ABSTRACT

We present a new algorithm for efficiently computing the $N$-point correlation functions (NPCFs) of a 3D density field for arbitrary $N$. This can be applied both to a discrete galaxy survey and a continuous field. By expanding the statistics in a separable basis of isotropic functions built from spherical harmonics, the NPCFs can be estimated by counting pairs of particles in space, leading to an algorithm with complexity $O(N_g^2)$ for $N_g$ particles, or $O(N_{FFT} \log N_{FFT})$ when using a Fast Fourier Transform with $N_{FFT}$ grid-points. In practice, the rate-limiting step for $N > 3$ will often be the summation of the histogrammed spherical harmonic coefficients, particularly if the number of bins is large. In this case, the algorithm scales linearly with $N_g$. The approach is implemented in the ENCORE code, which can compute the 3PCF, 4PCF, 5PCF, and 6PCF of a BOSS-like galaxy survey in ~ 100 CPU-hours, including the corrections necessary for non-uniform survey geometries. We discuss the implementation in depth, along with its GPU acceleration, and provide practical demonstration on realistic galaxy catalogs. Our approach can be straightforwardly applied to current and future datasets to unlock the potential of constraining cosmology from the higher-point functions.

Key words: methods: statistical, numerical – Cosmology: large-scale structure of Universe, theory – galaxies: statistics

1 INTRODUCTION

Amongst the most powerful tools in the survey analyst’s workshop are the $N$-point correlation functions (NPCFs), or their Fourier-space counterparts, the polyspectra. These encode the statistical properties of the galaxy overdensity field at sets of $N$ positions, and may be compared to data to give constraints on properties such as the Universe’s expansion rate and composition. Most inflationary theories predict density fluctuations in the early Universe to follow Gaussian statistics; in this case all the information is contained within the two-point correlation function (2PCF), or, equivalently, the power spectrum. For a homogeneous and isotropic Universe, both are simple functions of space positions, and may be expanded in isotropic basis of spherical harmonics, the NPCFs can be estimated by counting pairs of particles in space, leading to an algorithm with complexity $O(N_g^2)$ for $N_g$ particles, or $O(N_{FFT} \log N_{FFT})$ when using a Fast Fourier Transform with $N_{FFT}$ grid-points. In practice, the rate-limiting step for $N > 3$ will often be the summation of the histogrammed spherical harmonic coefficients, particularly if the number of bins is large. In this case, the algorithm scales linearly with $N_g$. The approach is implemented in the ENCORE code, which can compute the 3PCF, 4PCF, 5PCF, and 6PCF of a BOSS-like galaxy survey in ~ 100 CPU-hours, including the corrections necessary for non-uniform survey geometries. We discuss the implementation in depth, along with its GPU acceleration, and provide practical demonstration on realistic galaxy catalogs. Our approach can be straightforwardly applied to current and future datasets to unlock the potential of constraining cosmology from the higher-point functions.

Key words: methods: statistical, numerical – Cosmology: large-scale structure of Universe, theory – galaxies: statistics
The above discussion suggests that large-scale structure analyses should certainly be including statistics beyond the 2PCF. This is far from trivial however, since the higher-order NPCFs (or polyspectra) are (a) expensive to estimate, (b) difficult to model and (c) of high dimension. Naïve NPCF estimation requires counting all \( N \)-tuplets of galaxies (and random particles) and assigning them to bins; whilst possible for \( N = 2 \), this is prohibitively slow for the higher-point statistics, and scales as \( N_g^N \) for \( N_g \) particles. For the simplest beyond-Gaussian statistic, the isotropic 3PCF, a number of algorithms of varying efficiency have been proposed to circumvent this problem, using techniques such as \( kd \)-trees, Fourier Transforms, and basis decompositions (e.g., Szapudi & Szalay 1998; Moore et al. 2001; Gray et al. 2004; Szapudi 2004; Zhang & Pen 2005; Slepian & Eisenstein 2015; March et al. 2012; Slepian & Eisenstein 2016; Friesen et al. 2017; Portillo et al. 2018; Philcox & Eisenstein 2020; Philcox 2021 as well as Sabiu et al. 2019; Tomlinson et al. 2019 for the (possibly compressed) 4PCF.)

In terms of theory models, whilst a number exist for the galaxy 3PCF and bispectrum (e.g., Scoccimarro 2000; Takada & Jain 2003; Wang et al. 2004; Gaztañaga & Scoccimarro 2005; Marín et al. 2008; Slepian & Eisenstein 2017; Simonović et al. 2018; Umeh 2020), many of which are semi-analytic, much work remains to be done. For the matter field, perturbative approaches have been computed up to one-loop order (Baldauf et al. 2015; Angulo et al. 2015; Bertolini et al. 2016), but this has not yet been extended to galaxy surveys, hampered by the necessity to include a full set of quartic (quintic) galaxy bias parameters for the 3PCF (4PCF) model.

Finally, even when the statistics are measured and modeled, extracting information from them is non-trivial due to their high dimension. Accurate analyses are likely to require data compression techniques (e.g., Scoccimarro 2000; Heavens et al. 2000; Munshi et al. 2011; Burkhart & Lazarian 2016; Joachimi 2017; Alsing & Wandelt 2018; Gualdi et al. 2018; Gualdi et al. 2019; Philcox et al. 2021) as well as analytic covariance matrices (e.g., Slepian & Eisenstein 2015, 2018; Philcox & Eisenstein 2019; Sugiyama et al. 2020; Umeh 2020 for the 3PCF). To date, the isotropic 3PCF or bispectrum has been included in a number of analyses (Jing & Börner 1998; Scoccimarro et al. 2001; Jing & Börner 2004; Kayo et al. 2004; Nichol et al. 2006; Marín 2011; Gil-Marín et al. 2015, 2017; Slepian et al. 2017b, 2018; Pearson & Samushia 2018), but few use any higher-order statistics (though see Sabiu et al. 2019, Peebles 1978 and the review of Peebles 2001 for some notable exceptions, as well as Münchmeyer & Smith (2019) for the CMB).

