i)^k \langle t^k \rangle_I \) for \( I = A, B \). The average time spent in \( A \) or \( B \) in the rescaled system is \( \tau = (\langle t \rangle_A + \langle t \rangle_B)/2 \). Performing a second rescaling \( n_{ij} \mapsto \tau n_{ij} \), leaving \( \pi \) fixed, changes the rate of entropy production as \( \sigma \mapsto \tau \sigma \), and the moments as \( \langle t^k \rangle_I \mapsto \langle t^k \rangle_I / \tau^k \). Performing both rescalings allows us to rewrite Eq. (4) as

\[
\sigma(S) \geq \frac{1}{\tau} \min_{\mathcal{R}} \{ \sigma(\mathcal{R}) \mid \langle t^k \rangle_{I, \mathcal{R}} = \langle t^k \rangle_{I, S} / \tau^k \},
\]

allowing us to perform the optimization over a single canonical system and rescale as needed to gain a bound for any other non-canonical system.

After the canonical rescaling, to express constraints in terms of the transition rates, we label the states so that the first \( N \) belong to the macrostate \( A \), with \( 1 \leq N < N_T \), and define \( (W_A)_{ij} = W_{ij} \) for \( i, j \leq N \), so \( W_A \) represents the transitions within \( A \). We also write \( \pi = (\pi_A, \pi_B) \), with \( \pi_A \) the first \( N \) components of the stationary distribution. For any such Markovian process in the stationary distribution, we then have that \( f_A(t) = \pi_A W_A^T \exp(W_A t) 1^T / (-\pi_A W_A 1^T) \) [27, 34], a similar result holds for \( f_B \). As we are working with the rescaled system, we know that \( \langle t \rangle_{A, \mathcal{R}} = 1 \), so \( -\pi_A W_A 1^T = 1/2 \), and higher moment constraints become

\[
\langle t^k \rangle_{A, \mathcal{R}} = 2(-1)^{k+1} k! \pi_A W_A^{1-k} 1^T,
\]

and similar for \( B \). While this provides a general minimization framework, from now on we will minimize only...
imposing the constraint on \( \langle t^2 \rangle_{A,R} \), which allows us to assume \( B \) is a single state [27], and results in a single curve. Specifically, we minimize over \( \pi_i > 0, n_{ij} \geq 0 \), subject to the linear constraints \( n_{ii} = -\sum_{j \neq i} n_{ij} \), \( \sum_{j \neq i} n_{ij} = \sum_{j \neq i} n_{ji} \), together with \( \langle t \rangle_{A,R} = \langle t \rangle_{B,R} = 1 \), and \( \langle t^2 \rangle_{A,R} \) fixed, finding a curve \( k_B \Lambda(\langle t^2 \rangle_{A,R}) \) in the \( \sigma \)-(\( \langle t^2 \rangle \)) plane, or equivalently the \( \sigma \)-\( \text{Var} \) plane, above which all Markovian systems must lie [Fig. 2(a)]. In terms of arbitrary systems, this bound becomes

\[
\sigma_T = \left( \frac{2k_B}{\langle t \rangle_A + \langle t \rangle_B} \right) \Lambda \left( \frac{\text{Var} t_A}{\langle t \rangle_A} \right),
\]

which we will use throughout to calculate the entropy production rate. The function \( \Lambda(x) \) can be computed numerically [27]; it converges rapidly as the number \( N \) of internal states of \( A \) is increased [Fig. 2(a)]. Given the tabulated values of \( \Lambda \), we can apply Eq. (7) directly to experimental data. Before doing so, it is instructive to demonstrate the performance of \( \sigma_T \) in a simulated model of an active sensor.

To perform vital functions like chemotaxis, cells sense chemical concentration levels within their environment [8] through the stochastic binding and unbinding of molecules at surface receptors [9] [Fig. 3(a)]. It has been recently found that active sensors can overcome the equilibrium Berg-Purcell sensing limit by expending energy, with a trade-off between increased sensing accuracy, and energy expended [8, 9, 38]. We apply Eq. (7) to a simple model of an active sensor [9], with the receptor system modeled as a ring with 5 states, one of which corresponds to an unbound receptor, and with 4 internal states corresponding to a bound receptor [Fig. 3(a)]. The rate of clockwise transitions is taken to be \( W_+ \), with counterclockwise transitions occurring at rate \( W_- \), resulting in an entropy production rate of \( \sigma = (W_+ - W_-) \log (W_+/W_-) \). The \( \sigma_T \) bound is reasonably close to the exact value \( \sigma \) in intermediate regimes of entropy production [Fig. 3(c)]. For small values of \( \sigma \), the observed statistics could be generated by an equilibrium process, whereas for large values the statistics could be generated at much lower cost by a system with more internal states. The only other estimator we are aware of which provides a non-trivial bound when applied to this system uses a modified version of the thermodynamic uncertainty relation (TUR) [18, 19] to relate the mean and variance of the fraction of time spent bound to the entropy production rate [9, 27]. Figure 3(c) shows that the TUR bound is substantially lower, and for a finite sample size has a much larger variance, thus requiring a large amount of data for a reliable prediction compared to \( \sigma_T \).

As the first of many experimental applications of \( \sigma_T \), we consider stochastic gene regulatory networks [39, 40]. Cells regulate the intra-cellular concentration of proteins, changing the concentration in response to external stimuli, or maintaining a constant level by balancing production and degradation [40]. Proteins are created by enzymes translating mRNA, which is in turn is transcribed by enzymes from DNA instructions or genes [41]. Genes switch between active and inactive states, the rate of
switching regulated by protein concentration, amongst other things, and whilst in the active state mRNA is transcribed [39] [Fig. 2(b)]. With a typical protein present in concentrations of less than 100 per cell, these systems are sensitive to stochastic number fluctuations [39, 41, 42], and the exact details of the complex network may not be known [41]. By examining the distribution of times which a gene spends inactive, we can deduce that the regulatory system is out-equilibrium. Recent experiments [15] were able to temporally resolve the dynamics of mammalian gene transcription, measuring the times for which genes were active or inactive. From the measured distribution of inactivity periods [Fig 2(b)] for the Glutaminase gene, one finds \( \langle t^2 \rangle_{\text{off}} / \langle t \rangle_{\text{off}}^2 = 1.6 \) and \( \tau = 0.9 \text{h} \), so that the entropy production rate is \( \sigma \geq 2.2 k_B / \text{h} \), whereas for the Bmal1 promoter, \( \langle t^2 \rangle_{\text{off}} / \langle t \rangle_{\text{off}}^2 = 1.5 \), and \( \tau = 1.1 \text{h} \), resulting in the bound \( \sigma \geq 2.4 k_B / \text{h} \).

From complex neural networks to simple feedback loops, living systems make decisions on which behavior to execute, and such decision making requires the expenditure of free energy [43]. Recent experiments identified behavioral states of a different organism [44, 45], and from dynamics on these states, it can be possible to bound the rate of entropy production [45]. By attaching sensors to cows, the authors of Ref. [26] were able to record whether the cows were standing or lying, as well as the waiting time distribution of each state [Fig. 2(c)]. The time the cows spent lying (state \( A \)) satisfies \( \langle t^2 \rangle_A / \langle t \rangle_A^2 < 2 \), meaning we can calculate a non-zero bound on the entropy production rate. Specifically, for the three experiments involving pregnant indoor-housed beef cows, out-wintered beef cows, and indoor-housed dairy cows [26], we find bounds \( \sigma_T = 4.1 k_B / \text{h}, 3.2 k_B / \text{h}, 2.4 k_B / \text{h} \), respectively. Assuming \( k_B T \approx 9 \times 10^{-22} \text{Cal/h} \), we can therefore deduce that the cows consume at least \( 2.4 \times 10^{-21} \text{Cal/h} \), in deciding whether to lie or stand. While this is a significant underestimate, the \( \sigma_T \)-estimator does not assume any specific model of the decision making process, and so does not require the cows to ‘possess spherical symmetry’ [46].

The systems considered so far could be interpreted as timers; by paying an energetic cost they control the time spent in a subset of states more precisely than an equilibrium system would allow. Previous studies of biological clocks assume measurements of time are performed by counting the number of full cycles around a circular network topology [28], although such analysis can be extended to more general biological oscillators [29, 31]. Under these assumptions, if \( X_\tau \) is the stochastic variable counting the number of full rotations in time \( \tau \), the TUR implies \( \sigma \tau \geq 2 k_B (X_\tau)^2 / \text{Var} X_\tau \), which is a tight bound [28, 29]. However, this statement cannot be straightforwardly converted into bounds on \( \text{Var} t_A \), and moreover the networks which saturate the TUR bound do not perform better than equilibrium systems at minimizing \( \text{Var} t_A \) [27]. It is, therefore, necessary to distinguish a stochastic timer, a system which controls the time spent in a subset of states considered here, from the related problem of a stochastic clock which counts the net number of cycles taken around some network [28]. In the remainder, we seek to quantify the relationship between \( \sigma \) and \( \text{Var} t_A \) in a stochastic timer: since we are not interested in the dynamics of state \( B \), we let \( \langle t \rangle_B \rightarrow 0 \), so that \( \sigma \geq (2k_B / \langle t \rangle_A) \Lambda (\text{Var} t_A / \langle t \rangle_A^2) \). In particular, we would like to estimate a bound on the entropy production rate of precise timers exhibiting small variance \( \text{Var} t_A \) such as heart beats.

Unfortunately, it is not feasible to explore the limit \( \text{Var} t_A \rightarrow 0 \) numerically, as for a fixed number, \( N \), of states in \( A \), the largest precision possible is \( \text{Var} t_A / \langle t \rangle_A^2 \geq 1 / N \), so that numerical minimization becomes prohibitively expensive for \( N \gtrsim 20 \) [27]. To gain analytical insight, we consider a continuum limit by assuming that \( A \) contains an infinite number of internal states, \( N \rightarrow \infty \), such that the dynamics in \( A \) can be represented by a Langevin equation on a periodic interval [27]. Performing a minimization [27] over the continuous parameters of the Langevin dynamics provides an upper bound on the true optimal precision vs. entropy trade-off curve, as the minimized continuous system can be approximated arbitrarily.
FIG. 4. Entropy production rate in the small variance limit. (a) Numerical simulations (green) can only feasibly be performed for small $\sigma$, although extrapolating to $N = \infty$ extends this range (purple). Alternatively, minimizing over a continuous Langevin system extends beyond the range of finite networks, and from this an asymptotic limit can be found (dashed line). Using the asymptotic relation, we can examine the entropic cost of building an oscillator as precise as a heartbeat across different species (grey dotted lines). (b) Typical ECG measurements of heartbeats for humans, dogs and mice [32, 47]. (c) Distribution of time between beats, scaled so the mean time is 1, from a single experiment from each species.

well by a discrete system [27, 36]. Moreover, in the limit of infinite precision, $\operatorname{Var} t_A / \langle t_A \rangle \to 0$, we can find analytically [27] that the Langevin system obeys the asymptotic relation, $\operatorname{Var} t_A / \langle t_A \rangle = 1 / \hat{\sigma} + 4 \ln \hat{\sigma} / \hat{\sigma}^2 + o(\ln \hat{\sigma} / \hat{\sigma}^2)$, where $\hat{\sigma} = \sigma(t) / 2kB$, although to achieve this in practice would require many internal states, a common trade-off in stochastic networks [29, 42, 48]. We can apply the asymptotic prediction to heart beat data [49] reported for different age groups in humans [33] and other species [32]. Although, in each case, the precision of the beating pattern renders numerical $\sigma_T$-estimates unfeasible, our asymptotic formula demonstrates that it is possible to construct similarly precise systems with $\sigma = 280kB/s, 480kB/s, 270kB/s, 2360kB/s$, for young humans, older humans, dogs, and mouse heartbeats respectively (Fig 4).

To conclude, in addition to the systems discussed above, non-equilibrium waiting time distributions have been measured for switching processes in cell fate decision making [50], dwell times of kinesin motors [51, 52], cluster lifetimes of RNA polymerase [53], the directional switching of the bacterial motor [35, 54], swim-turn dynamics of algae and bacteria [55, 56], direction reversal in swarming bacteria [57–59], the repolarization times of migrating cancer cells [60], visual perception switching between metastable states [61], and the duration of animal and insect flights [62, 63]. The framework introduced here makes it possible to bound the extent to which these systems are out-of-equilibrium (see Table S1) and, thereby, to quantify the trade-offs which biological systems are forced to make.

INTRODUCTION AND PRELIMINARIES

We start with Markovian dynamics on a finite set of discrete states, \((1, \ldots, N)\), where a stochastic transition between states \(i\) and \(j\) occurs at a rate \(W_{ij} \geq 0\). It follows that a probability distribution, \(p_i(t)\) evolves through the master equation

\[
\frac{d}{dt} p_i = \sum_j p_j W_{ji}, \tag{A1}
\]

with \(W_{ii} = -\sum_{j \neq i} W_{ij}\). For irreducible, recurrent systems, meaning there exists a path of non-zero probability between any two states, the system has a unique steady state, \(\pi_i\), satisfying \(\sum_i \pi_i W_{ji} = 0\) for all \(i\), and all initial conditions will tend to this state. The steady state average entropy production rate is

\[
\sigma = k_B \sum_{i,j} \pi_i W_{ij} \log \frac{W_{ij}}{W_{ji}}. \tag{A2}
\]

Entropy production can be defined along single trajectories for systems starting with arbitrary probability distributions, but here we only consider this steady state expression [A1]. It will be useful to derive an equivalent form of Eq. (A2), namely

\[
k_B \sum_{i,j} \pi_i W_{ij} \log \frac{\pi_j W_{ij}}{W_{ji}} = k_B \sum_{i,j} \pi_i W_{ij} \log \frac{W_{ij}}{W_{ji}} + k_B \sum_{i,j} \pi_i W_{ij} \log \frac{\pi_i}{\pi_j} \tag{A3}
\]

\[
= \sigma + k_B \sum_i \pi_i \left[ \sum_j W_{ij} \right] \log \pi_i - k_B \sum_j \left[ \sum_i \pi_i W_{ij} \right] \log \pi_j
\]

\[
= \sigma,
\]

since \(\sum_j W_{ij} = \sum_i \pi_i W_{ij} = 0\). We also note here that upon arrival at a state \(i\), the distribution of time spent in that state is exponentially distributed with parameter \(\lambda = -W_{ii}\).

Once the \(N(N - 1)/2\) transition rates \(W_{ij} \geq 0\), \(i \neq j\) are specified, the steady state distribution follows from the eigenvalue problem, and the entropy production rate can then be computed. It will later be useful to take an alternative formulation where we specify \(N(N - 1)/2\) rates of mass transfer, \(n_{ij} = \pi_i W_{ij}\), together with the steady state distribution \(\pi_i\), and \(N\) linear constraints \(\sum_j n_{ij} = \sum_j n_{ji}\). After choosing \(n_{ij}\) and \(\pi_i\), we easily recover the transition rates as \(W_{ij} = n_{ij}/\pi_i\), for \(i \neq j\), \(W_{ii} = -\sum_{j \neq i} W_{ij} = -\sum_j n_{ji}/\pi_i\). We see that the relation \(\sum_i \pi_i W_{ij} = 0\) is satisfied, since this then becomes equivalent to the linear constraint on \(n_{ij}\) which was imposed. From Eq. (A3), we see that now \(\sigma\) depends only on the values of \(n_{ij}\), and so \(\pi_i\) can be specified independently.

Now we consider a system with two coarse grained states \(A\) and \(B\), and suppose that the first \(L\) states belong to the coarse grained state \(A\), with \(1 \leq L < N\). We can then write \(W\) as a block matrix, such that

\[
W = \begin{pmatrix}
W_A & W_{AB} \\
W_{BA} & W_B
\end{pmatrix}, \tag{A4}
\]

where \(W_A\) is of size \(L \times L\) and represents the within \(A\) transition rates. We then have the following lemma from Ref. [A2].

Lemma 1. For any such Markovian process in the stationary distribution, the distribution of time spent in a sojourn to \(A\) is given by \(f_A(t) = \frac{1}{K} \pi_A W_A^2 \exp(W_A t) \mathbf{1}^\top\), where \(K = -\pi_A W_A \mathbf{1}^\top\) and \(\mathbf{1}\) is a vector of ones.
From this lemma, it is straightforward to derive the moment statistics of the time spent in $A$, as

$$
\langle t^k \rangle_A = \int_0^\infty t^k f_A(t) dt
$$

(A5)

$$
= \left[ \frac{1}{K} W_A^T \exp(W_A t) \right]_t^{\infty} - \int_0^\infty kt^{k-1} \frac{1}{K} W_A \exp(W_A t) \, dt
$$

$$
= (-1)^k k! \int_0^\infty \frac{1}{K} W_A^{2-k} \exp(W_A t) \, dt
$$

$$
= (-1)^{k+1} k! W_A^{1-k} 1^T / K,
$$

and similar for $B$.

**NON-MONOTONIC WAITING TIMES IMPLY OUT OF EQUILIBRIUM DYNAMICS**

We rederive an expression for the waiting time distributions for a system in equilibrium, found earlier in Ref. [A3]. We start with the expression for the waiting time distribution for state $A$, $f_A(t) = \frac{1}{K} W_A \exp(W_A t) 1^T$, which holds regardless of whether detailed balance holds. If we further assume that the system is in thermal equilibrium so detailed balance applies, $\pi_i W_{ij} = \pi_j W_{ji}$, we can define a new matrix

$$
D_{ij} = \frac{\sqrt{\pi_A W_A^{ij}}}{\sqrt{\pi_A j}} = \frac{\sqrt{\pi_A W_A^{ji}}}{\sqrt{\pi_A i}} = D_{ji},
$$

(A6)

which is symmetric by construction. Therefore, $D$ admits a spectral decomposition,

$$
D_{ij} = \sum_k \lambda_k w^k_i w^k_j,
$$

(A7)

where $\lambda_k$ are the real eigenvalues, and $w^k$ are the orthonormal eigenvectors. Since $D$ is related to $W$ through a similarity transformation, $D = \Lambda W \Lambda^{-1}$, with $\Lambda_{ij} = \delta_{ij} \sqrt{\pi_A i}$, we have that

$$
f_A(t) = \frac{1}{K} \pi_A \Lambda^{-1} D^2 \exp(Dt) \Lambda 1^T,
$$

(A8)

where $[D^2 \exp(Dt)]_{ij} = \sum_k \lambda_k^2 e^{\lambda_k t} w^k_i w^k_j$. Therefore,

$$
f_A(t) = \frac{1}{K} \sum_{i,j} \sqrt{\pi_A i} \left( \sum_k \lambda_k^2 e^{\lambda_k t} w^k_i w^k_j \right) \sqrt{\pi_A j}
$$

$$
= \frac{1}{K} \sum_k \lambda_k^2 e^{\lambda_k t} (\sqrt{\pi_A}, w^k)^2.
$$

(A9)