The present work tackles the following problem: how can we efficiently measure the isotropic NPCFs for \( N > 3 \)? To do this, our starting point is the isotropic 3PCF algorithm of Slepian & Eisenstein (2015). By expanding the correlator's angular dependence into a Legendre polynomial basis and further factorizing these into spherical harmonics, the former work was able to estimate the 3PCF of \( N_g \) particles in \( O(N_g^2) \) time; much faster than a naïve triple count, which scales as \( O(N_g^3) \). This has facilitated a number of analyses, including detection of the 3PCF baryon acoustic oscillation (BAO) feature and a constraint on the baryon-dark matter relative velocity (Slepian et al. 2017a,b, 2018). Here, we consider whether such an approach is possible for higher-point functions. A crucial component is the choice of basis; for this we will use the separable isotropic \((N - 1)\)-point basis functions introduced in Cahn & Slepian (2020), which are a generalization of the polypolar spherical harmonics of zero total angular momentum (Varshalovich et al. 1988). Indeed, the principal conclusion of this work is that an \( O(N_g^2) \) NPCF estimator is possible for all \( N \); furthermore, its practical implementation scales linearly with \( N_g \) if \( N \) is large. In fact, such an estimator can be constructed in arbitrary dimensions, as long as the underlying space is homogeneous and isotropic; generalization to such cases is discussed in our companion work Philcox & Slepian (prep). Below, we will present a detection of the galaxy 4PCF and 5PCF by applying our algorithm, implemented in the Encore code, to mock catalogs. It is important to note that, for \( N > 3 \), only part of the information in the NPCF is independent from that in lower-point functions; there is also a ‘disconnected’ term that does not add further information.

A key assumption underlying the above discussion is that of isotropy. Arising from the projection of galaxies’ peculiar motions onto our line of sight, redshift-space distortions (RSD; Kaiser 1987; Hamilton 1998; Zaroubi & Hoffman 1996) break this ideal, introducing additional dependence on the line-of-sight angle. However, this effect also adds cosmological information in the form of the growth-rate \( f(z) \) and allows us to break degeneracies, for example those between linear galaxy bias and the primordial amplitude \( A_s \) in the 2PCF (e.g., Weinberg et al. 2013). Inclusion of such effects has become commonplace in any 2PCF analysis, but has been limited for higher-point functions, though Gualdi & Verde (2020); Sugiyama et al. (2021) show anisotropy to contain useful information. In general, whilst there are a handful of estimators dedicated to the measurement of the anisotropic 3PCF or bispectrum (e.g., Gardner et al. 2007; Scoccimarro 2015; Slepian & Eisenstein 2018; Sugiyama et al. 2019; García & Slepian 2020), they have been scarcely used. Whilst we consider only the isotropic NPCFs in this work, it is expected that the methodology can be extended further, utilizing basis functions with a non-zero total angular momentum; this is discussed in Philcox & Slepian (prep).

The remainder of this paper is structured as follows. We begin in §2 by introducing the basis functions underlying our algorithm (following Cahn & Slepian 2020), before presenting the NPCF estimators in §3, including discussion of the split into ‘connected’ and ‘disconnected’ components (§3.1), and the necessary corrections for non-uniform survey geometry (§3.3). §4 contains a detailed discussion of the Encore code, including its CPU and GPU implementations, before we present results in §5, both concerning the algorithm scalings and application to mock data. We conclude with a summary in §6, before presenting several useful mathematical results in Appendices A & B.

### 2 BASIS FUNCTIONS

To begin, we present the isotropic basis functions underlying our NPCF estimators and outline some of their key properties. Full details of these functions are presented in Cahn & Slepian (2020). Generalization anisotropic functions, as well as homogeneous and isotropic spaces of arbitrary dimension is presented in Philcox & Slepian (prep).
2.1 Definition

Consider a function, \( f \), depending on \((N-1)\) spatial coordinates in 3D Euclidean space, \( r_1, \ldots, r_{N-1} \). If the function is invariant under simultaneous rotations of all \((N-1)\) coordinates, i.e., \( f(R r_1, \ldots, R r_{N-1}) = f(r_1, \ldots, r_{N-1}) \) for any rotation matrix \( R \), \( f \) can be expanded in a basis of isotropic functions as

\[
f(r_1, \ldots, r_{N-1}) = \sum_{\Lambda} f_{\Lambda}(r_1, \ldots, r_{N-1}) \mathcal{P}_{\Lambda}((\hat{r}_1, \ldots, \hat{r}_{N-1}), \Lambda),
\]

where the set \( \Lambda \) indexes the basis function in question; the precise form of this will be given below. To fulfill the requirements of isotropy, the functions must satisfy

\[
\mathcal{P}_{\Lambda}(R \hat{r}) = \mathcal{P}_{\Lambda}(\hat{r})
\]

for all rotations \( R \), introducing the nomenclature \( \mathbf{R} = \{r_1, \ldots, r_{N-1}\}, \mathbf{R} = \{\hat{r}_1, \ldots, \hat{r}_{N-1}\} \).