As this represents a waiting time probability distribution which is normalizable, $f_A \to 0$ as $t \to \infty$, and so $\lambda_i < 0$, but $\lambda_k^2 (\sqrt{\pi_A}, w^k)^2 \geq 0$, so $f_A(t)$ is the sum of decaying exponentials, each with a non-negative weight. There are several natural corollaries of this result. As noted by Ref. [A3], this implies that waiting time distributions of equilibrium systems are monotonically decaying functions, and all derivatives are monotonic as well (see Eq. (1) and (2) in Ref [A3]). Here, we also note that the requirement that $f_A = \sum_i \rho_i |\lambda_i| \exp(-|\lambda_i| t)$, for $\rho_i > 0$, $\lambda_i < 0$, $\sum_i \rho_i = 1$, implies the moments $\langle t^n \rangle_A = n! \sum_i \rho_i / |\lambda_i|^n$, and hence the Cauchy-Schwarz inequality implies that

$$
\left( \sum_i \rho_i / |\lambda_i| \right)^2 \leq \left( \sum_i \rho_i / \lambda_i^2 \right) \left( \sum_i \rho_i \right),
$$

(A10)

and so $2\langle t^2 \rangle_A \leq \langle t^2 \rangle_A$ for equilibrium systems.
NUMERICAL MINIMIZATION

As discussed in the main text, we focus on the numerical minimization problem of finding the curve

$$\Lambda(\theta) = \min_{R} \{ \sigma(R)/k_B | \theta, R = \langle t \rangle_B, R = 1, \langle t^2 \rangle_A, R = \theta \},$$

(A11)

which yields the bound

$$\sigma \geq \frac{2k_B}{\langle t \rangle_A + \langle t \rangle_B} \Lambda \left( \frac{\langle t^2 \rangle_A}{\langle t \rangle_A^2} \right),$$

(A12)

for an arbitrary system. More specifically, finding $\Lambda$ results in the following constrained minimization problem,

$$\Lambda(\theta) = \min_{n, \pi} \sum_{i<j} (n_{ij} - n_{ji}) \log \left( \frac{n_{ij}}{n_{ji}} \right),$$

(A13)

s.t. $\pi_A \mathbf{1}^\top = \pi_B \mathbf{1}^\top = -n_A \mathbf{1}^\top = 1/2$,

$$-4\pi_A n_A^{-1} \pi_A^\top = \theta,$$

$$\pi \geq 0, n_{ij} \geq 0, n_{ii} = -\sum_{j \neq i} n_{ij} = -\sum_{j \neq i} n_{ji},$$

where the minimum is taken over all possible network topologies. We consider the subproblem $\Lambda_{L,M}(\theta)$, where the minimum is taken over $L$ internal states of $A$ (we take these as $i = 1, \ldots, L$), and $M$ internal states of $B$. We make the following claim

**Lemma 2.** The minimum is achieved when only 1 internal state of $B$, ($M = 1$), is used.

To see this, start from any solution that satisfies the constraints with $M$ internal states of $B$. Then take $(\pi_{L+1}, \ldots, \pi_{L+M}) \mapsto \hat{\pi}_{L+1} = 1/2$, and for $i \leq L$, $(n_{i,L+1}, \ldots, n_{i,L+M}) \mapsto \hat{n}_{i,L+1} = \sum_j n_{i,j,L}$, similar for $\hat{n}_{L+1,i}$, and $\hat{n}_{L+1,L+1} = -\sum_{i \leq L} \hat{n}_{i,L+1}$. This new system satisfies the constraints, as the $\theta$ constraint does not depend on $n_B$. To see that the entropy production rate does not increase,

$$\sum_{i<j} (n_{ij} - n_{ji}) \log \left( \frac{n_{ij}}{n_{ji}} \right) \geq \left( \sum_{i<j \leq L} + \sum_{i \leq L, j > L} \right) (n_{ij} - n_{ji}) \log \left( \frac{n_{ij}}{n_{ji}} \right),$$

(A14)

$$\geq \sum_{i<j \leq L} (n_{ij} - n_{ji}) \log \left( \frac{n_{ij}}{n_{ji}} \right) + \sum_{i \leq L} \left( \sum_{j > L} n_{ij} - \sum_{j > L} n_{ji} \right) \log \left( \frac{\sum_{j > L} n_{ij}}{\sum_{j > L} n_{ji}} \right)$$

$$= \sum_{i<j \leq L} (\hat{n}_{ij} - \hat{n}_{ji}) \log \left( \frac{\hat{n}_{ij}}{\hat{n}_{ji}} \right) + \sum_{i \leq L} (\hat{n}_{i,L+1} - \hat{n}_{L+1,i}) \log \left( \frac{\hat{n}_{i,L+1}}{\hat{n}_{L+1,i}} \right),$$

where we have used the convexity of the function $f(x, y) = (x - y) \log (x/y)$. Therefore, the new system $\hat{n}$ produces entropy at a rate less than or equal to the original system, and so it is unnecessary to minimize over multiple internal states of $B$. Therefore, from now on, we compute numerically $\Lambda_L(\theta)$, where the minimum is taken over $L$ internal states of $A$ and a single internal state of $B$.

To perform numerical minimization, we perform a global optimization using MATLAB’s fmincon function [A4], together with a global search strategy [A5], with random initial conditions. Since the curves $\Lambda_N(\theta)$ are monotonic, finding it is equivalent to fixing $\sigma$ and minimizing $\theta$, finding instead a curve $\theta = \Gamma_N(\sigma)$. We chose to solve this problem instead, as the minimization was found to convergence more consistently, although both approaches are ultimately equivalent. We sample feasible initial conditions by first sampling a random matrix with positive entries, and successively projecting onto constraint subspaces until convergence, where projection onto the entropy constraint is done approximately with a Newton step. We also supply the minimization algorithm with the gradient and Hessian information of the function and constraints, which we briefly derive here. We take $n^A, \pi_A$ as our variables, with the remaining variables determined by the constraints, where $n^{A}_{i,j} = n_{ij} = \pi_i W_{ij}$ for $i, j \leq L$. We therefore must consider the gradient and Hessian of

$$\sigma(n^A) = \sum_{i<j} (n^A_{ij} - n^A_{ji}) \log \left( \frac{n^A_{ij}}{n^A_{ji}} \right) + \sum_{i} (c_i - d_i) \log \left( \frac{c_i}{d_i} \right),$$

(A15a)

$$f(n^A, \pi_A) = \pi_A (n^A)^{-1} \pi_A^\top,$$

(A15b)
with $c_i = -\sum_j n^A_{ij}$, and $d_i = -\sum_j n^A_{ji}$, and we have defined $f = -\theta/4$ for clarity. We first note that

$$\frac{\partial[(n^A)^{-1}]_{ij}}{\partial n^A_{pq}} = -[(n^A)^{-1}]_{ip}[(n^A)^{-1}]_{qj},$$

(A16)

and define $y = (n^A)^{-1} \pi_A$, $z = (n^A)^{-T} \pi_A$, so that the first order derivatives in $f$ are

$$\frac{\partial f}{\partial \pi_{Ai}} = \left([(n^A)^{-1}]_{ij} + [(n^A)^{-1}]_{ji}\right) \pi_j = y_i + z_i,$$

(A17a)

$$\frac{\partial f}{\partial n^A_{ij}} = -\pi_{Ai}[(n^A)^{-1}]_{jp}[(n^A)^{-1}]_{qj} \pi_{Aj} = -z_p y_q,$$

(A17b)

and second order derivatives are

$$\frac{\partial^2 f}{\partial \pi_{Ai} \partial n^A_{pq}} = \left([(n^A)^{-1}]_{ip}[(n^A)^{-1}]_{qj} + [(n^A)^{-1}]_{jp}[(n^A)^{-1}]_{qi}\right) \pi_{Aj}$$

(A18a)

$$= -[(n^A)^{-1}]_{ip} y_q - z_p [(n^A)^{-1}]_{qi},$$

$$\frac{\partial^2 f}{\partial \pi_{Ai} \partial \pi_{Aj}} = \left([(n^A)^{-1}]_{ij} + [(n^A)^{-1}]_{ji}\right)$$

(A18b)

$$\frac{\partial^2 f}{\partial n^A_{pq} \partial n^A_{rs}} = \pi_{Ai} \left([(n^A)^{-1}]_{ir}[(n^A)^{-1}]_{sp}[(n^A)^{-1}]_{qj} + [(n^A)^{-1}]_{ip}[(n^A)^{-1}]_{qj} [(n^A)^{-1}]_{sr}[(n^A)^{-1}]_{sj}\right) \pi_{Aj}$$

(A18c)

$$= z_r [(n^A)^{-1}]_{sp} y_q + z_p [(n^A)^{-1}]_{qr} y_s.$$}

Moving to $\sigma$, for the purposes of numerical stability, we replace $\log(a/b)$ with $\log((a + \epsilon)/(b + \epsilon))$, where $\epsilon$ is a small numerical parameter which ensures that the constraint and derivatives remain finite at the boundaries. We introduce the functions

$$g(a, b) = g(b, a) = (a - b) \log \left( \frac{a + \epsilon}{b + \epsilon} \right),$$

(A19)

and

$$h(a, b) = \frac{\partial g}{\partial a} = \log \left( \frac{a + \epsilon}{b + \epsilon} \right) + \frac{a - b}{a + \epsilon},$$

(A20)

so that,

$$\sigma = \sum_{i<j} g(n^A_{ij}, n^A_{ji}) + \sum_i g(c_i, d_i),$$

(A21)

where we recall that $c_i = -\sum_j n^A_{ij}$, and $d_i = -\sum_j n^A_{ji}$. To calculate the derivatives, we make use of

$$\frac{\partial c_i}{\partial n^A_{jk}} = -\delta_{ij}, \quad \frac{\partial d_i}{\partial n^A_{jk}} = -\delta_{ik},$$

(A22)

to find

$$\frac{\partial \sigma}{\partial n^A_{ij}} = h(n^A_{ij}, n^A_{ji}) - h(c_i, d_i) - h(d_j, c_j),$$

(A23)

Defining the second derivative functions

$$h_a = \frac{\partial h}{\partial a} = \frac{a + b + 2\epsilon}{(a + \epsilon)^2},$$

(A24a)

$$h_b = \frac{\partial h}{\partial b} = -\frac{a + b + 2\epsilon}{(a + \epsilon)(b + \epsilon)},$$

(A24b)

we have that

$$\frac{\partial^2 \sigma}{\partial n^A_{ij} \partial n^A_{pq}} = h_a(n^A_{ij}, n^A_{ji}) \delta_{ip} \delta_{jq} + h_b(n^A_{ij}, n^A_{ji}) \delta_{iq} \delta_{jp}$$

$$+ \delta_{ip} h_a(c_i, d_i) + \delta_{iq} h_b(c_i, d_i) \delta_{jq} h_a(d_j, c_j) + \delta_{jp} h_b(d_j, c_j),$$

(A25)
ASYMPTOTIC SOLUTION

Here, we derive analytically the small and large entropy asymptotics for a system with a fixed number of internal states of \( A \). We use the asymptotic expansion notation \( f(x) \sim a_0 f_0(x) + a_1 f_1(x) \) to mean that \( f - a_0 f_0 = o(f_0) \), and \( f - a_0 f_0 - a_1 f_1 = o(f_1) \) in the limit.

Small entropy asymptotics

Numerically we find that the small entropy asymptotic bound is achieved with \( n = 2 \). Here, we find the asymptotic form \( \theta \sim 1 - \sigma / 16 \) for \( \sigma \ll 1 \). We take

\[
\begin{bmatrix}
A_{11} & A_{12} \\
A_{21} & A_{22}
\end{bmatrix}
\]

so that we must minimize

\[
\theta = \frac{-4}{A_{11} A_{22} - A_{12} A_{21}} \pi_A^\top \begin{bmatrix}
A_{22} & -A_{12} \\
-A_{21} & A_{11}
\end{bmatrix} \pi_A,
\]

subject to

\[
\sigma = (A_{12} - A_{21}) \log \left( \frac{A_{12}}{A_{21}} \right) - (A_{12} - A_{21}) \log \left( \frac{A_{11} + A_{12}}{A_{11} + A_{21}} \right) - (A_{12} - A_{21}) \log \left( \frac{A_{22} + A_{12}}{A_{22} + A_{21}} \right)
\]

\[
-\frac{1}{2} = A_{11} + A_{12} + A_{21} + A_{22},
\]

in addition to the inequality constraints

\[
A_{11}, A_{22} \leq 0,
\]

\[
A_{12}, A_{21} \geq 0,
\]

\[
A_{11} + A_{12}, A_{11} + A_{21}, A_{22} + A_{21}, A_{22} + A_{12} \leq 0.
\]

Let

\[
A_{12} = \alpha + \beta, \quad A_{21} = \alpha - \beta,
\]

and we assume that \( \alpha = O(1) \). We have that

\[
\theta = \frac{-4}{A_{11} A_{22} - \alpha^2 + \beta^2} \pi_A^\top \begin{bmatrix}
A_{22} & -\alpha \\
-\alpha & A_{11}
\end{bmatrix} \pi_A,
\]

where, since \( \pi_{A1} + \pi_{A2} = 1/2 \), we have that

\[
\theta = \frac{-A_{22} + 4(A_{22} + \alpha) \pi_{A2} - 4(A_{11} + A_{22} + 2\alpha) \pi_{A2}^2}{A_{11} A_{22} - \alpha^2 + \beta^2},
\]

\[
= \frac{2\pi_{A2} + 4(A_{22} + \alpha) \pi_{A2} - A_{22}}{A_{11} A_{22} - \alpha^2 + \beta^2},
\]

since \( A_{11} + A_{22} + 2\alpha = -1/2 \). This minimized when \( \pi_{A2} = -(A_{22} + \alpha) \), so that

\[
\theta \sim 2 - \frac{2\beta^2}{A_{11} A_{22} - \alpha^2}.
\]

The leading order expression for the entropy production rate is,

\[
\sigma = \frac{4\beta^2}{\alpha} - \frac{4\beta^2}{A_{11} + \alpha} - \frac{4\beta^2}{A_{22} + \alpha}.
\]
FIG. A1. Small entropy asymptotics, for $\sigma \ll 1$, predicts $\theta \sim 2 - \sigma/4$ (black dotted line), for the cannonically rescaled system. This agrees well with numerical results shown in shades of red for $N = 2, 3, 4, 5$ internal states, which rapidly converge to a single curve.

Since we can interchange $A_{11}$, $A_{22}$ without changing the function or constraints, the minimum has $A_{11} = A_{22}$, so that $A_{11} = -\alpha - 1/4$, and

$$\sigma = 4\beta^2(1/\alpha + 8), \quad (A35)$$

so

$$\theta \sim 2 - \frac{8\alpha\sigma}{(1 + 8\alpha)^2}, \quad (A36)$$

which is minimized when $\alpha = 1/8$, giving

$$\theta \sim 2 - \sigma/4. \quad (A37)$$

As a consistency check, we observe

$$n_A = \begin{bmatrix} -\frac{3}{8} & \frac{1}{8} + \frac{\sqrt{3}}{4} \\ \frac{1}{8} - \frac{\sqrt{3}}{8} & -\frac{3}{8} \end{bmatrix}, \quad c = \begin{bmatrix} \frac{1}{4} - \frac{\sqrt{\delta}}{8} & \frac{1}{4} + \frac{\sqrt{\delta}}{8} \\ \frac{1}{4} + \frac{\sqrt{\delta}}{8} & \frac{1}{4} - \frac{\sqrt{\delta}}{8} \end{bmatrix}, \quad d = \begin{bmatrix} \frac{1}{4} + \frac{\sqrt{\delta}}{8} & \frac{1}{4} - \frac{\sqrt{\delta}}{8} \\ \frac{1}{4} - \frac{\sqrt{\delta}}{8} & \frac{1}{4} + \frac{\sqrt{\delta}}{8} \end{bmatrix} \quad (A38)$$

which produces entropy at a rate

$$\sigma = \frac{\sqrt{\delta}}{4} \log \left( \frac{1 + \sqrt{\delta}}{1 - \sqrt{\delta}} \right) + \frac{\sqrt{\delta}}{2} \log \left( \frac{1 + \sqrt{\delta}/2}{1 - \sqrt{\delta}/2} \right) = \delta + O(\delta^3), \quad (A38)$$

while

$$\theta = \frac{2}{1 + \delta^2/8} \sim 2 - \delta^2/4 + O(\delta^4) \quad (A39)$$

This asymptotic solution agrees well with numerics for $\sigma \ll 1$, Fig. A1.

**Large entropy asymptotics**

In the limit of infinite entropy production, we can choose a deterministic path through the internal states, but uncertainty in the waiting time distribution still occurs due to the exponentially distributed dwell times in each internal state. However, the total uncertainty for the total wait duration can be minimized by choosing a path that sequentially moves through each internal state, so that