We now consider the functional form of such a basis, following Cahn & Slepian (2020) and Philcox & Slepian (prep). Firstly, we note that any scalar function of \((N-1)\) variables in 3D Euclidean space can be expanded in terms of \((N-1)\) spherical harmonics, regardless of isotropy:

\[
g(r_1, \ldots, r_{N-1}) = \sum_{\ell_1,\ldots,\ell_{N-1},m_1\ldots m_{N-1}} g_{\ell_1,\ldots,\ell_{N-1}}^{m_1\ldots m_{N-1}} (r_1, \ldots, r_{N-1}) Y_{\ell_1,\ldots,\ell_{N-1}}(\hat{r}_1, \ldots, Y_{\ell_{N-1},m_{N-1}}(\hat{r}_{N-1}), \Lambda
\]

where \( Y_{\ell_1,\ldots,\ell_{N-1}}(\hat{r}) \) is a spherical harmonic (in the Condon-Shortley phase convention), \( \ell \) and \( m \) are the orbital and magnetic angular momentum quantum numbers, and we sum over all \( \ell_i \geq 0 \) and \( |m_i| \leq \ell_i \). If we further assume \( g \) to be isotropic, relation (2) places constraints on the allowed values of \( m_i \); in particular, this enforces \( m_1 + \ldots + m_{N-1} = 0 \). To obtain an isotropic basis from (3), we must consider the possible ways in which to combine products of \((N-1)\) spherical harmonics to obtain a rotationally invariant state. As shown in Cahn & Slepian (2020), such an approach leads to the set of basis functions

\[
\mathcal{P}_{\Lambda}(\hat{r}) = \sum_{m_1,\ldots,m_{N-1}} C^\Lambda_{M} Y_{\ell m_1}(\hat{r}_1) \cdots Y_{\ell_{N-1},m_{N-1}}(\hat{r}_{N-1}),
\]

where \( C^\Lambda_{M} \) is a set of coupling coefficients (which enforce \( m_1 + \ldots + m_{N-1} = 0 \)) and \( M \equiv \{m_1 \ldots m_{N-1}\} \). The coupling coefficients can be written either in terms of Clebsch-Gordan coefficients or Wigner 3-\( j \) symbols (e.g., NIST DLMF, §34.2); in the latter case, we obtain

\[
C^\Lambda_{M} \equiv C_{m_1 m_2 \ldots m_{N-1}}^{(\ell_1 \ell_2 \ldots \ell_{N-1})} = E(\Lambda) \sqrt{2\ell_1 + 1} \times \cdots \times \sqrt{2\ell_{N-2} + 1} \times \sum_{m_{12} \ldots} (-1)^k \left( \begin{array}{ccc} \ell_1 & \ell_2 & \ell_{12} \\ m_1 & m_2 & -m_{12} \end{array} \right) \left( \begin{array}{ccc} \ell_3 & \ell_{12} & \ell_{13} \\ m_3 & m_{12} & -m_{13} \end{array} \right) \cdots \left( \begin{array}{ccc} \ell_{N-2} & \ell_{N-1} & \ell_{N-3} \\ m_{N-2} & m_{N-1} & -m_{N-3} \end{array} \right),
\]

with \( E(\Lambda) = (-1)^{\sum \ell_i} k \) and \( k = \ell_{12} - m_{12} + \ell_{13} - m_{13} + \ldots + \ell_{N-2} - m_{N-2} - \ell_{N-3} - m_{N-3} \). The basis (4) can be derived by considering the eigenstates of the angular momentum operators; in particular the basis is an eigenstate of \( \mathbf{L}_1 \) with eigenvalue \( \ell_1 (\ell_1 + 1) \), an eigenstate of \( (\mathbf{L}_1 + \mathbf{L}_2)^2 \) with eigenvalue \( \ell_{12} (\ell_{12} + 1) \) \textit{et cetera}, as well as a zero-eigenvalue eigenstate of the combined angular momentum operator \( (\mathbf{L}_1 + \ldots + \mathbf{L}_{N-1})^2 \). We note that this basis is simply related to the polytopal spherical harmonics of Varshalovich et al. (1988), except that we restrict to zero total angular momentum. Furthermore, the \( N = 4 \) case is a rescaled version of a subset of the tripolar spherical harmonics, which have been used a number of times in cosmological contexts (e.g., Shiraiishi et al. 2017).

Comparison to (1) shows that the parametrization is parameterized by sets of integers \( \Lambda = (\ell_1, \ell_2, (\ell_{12}), \ell_3, (\ell_{13}), \ldots, \ell_{N-1}) \), hereafter denoted \textit{multiplets}. These contain two types of contributions: (a) principal angular momenta \( \ell \) (which index the spherical harmonics), and (b) intermediate angular momenta \( (\ell_{12}, \ell_{13} \text{ et cetera}) \) appearing only in the coupling \( C_{M}^{\Lambda} \). For \( N > 4 \), intermediates are required since there is more than one way to combine the \((N-1)\) spherical harmonics to obtain a state of zero combined angular momentum; put another way, due to the vectorial-nature of angular momentum addition, the principal angular momenta \( (\ell_1, \ell_2, \ldots, \ell_{N-1}) \) are insufficient to fully define the state. From (5), we note several constraints on the values of \( \ell \) and \( m \). In particular, the \( 3-j \) symbols enforce that \( m_{12} = m_1 + m_2, m_{13} = m_1 + m_3 \) \textit{et cetera} and thus that \( \sum_i m_i = 0 \), giving invariance under \( z \)-axis rotations. This ensures that the basis function (4) is a state of zero combined orbital angular momentum. Furthermore, each \( 3-j \) symbol implies a triangle inequality of the form \( |\ell_1 - \ell_2| \leq \ell_{12} \leq \ell_1 + \ell_2 \). This restricts the number of physical \( \Lambda \) states.

2.2 Basic Properties

The coupling coefficients, \( C_{M}^{\Lambda} \), appearing in (4) satisfy

\[
C_{M}^{\Lambda} = E(\Lambda) C_{M}^{\Lambda},
\]

\footnote{1}{Foreshadowing the application to \( N \)-point functions, we consider only basis functions involving \((N-1)\) coordinates in this section. Statistical homogeneity dictates that the NPCFIs are independent of the \( N \)-th spatial position.}

\footnote{2}{Throughout this work, we indicate intermediate angular momentum components by parentheses.}
where \(-M = \{-m_1, -m_2, \ldots, -m_{N-1}\}\), and \(E(\Lambda) = +1\) if the sum of all principal angular momentum (\(\sum_i \ell_i\)) is even, and \(-1\) else. Consequently the isotropic basis functions obey the conjugate condition
\[
P^\ast_A(\hat{\mathbf{R}}) = E(\Lambda)P_A(\hat{\mathbf{R}})
\]  
(7) (Cahn & Slepian 2020). Under parity transformations, \(\mathbb{P}[Y_{\ell m}(\hat{\mathbf{r}})] \equiv Y_{\ell m}(-\hat{\mathbf{r}}) = (-1)^\ell Y_{\ell m}(\hat{\mathbf{r}})\), with parity operator \(\mathbb{P}\). Thus
\[
P[\mathbb{P}A(\hat{\mathbf{R}})] = E(\Lambda)P_A(\hat{\mathbf{R}}).
\]  
(8) Due to this property, we will refer to the cases \(E(\Lambda) = +1\) and \(-1\) as parity-even and parity-odd respectively. We further note that (7) implies that \(P_A(\hat{\mathbf{R}})\) is purely real for even-parity \(\Lambda\) and purely imaginary for odd-parity \(\Lambda\).

Secondly, the basis functions are orthonormal when integrated over \(\hat{\mathbf{R}}\):
\[
\int d\hat{\mathbf{R}} \mathcal{P}_A(\hat{\mathbf{R}}) \mathcal{P}_A^\dagger(\hat{\mathbf{R}}) = \delta_{\Lambda\Lambda'},
\]  
(9) where \(d\hat{\mathbf{R}} = d\hat{r}_1 \ldots d\hat{r}_{N-1}\) and the Kronecker delta is unity if all components of \(\Lambda\) and \(\Lambda'\) match and zero else. This follows straightforwardly from (5) and the orthonormality of the spherical harmonics. Given the expansion (1), this allows the basis coefficients \(f_\Lambda\) to be written as
\[
f_\Lambda(R) = \int d\hat{\mathbf{R}} f(\hat{\mathbf{R}}) \mathcal{P}_A^\dagger(\hat{\mathbf{R}}),
\]  
(10) adopting the notation \(R = \{r_1, \ldots, r_{N-1}\}\). For \(\Lambda = 0\), the basis functions take the simple form
\[
\mathcal{P}_0(\hat{\mathbf{R}}) = (4\pi)^{-(N-1)/2},
\]  
(11) using \(Y_{00}(\hat{\mathbf{r}}) = (4\pi)^{-1/2}\) and \(C_0^0 = 1\).

An additional property of interest is the contraction of two basis functions of the same arguments. This is the analog of the well-known spherical harmonic product-to-sum relation:
\[
Y_{\ell_1 m_1}(\hat{\mathbf{r}})Y_{\ell_2 m_2}(\hat{\mathbf{r}}) = \sum_{\ell_3 m_3} G_{\ell_1 m_1 \ell_2 m_2}^{\ell_3 m_3} (-1)^{m_3} Y_{\ell_3 m_3}(\hat{\mathbf{r}})
\]  
(12) (NIST DLMF, Eq. 34.3.22), where \(G_{\ell_1 m_1 \ell_2 m_2}^{\ell_3 m_3}\) is the Gaunt integral, defined by
\[
G_{\ell_1 m_1 \ell_2 m_2}^{\ell_3 m_3} = \frac{(2\ell_1 + 1)(2\ell_2 + 1)(2\ell_3 + 1)}{4\pi} \left[ \begin{array}{ccc} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & m_3 \end{array} \right] \left[ \begin{array}{ccc} \ell_1 & \ell_2 & \ell_3 \\ 0 & 0 & 0 \end{array} \right].
\]  
(13) In our context, we find
\[
\mathcal{P}_\Lambda(\hat{\mathbf{R}}) \mathcal{P}_{\Lambda'}(\hat{\mathbf{R}}) = \sum_{\Lambda''} E(\Lambda'') \mathcal{G}_{\Lambda\Lambda'}^{\Lambda''} \mathcal{P}_{\Lambda''}(\hat{\mathbf{R}})
\]  
(14) (Cahn & Slepian 2020, §6), where \(\mathcal{G}_{\Lambda\Lambda'}^{\Lambda''}\) is the generalized Gaunt integral, defined as
\[
\mathcal{G}_{\Lambda\Lambda'}^{\Lambda''} = \int d\hat{\mathbf{R}} \mathcal{P}_\Lambda(\hat{\mathbf{R}}) \mathcal{P}_{\Lambda'}(\hat{\mathbf{R}}) \mathcal{P}_{\Lambda''}(\hat{\mathbf{R}}).
\]  
(15) In Appendix A, we provide expressions for \(\mathcal{G}_{\Lambda\Lambda'}^{\Lambda''}\) with \(N = 3, 4, 5\), involving Wigner 9-\(j\) symbols.