$$n^A = \frac{1}{2} \begin{bmatrix} -1 & 1 \\ -1 & -1 \\ \vdots \\ -1 & 1 \\ -1 & -1 \end{bmatrix}, \quad (A40)$$
with \( c = (0, \ldots, 0, 1/2) \), \( d = (1/2, 0, \ldots, 0) \), and
\[
(n^A)^{-1} = -2 \begin{bmatrix}
1 & 1 & \cdots & 1 \\
1 & 1 & & \\
& \ddots & \ddots & \\
1 & 1 & & 1
\end{bmatrix},
\]
(A41)
and \( \pi_A = 1/(2n) \), so \( \theta = 1 + 1/n \). Thus with more states we can reach \( \theta = 1 \) in the \( n \to \infty \) limit, corresponding to zero variance in wait time. Taking a perturbation from this solution, we find that to leading order
\[
\delta \theta = 4 \pi_A^T (n^A)^{-1} \delta n^A + 4 \pi_A^T (n^A)^{-1} \delta \pi_A - 4 \delta \pi_A^T (n^A)^{-1} \pi_A,
\]
(A42)
since \( \pi_A = 1/(2n) \), and \( [(n^A)^{-1} + (n^A)^{-T}]_{ij} = -2 - 2 \delta_{ij} \), so the condition \( 1^T \delta \pi_A = 0 \) causes the term linear in \( \delta \pi_A \) to vanish. We can write
\[
\delta \theta = 4 \sum_{i,j} X_{ij} \delta n_{ij},
\]
(A43)
where
\[
X_{ij} = \frac{1}{n^2} i(n + 1 - j).
\]
That this linear term does not vanish is due to it being on the boundary of the feasible set. The entropy production rate to leading order is
\[
\sigma = \sum_{i=1}^{n-1} -\frac{1}{2} \log (2 \delta n_{i+1,i}) - \frac{1}{2} \log \left( -2 \sum_j \delta n_{ij} \right) - \frac{1}{2} \log \left( -2 \sum_j \delta n_{ij} \right).
\]
We solve the perturbation problem by fixing \( \delta \theta = \epsilon \), and minimize \( \sigma \), with \( \delta n_{ij} = \epsilon Y_{ij} \), so that we solve
\[
\min_Y \sigma(Y) = \frac{n+1}{2} \log(1/2\epsilon) - \frac{1}{2} \sum_{i=1}^{n-1} \log\left( Y_{i+1,i} \right) - \frac{1}{2} \log \left( -\sum_j Y_{1j} \right) - \frac{1}{2} \log \left( -\sum_j Y_{jn} \right),
\]
(A45a)
\[
s.t. 4 \sum_{i,j} X_{ij} Y_{ij} = 1,
\]
(A45b)
\[
\sum_{i,j} Y_{ij} = 0
\]
(A45c)
\[
\sum_j Y_{ij} \leq 0, \text{ for } i = 1, \ldots, n - 1
\]
(A45d)
\[
\sum_j Y_{ji} \leq 0, \text{ for } i = 2, \ldots, n
\]
(A45e)
\[
Y_{ij} \geq 0, \text{ for } i \neq j \text{ and } i \neq j - 1
\]
(A45f)
We can already predict that \( \sigma = \frac{1}{2} (n+1) \log(1/2\epsilon) + C \), where \( C = O(1) \), to find the asymptotic formula,
\[
\theta(\sigma) \sim 1 + \frac{1}{n} + \frac{1}{2} \exp \left( \frac{C - \sigma}{n + 1} \right),
\]
(A46)
in the large \( \sigma \) limit. To find \( C \), we take \( Y_{i,i} \neq 0 \), \( Y_{i+1,i} \neq 0 \), and \( Y_{ij} = 0 \) otherwise, and suppose the constraints on
FIG. A2. (a) Numerical convergence of $\Gamma_N - 1 - 1/N \to 0$ as $\sigma \to \infty$, against predicted asymptotic formula, Eq. (A51). Curves for $2 \leq N \leq 6$ are shown from bottom to top (green points) together with respective asymptotic predictions (dotted lines). As $N$ increases, larger values of $\sigma$ are required for the asymptotic regime to hold. (b) Exponential convergence of $\Gamma_N$ to our estimate of $\Gamma$, for $\sigma = 5, 10, \ldots, 35$ bottom to top. Values of $\Gamma_N$ from $N = 12, \ldots, 18$ were used to fit the estimate of $\Gamma$.

row and column sums on $Y_{ij}$ are tight. Then

$$Y = \begin{bmatrix} -b \\ a & -a \\ & a & -a \\ & & \ddots & \ddots \\ & & & -a \\ & & & & a & -c \end{bmatrix},$$

(A47)

where $a, b, c > 0$ are some variables to be minimized over. Since $b$ and $c$ can be interchanged without changing the objective or constraints, and the current linearized problem is convex, we may take $b = c$, so that $b = c = a/2$ from the constraint $\sum_{i,j} Y_{ij} = 0$. The constraint $4 \sum_{i,j} Y_{ij} X_{ij} = 1$ gives

$$1 = \frac{4}{n^2} \left[ -a \sum_{i=1}^{n-1} i(n+1-i) + a \sum_{i=1}^{n-1} (i+1)(n+1-i) \right] = \frac{2a(n^2 + n + 2)}{n^2}$$

(A48)

so that

$$a = \frac{n^2}{2(n^2 + n - 2)};$$

(A49)

and hence

$$\sigma = \frac{n + 1}{2} \log(1/2\epsilon) - \frac{n + 1}{2} \log \left( \frac{n^2}{2(n^2 + n - 2)} \right) + \log 2$$

(A50)

meaning that

$$\theta(\sigma) \sim 1 + \frac{1}{n} + \left( \frac{n^2 + n - 2}{n^2} \right)^{2/(n+1)} \exp \left( -\frac{2\sigma}{n+1} \right).$$

(A51)

This agrees well with with numerical results, Fig. A2(a), although for larger $n$, the asymptotic correction to $\theta = 1+1/n$ only holds for very large $\sigma$. This means that for larger $n$, this asymptotic formula does not provide much insight into the intermediate values of $\sigma$, and so can not replace performing a full numerical minimization within those regions.

### NUMERICAL CONVERGENCE

To determine the exact bound $\Lambda(\theta)$, we need to take the limit, $N \to \infty$ of infinitely many internal states. Of course, this is not practical numerically, so we must verify that finite $N$ values converge, and estimate their error. Recall that

"..."
we find successive values of $\theta$ for fixed $\sigma$, calling these $\Gamma_N(\sigma) = \Lambda_N^{-1}(\sigma)$. We see convergence appears exponential,

$$\Gamma_N \approx \Gamma + \Gamma_0 e^{-kN},$$

(A52)

from which we wish to estimate $\Gamma$ from finite $N$ data. To do so, we define a residual

$$R = \sum_{N=M}^{N=L} (\log[\Gamma_N - C_1] - C_2 - C_3 N)^2,$$

(A53)

where by minimizing the residual with respect to $C_1, C_2, C_3$, we find the best exponential fit, and can estimate $\Gamma \approx C_1$. Calling $y_N = \log[\Gamma_N - C_1]$, and $x_N = N$, finding the values of $C_2$, and $C_3$ that minimize the residual is straightforward linear regression,

$$C_3 = \frac{\sum_N (x_N - \bar{x})(y_N - \bar{y})}{\sum_N (x_N - \bar{x})^2},$$

$$C_2 = \bar{y} - C_3 \bar{x},$$

(A54)

The resulting residual is a non-linear function of $C_1$, and so we find the minimum numerically. This serves as an estimate for $\Gamma$, and indeed we see exponential convergence to zero of $\Gamma_N - \Gamma$, Fig. A2(b). Moreover, the discrepancy between $\Gamma_N$ and our estimate for $\Gamma$ serves as an order of magnitude estimate for the error of our $\Gamma$ estimate. This ranges from $10^{-3}$ for $\sigma = 5$, to $1.5 \times 10^{-2}$ for $\sigma = 35$, which is small compared to the other sources of error introduced here by estimates of the mean and second moment of the waiting time distribution.

**THERMODYNAMIC UNCERTAINTY RELATION**

Given two states $i$ and $j$, suppose $J_T(i, j)$ counts the number of transitions $i \rightarrow j$ in some time $T$, then we can define a coarse grained current, $J_T = \sum_{i<j} d(i, j) J_T(i, j)$ for some weights $d$, with $d(i, j) = -d(j, i)$. The thermodynamic uncertainty relation (TUR) states that $\sigma_T \geq 2k_B (J_T)^2 / \text{Var} J_T$, for any time $T$ [A1]. Whilst this has proved a valuable tool for inference [A1, A13], for our two macro-state systems, no coarse grained currents ($\langle J_T \rangle \neq 0$) can be observed. Recently however, an extension of this inequality has been derived [A7], which states that for two state systems,

$$\sigma \geq \frac{8q_A^2 q_B^2}{T \text{Var} q_A} - \frac{4}{\langle t \rangle_A + \langle t \rangle_B},$$

(A55)

where $q_A$ is the average fraction of time spent in $A$, and $\text{Var} q_A$ is the variance of the empirically observed $q_A$ for an observation of length $T$. This result does not hold for finite $T$, but holds in the limit $T \rightarrow \infty$. To compare against this result for the active sensor example, we simulated 200 long trajectories of length $T = 2000$ so the trajectory completes $O(400)$ cycles, and computed this modified TUR bound by calculating the average fraction of time spent in $A$ and $B$, as well as the variance of these across trajectories, as described in the main text.

**CONTINUOUS LANGEVIN SYSTEM**

Gaining some understanding of the behavior of the curve $\theta = \Gamma(\sigma)$ in the large $\sigma$ limit is important to understanding the precision limits of stochastic clocks and timers. When time is counted by counting the number of full rotations around some circular topology, the thermodynamic uncertainty relation (TUR) requires that $\sigma_T \geq 2k_B (X_\tau)^2 / \text{Var} X_\tau$, where $X_\tau$ is the stochastic variable counting the number of full rotations in time $\tau$. This bound can be saturated, for instance consider a periodic interval, $S^1$, where the system evolves through a Langevin equation,

$$dY_t = Fdt + \sqrt{2D}dW_t,$$

(A56)

for $F$ and $D$ constant. In this case, $Y_\tau \sim Y_0 + F \tau + \sqrt{2D}N(0, \tau)$, so in the large $\tau$ limit, the average number of rotations is $\langle X_\tau \rangle \approx F \tau$, whereas the variance of this will be $\text{Var} X_\tau \approx 2D\tau$. Then $2k_B (X_\tau)^2 / \text{Var} X_\tau \approx 2k_B (F \tau)^2 / 2D\tau = k_B F^2 \tau / D = \sigma_T$, since the entropy production rate for such a continuous system is $k_B F^2 / D$ [A8]. One can construct a discrete Markov system which approximates the continuous one arbitrarily well [A9]. However, whilst this system
may saturate the TUR bound, it will be no more precise than an equilibrium system. To see this with $A$ defined as some subset of $S^1$, note that the Langevin system at small times is dominated by diffusive behavior, with short time trajectories approximating Brownian motion. For a trajectory which starts in $A$ and ends in $B$, it will cross the boundary infinitely many times on short time scales before eventually leaving for good, meaning the waiting time statistics are dominated by this short term diffusive behavior, which could be generated by an equilibrium system.