### 2.3 Special Cases

For later use, we give the explicit forms of the basis functions for \(N = 3, 4, 5\). For \(N = 3\), the basis is specified by two components \(\Lambda = \{\ell_1, \ell_2\}\), with
\[
C_M^\Lambda = C_{\ell_1 \ell_2}^{\ell_1 \ell_2} = \frac{(-1)^{\ell_1 m_1}}{\sqrt{2\ell_1 + 1}} \frac{\delta_{\ell_1 \ell_2}}{\delta_{m_1 m_2}}
\]  
(16) which enforces \(\ell_1 = \ell_2, m_1 = m_2 = 0\). From (4), the full basis function can thus be written
\[
\mathcal{P}_{\ell}(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2) = \sum_{m = -\ell}^{\ell} \frac{(-1)^{\ell-m}}{\sqrt{2\ell + 1}} Y_{\ell m}(\hat{\mathbf{r}}_1) Y_{\ell-m}(\hat{\mathbf{r}}_2) = \frac{\sqrt{2\ell + 1}}{4\pi} (-1)^{\ell} L_{\ell}(\hat{\mathbf{r}}_1 \cdot \hat{\mathbf{r}}_2),
\]  
(17) where \(L_{\ell}(\mu)\) is the Legendre polynomial of order \(\ell\). In this case, our basis is simply a rescaled version of a Legendre expansion into multipoles. Note that \(\ell_1 + \ell_2 \equiv 2\ell\) is always even, thus all \(N = 3\) basis functions are parity-even. This occurs since the \(N = 3\) parity transformation is equivalent to a rotation, and the basis functions are invariant under rotations.

For \(N = 4\), simplifying the coefficients of (5) gives
\[
C_M^\Lambda = C_{\ell_1 \ell_2 \ell_3}^{\ell_1 \ell_2 \ell_3} = \frac{-1^{\ell_1 + \ell_2 + \ell_3}}{\sqrt{2\ell_1 + 1}} \frac{\delta_{\ell_1 \ell_2 \ell_3}}{\delta_{m_1 m_2 m_3}}
\]  
(18) noting that these are equivalent to the \(N = 2\) basis functions of Cahn & Slepian (2020).
depending on three principal momenta, $\Lambda = (\ell_1, \ell_2, \ell_3)$. The full basis function becomes

$$\mathcal{P}_{\ell_1\ell_2\ell_3}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3) = (-1)^{\ell_1+\ell_2+\ell_3} \sum_{m_1 m_2 m_3} \left( \begin{array}{ccc} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & m_3 \end{array} \right) Y_{\ell_1 m_1}(\mathbf{r}_1) Y_{\ell_2 m_2}(\mathbf{r}_2) Y_{\ell_3 m_3}(\mathbf{r}_3).$$

(19)

As before this is just a simple combination of spherical harmonics with the coupling chosen to ensure rotational invariance. Here, the sum of the principal angular momenta, $\ell_1 + \ell_2 + \ell_3$, can be either even or odd, thus both even- and odd-parity functions are permitted.

Finally, we remark on the form for $N = 5$. Here, we require five sets of angular momentum coefficients to fully specify each basis function, $\Lambda = (\ell_1, \ell_2, (\ell_12), \ell_3, \ell_4)$. An intermediate angular momentum $\ell_12$ appears as there are multiple ways to combine four spherical harmonics with given principal angular momenta $\ell_i$ such that the total angular momentum is zero. In this case, the coupling coefficients and associated basis functions are

$$C^\Lambda_M = C_{m_1 m_2 m_3 m_4}^{\ell_1 \ell_2 \ell_3 \ell_4} = (-1)^{\ell_1+\ell_2+\ell_3+\ell_4} \sum_{m_1 m_2 m_3 m_4} (-1)^{\ell_12-m_12} \left( \begin{array}{ccc} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & m_3 \end{array} \right) \left( \begin{array}{ccc} \ell_12 & \ell_3 & \ell_4 \\ m_12 & m_3 & m_4 \end{array} \right),$$

$$\mathcal{P}_{\ell_1 \ell_2 \ell_3 \ell_4}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4) = (-1)^{\ell_1+\ell_2+\ell_3+\ell_4} \sum_{m_1 m_2 m_3 m_4} (-1)^{\ell_12-m_12} \sum_{m_1 m_2 m_3 m_4} \left( \begin{array}{ccc} \ell_1 & \ell_2 & \ell_3 \\ m_1 & m_2 & m_3 \end{array} \right) \left( \begin{array}{ccc} \ell_12 & \ell_3 & \ell_4 \\ m_12 & m_3 & m_4 \end{array} \right) Y_{\ell_1 m_1}(\mathbf{r}_1) Y_{\ell_2 m_2}(\mathbf{r}_2) Y_{\ell_3 m_3}(\mathbf{r}_3) Y_{\ell_4 m_4}(\mathbf{r}_4).$$

Higher orders proceed similarly, with the basis function of $(N-1)$ coordinates involving $(N-4)$ intermediate angular momenta.

3 THE NPCF ESTIMATOR

3.1 Definition

The $N$-point correlation function is defined as a statistical average over the product of $N$ overdensity fields, $\delta$:

$$\zeta(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1}) = \langle \delta(\mathbf{s}) \delta(\mathbf{s} + \mathbf{r}_1) \ldots \delta(\mathbf{s} + \mathbf{r}_{N-1}) \rangle = \int \frac{d\mathbf{s}}{V} \delta(\mathbf{s}) \delta(\mathbf{s} + \mathbf{r}_1) \ldots \delta(\mathbf{s} + \mathbf{r}_{N-1}),$$

(21)

using the ergodic theorem to convert the statistical average into a spatial integral in the second line, assuming the volume $V$ to be large. By statistical homogeneity, the NPCF cannot depend on the absolute position $\mathbf{s}$, thus it is a function of only $(N-1)$ sets of coordinates. Further, if one assumes $\delta$ to be statistically isotropic, the function must be invariant under any global rotation, i.e. one in which all separation vectors $\mathbf{r}$ are simultaneously rotated about some common origin. This is exactly the condition for the function to be expressed in the isotropic basis of §2; thus we may write

$$\zeta(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1}) = \sum_{\Lambda} \zeta_{\Lambda}(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1}) \mathcal{P}_{\Lambda}(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1})$$

(22)

without loss of generality, where $\mathcal{P}_{\Lambda}$ are the isotropic basis functions of $(N-1)$ coordinates defined in §4. As before, $\Lambda$ specifies the basis function, and is composed of angular momentum coefficients $\ell_1, \ell_2, \ell_12, \ldots$, which take integer values, with $\ell_i$ corresponding to the side of the $N$-hedron (formed from the $N$ particles) with length $r_i$. For $N = 3$, inserting the explicit basis function of (17) gives

$$\zeta(\mathbf{r}_1, \mathbf{r}_2) = \sum_{\ell} \frac{\sqrt{2\ell + 1}}{4\pi} (-1)^{\ell} \zeta_{\ell}(\mathbf{r}_1, \mathbf{r}_2) L_{\ell}(\hat{\mathbf{r}}_1 \cdot \hat{\mathbf{r}}_2),$$

(23)

thus the 3PCF basis coefficients $\zeta_{\ell}$ are simply rescaled Legendre multipolles. This matches the approach of Slepian & Eisenstein (2015).

As noted in §2.2, the basis functions come in two forms; parity-odd (with even $\ell_1 + \ldots + \ell_{N-1}$) and parity-even (with odd $\ell_1 + \ldots + \ell_{N-1}$). To understand our notation, first consider the NPCF under parity transforms:

$$\mathbb{P} [\zeta(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1})] = \zeta(-\mathbf{r}_1, \ldots, -\mathbf{r}_{N-1})$$

(24)

$$= \sum_{\Lambda} \zeta_{\Lambda}(\mathbf{r}_1, \ldots, -\mathbf{r}_{N-1}) \mathcal{P}_{\Lambda}(\mathbf{-r}_1, \ldots, -\mathbf{r}_{N-1}) = \sum_{\Lambda} \mathcal{E}(\Lambda) \zeta_{\Lambda}(\mathbf{r}_1, \ldots, -\mathbf{r}_{N-1}) \mathcal{P}_{\Lambda}(\mathbf{r}_1, \ldots, -\mathbf{r}_{N-1}) = \sum_{\Lambda} \mathcal{E}(\Lambda) \zeta_{\Lambda}(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1}) \mathcal{P}_{\Lambda}(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1}),$$

where $\mathbb{P}$ is the parity operator and we have used the basis decomposition (22) and the parity inversion formula (8) in the second line. Invoking orthogonality (9), we find that multiplets $\zeta_{\Lambda}$ with odd $\ell_1 + \ldots + \ell_{N-1}$ are odd under parity-inversion, whilst those with even $\ell_1 + \ldots + \ell_{N-1}$ are even under parity-inversion. Furthermore, given that the odd-parity basis functions are imaginary (§2.2), this implies that all $\zeta_{\Lambda}$ with odd-parity $\Lambda$ are also purely imaginary (as found in Appendix B). Assuming the NPCF to be parity-symmetric, we expect $\zeta_{\Lambda}$ to vanish for odd $\ell_1 + \ldots + \ell_{N-1}$. We further note that odd-parity terms appear only for $N > 3$, as noted in §2.2. This occurs since parity inversion is equivalent to a 3D rotation for $N \leq 3$, and the isotropic NPCF is rotationally invariant.

Finally, we note that the general NPCF is a sum of two contributions: ‘connected’ and ‘disconnected’. The first involves the joint probability of $N$ points in space, whilst the second factorizes into multiple independent components. For example, the cosmological 4PCF contains contributions both from the intrinsic non-Gaussian 4PCF (the connected piece), and the product of two 2PCFs (the disconnected piece).
3.2 General Estimator

To extract the NPCF multiplets \( \zeta_A(r_1, \ldots, r_{N-1}) \), we may use the orthogonality relation (10):

\[
\zeta_A(r_1, \ldots, r_{N-1}) = \int d\mathbf{r}_1 \ldots d\mathbf{r}_{N-1} \zeta_A(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1}) \mathcal{P}_A(\mathbf{r}_1, \ldots, \mathbf{r}_{N-1})
\]

(26)

using the conjugation rule (7) to obtain the second line. Inserting the NPCF definition (21) and the explicit forms of the basis functions (4) gives an estimator for \( \zeta_A \):

\[
\hat{\zeta}_A(r_1, \ldots, r_{N-1}) = \frac{1}{V} \int ds \sum_{m_1 \ldots m_{N-1}} \mathcal{E}(\Lambda) C^A_M \int d\mathbf{r}_1 \ldots d\mathbf{r}_{N-1} \delta(s) \delta(s + r_1) \ldots \delta(s + r_{N-1}) Y_{\ell_m r_m^{-1}}(\mathbf{r}_1) \ldots Y_{\ell_{N-1} r_{N-1}^{-1}}(\mathbf{r}_{N-1}).
\]