We therefore cannot use directly the TUR bound to understand $\Gamma(\sigma)$ in the large $\sigma$ limit. Previously we have minimized over all unknown discrete network topologies with $N$ unknown states, and for large values of $\sigma$, or small values of $\sigma$, the minimum is accessible for values of $N \leq 20$. However the asymptotic regime, $\theta \to 1$ would require larger $N$ values than are numerically feasible. Instead, we formally take $N \to \infty$, and suppose that the region $A$ can be described through continuous coordinates undergoing Langevin dynamics. Conversely, it is not known if minimizing over a one-dimensional Langevin system approximates the curve $\theta = \Gamma(\sigma)$ in the $\sigma \to \infty$ limit, but we are motivated by the one-dimensional system saturating TUR in this limit. Thus, by minimizing over the Langevin system we provide an upper bound for the most optimized finite state Markov process, and in particular will show that a similar performance as the TUR saturating system holds in this limit. Formally, we take $B$ to be a single point, with $p^B = 1/2$, and $A$ to be $S^1$ with

$$p^B + \int_0^1 dx \, p(x) = 1,$$

as the total probability. Whilst in $B$, the system jumps to $x \in A$ at rate $a(x)dx$, and whilst at $x \in A$, the system jumps to $B$ at rate $b(x)$. Thus,

$$\int dx \, p(x)b(x) = \frac{1}{2} \int dx \, a(x) = \frac{1}{2}.$$

Whilst in $A$, we assume trajectories $X_t$, follow the stochastic Itô equation,

$$dX_t = Fdt + \sqrt{2D}dW_t,$$

where $W_t$ is Brownian motion, and the decision to jump to $B$ or stay in $A$ is made at the start of the time step, i.e. at $b(X_t)$, not $b(X_{t+dt})$. We assume $F$ and $D$ are constants which greatly simplifies the analysis. To calculate the entropy production rate of this system, we use that the entropy production rate is related to the relative probability of observing forward and reverse trajectories,

$$\sigma = k_B \lim_{\tau \to \infty} \frac{1}{\tau} \int_0^\tau \log \left[ \frac{\mathbb{P}(\{x\})}{\mathbb{P}(\{\bar{x}\})} \right] \mathbb{P}(\{x\})d\tau,$$

where $\mathbb{P}(\{x\})$ is the probability of seeing some trajectory $\{x\}$ in $[0,\tau]$, with $\{\bar{x}\}$ its time reversed counterpart. To evaluate this, we discretize time whilst in $A$, so $X_t$ becomes $X_0, X_1, \ldots X_t$ with a time step $\Delta t$, so $X_{i+1} = X_i + F\Delta t + \sqrt{2D}\Delta W_i$, given that no jump to $B$ occurred, with $\Delta W_i \sim \mathcal{N}(0,\Delta t)$. Then

$$\mathbb{P}(X_{i+1}|X_i) = \frac{1 - b(X_i)\Delta t}{\sqrt{2\pi\Delta t}} \exp \left[ -\frac{(X_i - F\Delta t)^2}{2D\Delta t} \right],$$

where $\Delta x_i = X_{i+1} - X_i$. We have therefore that

$$\log \frac{\mathbb{P}(X_{i+1}|X_i)}{\mathbb{P}(X_i|X_{i+1})} = \log \left[ \frac{1 - b(X_i)\Delta t}{1 - b(X_{i+1})\Delta t} \right] + \frac{1}{4\Delta t} \left[ \frac{(X_i + F\Delta t)^2}{D} - \frac{(-X_i + F\Delta t)^2}{D} \right]$$

$$= \frac{F}{D} \Delta x_i + O(\Delta t^{3/2}) = \frac{F^2}{D} \Delta t + \frac{F}{D} \sqrt{2D} \Delta W_i + O(\Delta t^{3/2})$$

in the limit $\Delta t \to 0$, and we have neglected higher order terms. In particular, for a continuous trajectory $\{x\}$ that stays entirely within $A$,

$$\log \left[ \frac{\mathbb{P}(\{x\})}{\mathbb{P}(\{\bar{x}\})} \right] = \log \left[ \frac{\mathbb{P}(x(\tau))}{\mathbb{P}(\bar{x}(0))} \right] + \frac{F^2\tau}{D} + F \sqrt{2/D} \int_0^\tau dW_t,$$

and so for a trajectory $\{x\}$ that starts in $B$, jumps to $A$ at time $t = 0$ and returns to $B$ at time $t = \tau$,

$$\log \left[ \frac{\mathbb{P}(\{x\})}{\mathbb{P}(\{\bar{x}\})} \right] = \log \left[ \frac{a(x(0))b(x(\tau))}{a(x(\tau))b(x(0))} \right] + \frac{F^2\tau}{D} + F \sqrt{2/D} \int_0^\tau dW_t.$$
Therefore, every jump from $B$ to $x \in A$ picks up an entropic contribution of $\log a(x)/b(x)$, the reverse jump picks up a contribution of $\log b(x)/a(x)$, and while in $A$ entropy increases at a rate $F^2/D$, with the contribution from the integral $\int_0^t dW_i$ being zero on average. Taking the long time limit, as the probability distribution tends to the steady state $\{p(x), p^B\}$, the average rate of entropy production becomes

$$\sigma = \frac{F^2}{2D} + \int dx \left[ p(x) b(x) \log(b(x)/a(x)) + p^B a(x) \log(a(x)/b(x)) \right]. \quad (A65)$$

In addition to the normalization conditions, the steady state probability distribution obeys the Fokker-Planck equation,

$$0 = -\partial_x (F p) + \partial^2_{x} (Dp) + p^B a - pb. \quad (A66)$$

All that remains to formalize the minimization problem, is to calculate expressions for the first and second moments for the distribution of time spent in $A$. Since the rate at which the process leaves $A$ is $b(x)$, the probability that a specific trajectory is still in $A$ at time $t$ is $\exp(-\int_0^t b(X_s)ds)$, and therefore, if $v(x,t)$ is the probability of still being in $A$ at time $t$, given that at $t = 0$, the system was in state $x \in A$, then

$$v(x,t) = \mathbb{E} \left[ e^{-\int_0^t b(X_s)ds} | X_0 = x \right]. \quad (A67)$$

The Feynman-Kac formula allows us to instead solve the following PDE to calculate $v(x,t)$,

$$\partial_t v = F \partial_x v + D \partial^2_{x} v - bv, \quad (A68)$$

$$v(x,0) = 1$$

This tells us the full wait time distribution given the initial condition by solving a PDE, to just calculate the first and second moments, we need only solve ODEs. Let $T^{(1)}(x)$ be the average wait time in $A$, given the initial condition $x$, and $T^{(2)}(x)$ be the second moment. Now

$$T^{(1)}(x) = \int_0^\infty t (-\partial_t v) dt = \int_0^\infty v dt, \quad (A69)$$

but if $\mathcal{L} = F \partial_x + D \partial^2_{x} - b$, acts only on $x$, then

$$\mathcal{L} T^{(1)}(x) = \int_0^\infty \mathcal{L} v dt = \int_0^\infty \partial_t v dt = -1. \quad (A70)$$

Similarly, as

$$T^{(2)} = \int_0^\infty t^2 (-\partial_t v) dt = 2 \int_0^\infty t v dt, \quad (A71)$$

we have that

$$\mathcal{L} T^{(2)} = 2 \int_0^\infty t \partial_t v dt = -2T^{(1)}. \quad (A72)$$

We therefore need only solve two second order differential equations to recover the waiting time moments given by

$$\langle t \rangle_A = \int T^{(1)} a dx, \quad \langle t^2 \rangle_A = \int T^{(2)} a dx. \quad (A73)$$

The full minimization problem can therefore be described as

$$\min \sigma = \sigma [a, b, F, D] \quad \text{subject to} \quad (A74a)$$

$$\langle t^2 \rangle_A = \int T^{(2)} a dx, \quad (A74b)$$

$$\mathcal{L}^2 T^{(2)} = 2, \quad (A74c)$$

$$\int adx = 1, \quad (A74d)$$

$$\int pdx = 1/2, \quad (A74e)$$

$$\mathcal{L}^* p + \frac{1}{2} a = 0, \quad (A74f)$$

where $\mathcal{L}^* f = -\partial_x (F f) + \partial^2_x (D f) - bf$, and the condition of $\langle t \rangle_A = 1$, is enforced implicitly by the constraints on $a$ and $p$. 
Numerical minimization