(27)

where we have integrated the absolute position \( s \) over a volume \( V \), as in (21). Note that we have not yet introduced radial binning. The appeal of this decomposition is clear; the estimator is exactly separable in \( \mathbf{r} \). Explicitly, we may define:

\[
a_{\ell m}(s; r) = \int d\mathbf{r} \delta(s + \mathbf{r}) Y_{\ell m}(\mathbf{r})
\]

(28)

which is simply a convolution of \( \delta \) and \( Y_{\ell m}(r) \), and write (27) as

\[
\hat{\zeta}_A(r_1, \ldots, r_{N-1}) = \frac{1}{V} \int ds \sum_{m_1 \ldots m_{N-1}} \mathcal{E}(\Lambda) C^A_M a_{\ell m_1}(s; r_1) \ldots a_{\ell_{N-1} m_{N-1}}(s; r_{N-1}).
\]

(29)

Given the harmonic coefficients \( a_{\ell m}(s; r) \), the NPCF is formed by summing over the \( m \) indices, weighted by the coupling coefficients \( \mathcal{E}(\Lambda) C^A_M \), and integrating over position \( s \). Restricting to \( \ell \leq \ell_{\text{max}} \), an upper bound to the number of summation terms is given by \((1 + 2\ell_{\text{max}})^{N-2}\). Whilst (29) is unbiased (as shown by inserting \( 21 \) and \( 22 \), then using orthonormality), it is not strictly optimal, i.e. it is not minimum variance. Optimal estimation of the higher-point functions is possible (and discussed for example in Smith & Zaldarriaga (2011); Smith et al. (2015); Fergusson & Shellard (2011); Fergusson et al. (2012); Philcox (prep) for Fourier-space statistics); this generally involves extra additive terms. We do not explore such complications in this work.

In practice, one usually bins the NPCFs in radius. To do so, we introduce a binning function \( \Theta^B(r) \) which is unity if \( r \) is in bin \( b \) and zero else. In this case, the binned NPCF becomes:

\[
\zeta_A^B = \frac{1}{v_B} \int \left[ \prod_{i=1}^{N-1} r_i^2 d\mathbf{r}_i \Theta^B(r_i) \right] \zeta_A(r_1, \ldots, r_{N-1}),
\]

(30)

where the second line gives the bin volume. We denote the set of all bin indices by \( B = \{b_1, \ldots, b_{N-1}\} \), with \( b_i \) referring to the \( N \)-hedron side with radius \( r_i \) and thus angular momentum coefficient \( \ell_i \). Since the binning is separable in \( r_i \), the corresponding NPCF estimator may be written

\[
\hat{\zeta}_A^B = \frac{1}{V} \int ds \sum_{m_1 \ldots m_{N-1}} \mathcal{E}(\Lambda) C^A_M a_{\ell m_1}^{b_1}(s) \ldots a_{\ell_{N-1} m_{N-1}}^{b_{N-1}}(s),
\]

(31)

with the new harmonic coefficients

\[
a_{\ell m}^B(s) = \frac{1}{v_B} \int d\mathbf{r} \delta(s + \mathbf{r}) Y_{\ell m}(\mathbf{r}) \Theta^B(r),
\]

(32)

where \( v_B = \int d\mathbf{r} \Theta^B(r) \) is the bin volume. This is again a simple convolution of \( \delta \) and \( Y_{\ell m}^B(\mathbf{r}) \). In this approach, binning has an important function; it allows us to estimate only a finite number of \( a_{\ell m}^B(s) \) harmonic coefficients, before performing the summation of (31).
3.2.1 Discrete Data

In most contexts, we are interested in the estimation of NPCFs from discrete data. Given a set of \( N_p \) particle positions at \( \{ r_i \} \), the discrete density field may be written as a sum of Dirac delta functions and weights \( w_i \):

\[
\delta(r) = \sum_{i=1}^{N_p} w_i \delta_D(r - r_i).
\]

Using this, the \( s \) integral in the NPCF estimator becomes a sum over particle positions as

\[
\xi^B = \frac{1}{V} \sum_i w_i \sum_{m_1, \ldots, m_{N-1}} E(\Lambda) \frac{a^{b\ell}_l}{M} a^{b\ell}_l (s_i) \cdots a^{b\ell}_{N-1} (s_i),
\]

and the harmonic coefficients \( a^{b\ell}_l \) can be written

\[
a^{b\ell}_l (s_i) = \frac{1}{v_B} \sum_j w_j y^{b\ell}(r_j - s_i) \Theta^b (r_j - s_i).
\]

Note that the \( a^{b\ell}_l \) harmonic coefficients need to be evaluated only at the locations of the particles, \( \{ r_i \} \). The interpretation of (35) is straightforward; for a given primary position \( s_i \), we sum over all secondary positions \( r_j \) which lie within bin \( b \) of \( s_i \), weighted by the spherical harmonics evaluated at the separation vector \( r_j - s_i \). Practically this is evaluated as a weighted sum of pairs of particles, i.e. a pair-count.

The full procedure for estimating the binned NPCF from a discrete set of particles is thus:

(i) For a given primary particle \( i \), compute \( a^{b\ell}_l (s_i) \) as a weighted sum of spherical harmonics.

(ii) For each \( \Lambda \) multiplet and bin combination \( B \), sum the product of \( (N - 1) \) harmonic coefficients over all \( m_1 \), weighting by the coupling coefficient \( E(\Lambda) C^{\Lambda}_M \).