In order to minimize the constrained optimization problem over the infinite dimensional function space $C(S^1)$, we instead minimize over a finite dimensional Fourier basis, so that

$$a(x) = \sum_{k=-N/2}^{N/2} a_k e^{2\pi ikx}, \quad (A75)$$

and similar for $b, F, D$, where now we minimize over the $N/2 + 1$ complex coefficients, $a_0, \ldots, a_{N/2}$, with $a_{-k} = a_k^*$. Taking a Fourier-Galerkin approach to solving the differential equations, the solution $g(x)$ to $\mathcal{L}g = f$ is approximated as the $g$ for which

$$\langle \mathcal{L}g - f, e^{2\pi ik} \rangle = 0 \quad (A76)$$

for $-N/2 \leq k \leq N/2$. Specifically,

$$\mathcal{L}g - f = \sum_{k,k'} (F_{k'}(2\pi ik) + D_{k'}(2\pi ik)^2 - b_{k'})g_k e^{2\pi i(k+k')x} - \sum_k f_k e^{2\pi ik}, \quad (A77)$$

so we have that

$$\sum_{k=-N/2}^{N/2} \mathcal{L}_{rk} g_k = f_r, \quad (A78)$$

where

$$\mathcal{L}_{rk} = (2\pi ik)F_{r-k} - D_{r-k}(2\pi k)^2 - b_{r-k}, \quad (A79)$$

and terms $f_{r-k}$ for $|r-k| > N/2$ are taken as zero. Since the operator $\mathcal{L}^*$ is the adjoint of $\mathcal{L}$, solving the equation for $p$ uses the Hermitian adjoint of $\mathcal{L}_{rk}$, as

$$\sum_k (\mathcal{L}^*)_{rk} p_k = -\frac{1}{2} a_r. \quad (A80)$$

The minimization problem can now be stated as

$$\min \sigma = \sigma(a_k, b_k, F_k, D_k) \text{ subject to}$$

$$\langle t^2 \rangle_A = \sum_k T_k^{(2)} a_{-k} \quad (A81a)$$

$$T_r^{(2)} = 2 \sum_k (\mathcal{L}^{-2})_{rk} \delta_{k0} \quad (A81c)$$

$$a_0 = 1 \quad (A81d)$$

$$p_0 = \frac{1}{2} \quad (A81e)$$

$$p_r = -\frac{1}{2} \sum_k (\mathcal{L}^{-1})_{rk} a_k \quad (A81f)$$

No explicit expression for $\sigma$ in terms of the coefficients is possible due to the non-linear terms, but we can evaluate it by numerical integration, which converges exponentially fast for periodic functions. The condition $a, b, D \geq 0$ is not enforced directly, but through a series of trial points $x_i$, so $a(x_i) \geq 0$, which is a linear constraint on the coefficients $a_k$. In addition, we take only the first $M/2$ coefficients of $a, b$ to be non-zero, and for now take $F$ and $D$ to be constant. This ensures that we solve the problem accurately for given $a, b$, and regularizes the solution.
Analytic gradients

We calculate the following gradients analytically to perform the minimization,

\[
\frac{\partial \sigma}{\partial F} = F/D + \int dx \frac{\partial p}{\partial F} b \log(b/a) \tag{A82a}
\]

\[
\frac{\partial \sigma}{\partial D} = -F^2/2D^2 + \int dx \frac{\partial p}{\partial D} b \log(b/a) \tag{A82b}
\]

\[
\frac{\partial \sigma}{\partial b_0} = \int dx \left[ \frac{\partial p}{\partial b_0} b \log(b/a) + p \log(b/a) + 1 - p^B a/b \right], \tag{A82c}
\]

where \( \frac{\partial p}{\partial b_0} \) can be computed from

\[
\frac{\partial p_k}{\partial b_0} = \sum_r (L^{-1})_{kr} p_r \tag{A83}
\]

and

\[
\frac{\partial p_k}{\partial F} = \sum_j (L^{-1})_{kj} (2\pi i) p_j \tag{A84a}
\]

\[
\frac{\partial p_k}{\partial D} = \sum_j (L^{-1})_{kj} (2\pi j)^2 p_j \tag{A84b}
\]

The rest are more involved as we must differentiate with respect to both the real and imaginary parts \( a_k^r \) and \( a_k^i \) respectively. We first note that

\[
\frac{\partial a}{\partial a_k^r} = 2 \cos(2\pi k x) \tag{A85a}
\]

\[
\frac{\partial a}{\partial a_k^i} = -2 \sin(2\pi k x) \tag{A85b}
\]

\[
\frac{\partial \sigma}{\partial a_k^r} = \int dx \left[ \frac{\partial p}{\partial a_k^r} b \log(b/a) - \frac{p b \cos(2\pi k x)}{a} + 2p^B \cos(2\pi k x)(\log(a/b) + 1) \right] \tag{A85c}
\]

\[
\frac{\partial \sigma}{\partial a_k^i} = \int dx \left[ \frac{\partial p}{\partial a_k^i} b \log(b/a) + \frac{p b \sin(2\pi k x)}{a} - 2p^B \sin(2\pi k x)(\log(a/b) + 1) \right], \tag{A85d}
\]

where

\[
\frac{\partial p_k}{\partial a_j^r} = -\frac{1}{2} [(L^{-1})_{kj} + (L^{-1})_{k,-j}], \tag{A86a}
\]

\[
\frac{\partial p_k}{\partial a_j^i} = -\frac{i}{2} [(L^{-1})_{kj} - (L^{-1})_{k,-j}], \tag{A86b}
\]

Next,

\[
\frac{\partial \sigma}{\partial b_k^r} = \int dx \left[ \frac{\partial p}{\partial b_k^r} b \log(b/a) + 2p \cos(2\pi k x)(\log(b/a) + 1) - 2p^B a \cos(2\pi k x)/b \right] \tag{A87a}
\]

\[
\frac{\partial \sigma}{\partial b_k^i} = \int dx \left[ \frac{\partial p}{\partial b_k^i} b \log(b/a) - 2p \sin(2\pi k x)(\log(b/a) + 1) + 2p^B a \sin(2\pi k x)/b \right], \tag{A87b}
\]

where

\[
\frac{\partial p_k}{\partial b_j^r} = \sum_l (L^{-1})_{kl} (p_l - p_j + i), \tag{A88a}
\]

\[
\frac{\partial p_k}{\partial b_j^i} = i \sum_l (L^{-1})_{kl} (p_l - p_j - i). \tag{A88b}
\]
Now, defining

\[ P_l = \int dx e^{2\pi i x b \log(b/a)}, \quad (A89a) \]
\[ Q_l = \int dx e^{2\pi i x [-2pb/a + 2p^B \log(a/b) + 1]}, \quad (A89b) \]
\[ R_l = \int dx e^{2\pi i x [2p(\log(b/a) + 1) - 2p^B a/b]}, \quad (A89c) \]

we can write the derivatives as

\[ \frac{\partial \sigma}{\partial F} = F/D + \sum_l P_l \frac{\partial p_l}{\partial F} \quad (A90a) \]
\[ \frac{\partial \sigma}{\partial D} = -F^2/2D^2 + \sum_l P_l \frac{\partial p_l}{\partial D} \quad (A90b) \]
\[ \frac{\partial \sigma}{\partial a_k} = \sum_l P_l \frac{\partial p_l}{\partial a_k} + \text{Re}(Q_k) \quad (A90c) \]
\[ \frac{\partial \sigma}{\partial a_k^*} = \sum_l P_l \frac{\partial p_l}{\partial a_k^*} - \text{Im}(Q_k) \quad (A90d) \]
\[ \frac{\partial \sigma}{\partial b_0} = \sum_l P_l \frac{\partial p_l}{\partial b_0} + \frac{1}{2} R_0 \quad (A90e) \]
\[ \frac{\partial \sigma}{\partial b_k} = \sum_l P_l \frac{\partial p_l}{\partial b_k} + \text{Re}(R_k) \quad (A90f) \]
\[ \frac{\partial \sigma}{\partial b_k^*} = \sum_l P_l \frac{\partial p_l}{\partial b_k^*} - \text{Im}(R_k). \quad (A90g) \]

The only integrals now occur within the terms \( P_l, Q_l, R_l \), and can be evaluated by using a fast fourier transform. If we further identify \( w_j = \sum_l \mathcal{L}_j^{-1} P_l \), then

\[ \frac{\partial \sigma}{\partial F} = F/D + i \sum_j 2\pi j w_j \quad (A91a) \]
\[ \frac{\partial \sigma}{\partial D} = -F^2/2D^2 + \sum_j (2\pi j)^2 w_j \quad (A91b) \]
\[ \frac{\partial \sigma}{\partial a_k} = -\frac{1}{2} (w_k + w_{-k}) + \text{Re}(Q_k) \quad (A91c) \]
\[ \frac{\partial \sigma}{\partial a_k^*} = -i \frac{1}{2} (w_k - w_{-k}) - \text{Im}(Q_k) \quad (A91d) \]
\[ \frac{\partial \sigma}{\partial b_0} = \sum_l w_l p_l + \frac{1}{2} R_0 \quad (A91e) \]
\[ \frac{\partial \sigma}{\partial b_k} = \sum_l w_l (p_{l-k} + p_{l+k}) + \text{Re}(R_k) \quad (A91f) \]
\[ \frac{\partial \sigma}{\partial b_k^*} = i \sum_l w_l (p_{l-k} - p_{l+k}) - \text{Im}(R_k). \quad (A91g) \]

We must also differentiate the constraints, the first of which can be expressed as \( c_1 = \sum_k T_k^{(2)} a_{-k} - \langle t^2 \rangle_A \), so that
\( c_1 = 0 \). We have immediately that

\[
\frac{\partial c_1}{\partial F} = \sum_l a_{-l} \frac{\partial T_l^{(2)}}{\partial F} \quad \text{(A92a)}
\]

\[
\frac{\partial c_1}{\partial D} = \sum_l a_{-l} \frac{\partial T_l^{(2)}}{\partial D} \quad \text{(A92b)}
\]

\[
\frac{\partial c_1}{\partial a_k^r} = T_k^{(2)} + T_{-k}^{(2)} \quad \text{(A92c)}
\]

\[
\frac{\partial c_1}{\partial a_k^i} = -iT_k^{(2)} + iT_{-k}^{(2)} \quad \text{(A92d)}
\]

\[
\frac{\partial c_1}{\partial b_0^r} = \sum_l a_{-l} \frac{\partial T_l^{(2)}}{\partial b_0} \quad \text{(A92e)}
\]

\[
\frac{\partial c_1}{\partial b_k^i} = \sum_l a_{-l} \frac{\partial T_l^{(2)}}{\partial b_k^i} \quad \text{(A92f)}
\]

\[
\frac{\partial c_1}{\partial b_k^s} = \sum_l a_{-l} \frac{\partial T_l^{(2)}}{\partial b_k^s} \quad \text{(A92g)}
\]

and

\[
\sum_{k,l} \mathcal{L}_{jk} \mathcal{L}_{kl} \frac{\partial T_l^{(2)}}{\partial F} = \frac{-i}{2} \sum_l \left[ (2\pi j) \mathcal{L}_{jl} T_l^{(2)} + \mathcal{L}_{jl}(2\pi l) T_l^{(2)} \right] \quad \text{(A93a)}
\]

\[
\sum_{k,l} \mathcal{L}_{jk} \mathcal{L}_{kl} \frac{\partial T_l^{(2)}}{\partial D} = \sum_l \left[ (2\pi j)^2 \mathcal{L}_{jl} T_l^{(2)} + \mathcal{L}_{jl}(2\pi l)^2 T_l^{(2)} \right] \quad \text{(A93b)}
\]

\[
\sum_{k,l} \mathcal{L}_{jk} \mathcal{L}_{kl} \frac{\partial T_l^{(2)}}{\partial b_0^i} = \sum_l \left[ \mathcal{L}_{j-s,l} + \mathcal{L}_{j+s,l} + \mathcal{L}_{j,l+s} + \mathcal{L}_{j,l-s} \right] T_l^{(2)} \quad \text{(A93c)}
\]

\[
\sum_{k,l} \mathcal{L}_{jk} \mathcal{L}_{kl} \frac{\partial T_l^{(2)}}{\partial b_k^i} = i \sum_l \left[ \mathcal{L}_{j-s,l} - \mathcal{L}_{j+s,l} + \mathcal{L}_{j,l+s} - \mathcal{L}_{j,l-s} \right] T_l^{(2)} \quad \text{(A93d)}
\]

The common form is \( \frac{\partial c}{\partial y} = \sum_I a_{-I} f_I \), where \( f \) is some vector solving \( \mathcal{L}^2 f = g \). There are many such \( y \) however, and we wish to solve as few linear equations as possible. However, we can rewrite as \( \frac{\partial c}{\partial y} = \sum_{k,l} \left[ (\mathcal{L}^2)^{-1} a_l \right]^* g_k = \sum_k v_k^* g_k \), where \( v_k = (\mathcal{L}^2)^{-1} a_l \). We therefore have that

\[
\frac{\partial c_1}{\partial F} = -i \sum_{l,j} v_j^* \left[ (2\pi j) \mathcal{L}_{jl} T_l^{(2)} + \mathcal{L}_{jl}(2\pi l) T_l^{(2)} \right] \quad \text{(A94a)}
\]

\[
\frac{\partial c_1}{\partial D} = \sum_{l,j} v_j^* \left[ (2\pi j)^2 \mathcal{L}_{jl} T_l^{(2)} + \mathcal{L}_{jl}(2\pi l)^2 T_l^{(2)} \right] \quad \text{(A94b)}
\]

\[
\frac{\partial c_1}{\partial b_0^i} = \sum_{l,j} v_j^* \left[ \mathcal{L}_{j-s,l} + \mathcal{L}_{j+s,l} + \mathcal{L}_{j,l+s} + \mathcal{L}_{j,l-s} \right] T_l^{(2)} \quad \text{(A94c)}
\]

\[
\frac{\partial c_1}{\partial b_k^i} = i \sum_{l,j} v_j^* \left[ \mathcal{L}_{j-s,l} - \mathcal{L}_{j+s,l} + \mathcal{L}_{j,l+s} - \mathcal{L}_{j,l-s} \right] T_l^{(2)} \quad \text{(A94d)}
\]
We can simplify further by defining \( u_j = \sum_i L_{ji} T_i^{(2)} \), and recall that \(-2p_j = \sum_i L_{ji}^{-1} a_i\), so that 
\[
\frac{\partial c_i}{\partial F} = -2\pi^2 \sum_j j[v^*_j u_j - 2p^*_j T_j^{(2)}] 
\] (A95a)
\[
\frac{\partial c_i}{\partial D} = (2\pi)^2 \sum_j j^2[v^*_j u_j - 2p^*_j T_j^{(2)}] 
\] (A95b)
\[
\frac{\partial c_i}{\partial b^*_k} = \sum_j v^*_j(u_{j-s} + u_{j+s}) - 2(p^*_{l+s} + p^*_{l-s})T_l^{(2)} 
\] (A95c)
\[
\frac{\partial c_i}{\partial b^*_k} = \sum_{i,j} v^*_j(u_{j-s} - u_{j+s}) - 2(p^*_{l+s} - p^*_{l-s})T_l^{(2)} 
\] (A95d)

Asymptotic limit

Using the continuous Langevin equations, we can reach larger values of \( \sigma \) in our numerical minimization than we could by working with the finite state Markov system. However, we still seek an asymptotic formula that will allow us to extend to arbitrarily large values of \( \sigma \) beyond what is numerically possible.

In the formal limit of infinite precision, a system would have \( D = 0, F > 0 \), together with \( a \) and \( b \) as \( \delta \)-functions, so that a trajectory would enter \( A \) at a point specified by \( a \), travel deterministically with velocity \( F \), before leaving at the point specified by \( b \) after spending exactly \( t = 1 \) in \( A \). Based on intuition from this infinite precision system, we will derive an asymptotic limit as \( \text{Var}_t A \to 0 \). Specifically, for analytic tractability we take \( a(x) = a_0\delta(x_0) + a_1\delta(x_1) \), \( b(x) = b_0\delta(x_0) + b_1\delta(x_1) \), allowing us to minimize over a system specified by a finite number of variables rather than arbitrary functions \( a(x), b(x) \). Whilst we expect, and observe numerically, the functions \( a(x) \) and \( b(x) \) to be sharply peaked in the limit, initially assuming \( \delta \)-functions rather than finite width Gaussians or arbitrary peaked functions may affect terms in the asymptotic expansion. However, after we perform this minimization, we find \( a \) and \( b \) do not show up at leading order, and hence we expect that the effect of changing from a \( \delta \)-function to a sharply peaked Gaussian will show up at terms smaller than the largest terms involving \( a \) and \( b \), which is higher than the leading two term asymptotic expansion derived here.

The problem is then as follows,
\[
\min \sigma[D, F, a_0, a_1, b_0, b_1] = \frac{F^2}{2D} + \sum_{i=1,2} p(x_i)b_i \log(b_i/a_i) + \frac{1}{2}a_i \log(a_i/b_i) \quad \text{subject to,} 
\] (A96a)
\[
\langle t^2 \rangle_A = a_0T^{(2)}(x_0) + a_1T^{(2)}(x_1) 
\] (A96b)
\[
L^2 T^{(2)} = 2 
\] (A96c)
\[
a_0 + a_1 = 1 
\] (A96d)
\[
\int p \, dx = 1 
\] (A96e)
\[
L^*p + \frac{1}{2}a = 0, 
\] (A96f)

where the presence of \( \delta \)-functions leads to jump conditions for the differential equations. For instance the equation for \( p \) becomes \( D\partial_x^2 p - F\partial_x p = 0 \), away from \( x_i \), where \( p \) is everywhere continuous with discontinuous first derivative satisfying the jump conditions \( D[\partial_x p]_{x_i}^+ - b_i p(x_i) + \frac{1}{2}a_i = 0 \) for \( i = 1, 2 \). Solving these equations to find \( p \) is possible analytically, and moreover it is possible to eliminate \( a_0, a_1 \) from the equations, but the resulting expressions are complex. We therefore provide a Mathematica notebook\(^1\), which contains explicit expressions for \( p, a_0, a_1 \), and hence \( \sigma \) and \( \langle t^2 \rangle_A \) in terms of the variables \( b_i, F, D, x_i \). Taking the limit \( D \to 0 \), and exploring how the remaining parameters scale, we find the asymptotic relation
\[
\langle t^2 \rangle_A \sim 1 + \frac{1}{\sigma} + \frac{4\log \sigma}{\sigma^2}, 
\] (A97)

FIG. A3. Comparison of asymptotic bounds and numerical minimization for the continuous Langevin system. The one term, \( \text{Var}_A \sim 1/\sigma \) (grey), and two term \( \text{Var}_A \sim 1/\sigma + 4\log\sigma/\sigma^2 \) (black), asymptotic results are shown. Minimizing over the full Langevin system (purple), with \( a, b \) arbitrary functions, shows the two term asymptotic result is achievable, although computational constraints prevent extending this curve for larger \( \sigma \). Performing a numerical minimization with \( a, b \) as \( \delta \)-functions, as was assumed to derive the asymptotics, also agrees with the asymptotics in the limit, but takes longer to converge (green).

provides the most precision for a given \( \sigma \) in the \( \sigma \rightarrow \infty \) limit. We see that the numerical minimization agrees well with this asymptotic formula for values of \( \sigma \) as low as 20, Fig. A3. We can interpret the resulting system as essentially the continuous Langevin system which saturates the TUR bound, but with an additional cost of having to determine exactly when one rotation has occurred and subsequently changing to state \( B \) [A10, A30]. However, this additional cost is of order \( O(\log\sigma/\sigma^2) \), and so is not leading order in the \( \sigma \rightarrow \infty \) limit.

**FURTHER EXAMPLES FROM THE LITERATURE**

In addition to the examples investigated in the main text, there are a large number of examples in the literature which measure non-equilibrium waiting time distributions from which we can bound the entropy production rate. We include a number of examples in Table I, where we have computed \( \sigma_T \) directly from experimental waiting time distribution histograms. Where both states of the two state system have non-equilibrium waiting time distributions we selected \( A \) as the one to give the largest \( \sigma_T \) bound, and where \( \langle t \rangle_B \) is not explicitly given we use an order of magnitude estimate.