(iii) Repeat for each primary particle and sum.

Since it is a sum over secondary positions \( r_j \), computation of (35) scales as \( N_p^2 \) for total particle number \( N_p \). Given that each \( a^{b\ell}_l \) function must be evaluated at the location of each particle, the algorithm has complexity \( O(N_p^3) \). This is the same scaling as for the 3PCF (Slepian & Eisenstein 2015), and much better than the naive \( O(N_p^N) \) scaling expected from counting every possible \( N \)-tuplet of particles and assigning them to bins.

For discrete data, an important subtlety should be noted. If the bins \( B = \{ b_1, \ldots, b_{N-1} \} \) are not disjoint (i.e. we include scenarios in which multiple side-lengths of the \( N \)-hedron fall into the same radial bin), the same secondary particle can contribute to multiple \( a^{b\ell}_l \) harmonic coefficients. Physically this corresponds to a scenario in which we have an \( N \)-point function with multiple coincident points. As discussed in Philcox (2021), these ‘self-count’ contributions can be removed by subtracting a hierarchy of lower \( N \)-point functions.\(^4\) However, given that these NPCF regimes are difficult to model and interpret, a simpler approach is to enforce that all \( b_i \) bins are distinct, effectively enforcing some minimum separation on the side lengths of the \( N \)-hedron. In this work, we assume \( b_1 < b_2 < \ldots < b_{N-1} \) for this reason.

3.2.2 Gridded Data

Estimator (31) may be similarly applied to data discretized onto a grid, for example a matter density field in an \( N \)-body simulation, or some fluid in a hydrodynamic simulation. If the density field \( \delta \) is defined on some grid, we may compute the harmonic coefficients using a Fast Fourier Transform (FFT):

\[
a^{b\ell}_l (s) = \mathcal{F}^{-1} \left[ \mathcal{F} [\delta (k)] \mathcal{F} [y^{b\ell}(r)] \Theta^b (r) \right] (s) \left[ \int dr \Theta^b (r) \right],
\]

where \( \mathcal{F} (\mathcal{F}^{-1}) \) is the forward (reverse) Fourier operator. Assuming \( N_{\text{FFT}} \) grid-points, this has complexity \( O(N_{\text{FFT}} \log N_{\text{FFT}}) \) and allows estimation of \( a^{b\ell}_l \) in all grid-cells simultaneously.\(^5\) Practically, we may use (31) to compute the NPCF of a gridded field \( \delta \) in the following fashion:

(i) For each \( \ell, m \) up to some \( \ell_{\text{max}} \) and radial bin \( b \), estimate \( a^{b\ell}_l (s) \) using FFTs.

(ii) Take the product of \( N - 1 \) \( a^{b\ell}_l \) fields and integrate over space, weighted by \( \delta (s) \).

(iii) Sum over \( M = \{ m_1, \ldots, m_{N-1} \} \), weighted by the coupling coefficients \( E(\Lambda) C^{\Lambda}_M \).

This generalizes the approach of Portillo et al. (2018), which computed the 3PCF of gridded data via Fourier methods. Whilst this approach may prove useful for the analysis of simulations and applications beyond cosmology, we focus on discrete data for the remainder of this work, though much of the discussion applies to both cases.

\(^4\) Specifically, we must subtract off basis functions with two coincident points, e.g., \( \mathcal{P}_\Lambda (r_1, r_1, \ldots, r_{N-2}) \), those with three coincident points, e.g., \( \mathcal{P}_\Lambda (r_1, r_1, r_1, \ldots, r_{N-3}) \), et cetera. Using the contraction formulae of Cahn & Slepian (2020, §5), these can be written as lower-order basis functions.

\(^5\) We caution that this approach requires many \( a^{b\ell}_l (s) \) fields must be stored in order to compute (31); this results in significant memory usage.
3.2.3 Dimensionality

Before continuing, we discuss the dimension of the $\xi_A$ NPCF statistic. Assuming $N_r$ radial bins per dimension, and asserting that radial bins do not overlap (cf. §3.2.1), $B$ contains $\binom{N_r}{-1}$ elements, which asymptotically scales as $N_r^{-1}$. The NPCF requires isotropic basis functions of $(N - 1)$ coordinates; for $N > 3$ these contain $(N - 1)$ principal angular momenta $\ell_i$, each of which runs from 0 to $\ell_{\text{max}}$, and $(N - 4)$ intermediate angular momenta $\ell_{12}, \ldots$, each of which runs from 0 to $2\ell_{\text{max}}$ (cf. §2.3). This implies that the number of elements in $\Lambda$ is bounded from above by $(1 + \ell_{\text{max}})^{N-1}(1 + 2\ell_{\text{max}})^{N-4}$; the true number is somewhat smaller due to the triangle conditions. Furthermore, we must sum over $(N - 2)$ integers $m_i$, each of which can run from $-\ell_i$ to $\ell_i$ (with $m_{N-1}$ set by $\sum_i m_i = 0$), giving a maximum of $(1 + 2\ell_{\text{max}})^{N-2}$ summation terms in (31) for each choice of $\Lambda$ and $B$. This further bounds the dimensionality of the coupling coefficient $C_M$ to $(1 + \ell_{\text{max}})^{N-1}(1 + 2\ell_{\text{max}})^{2N-6}$. Asymptotically, the dimension of the NPCF statistic, $\xi_A^r$, scales as $N_r^{-1}(2N_r-5)$, which quickly becomes very large as $N$ increases. Given that our eventual goal is to compute $O(10)$ parameters from the statistic, it is likely that data compression methods (e.g., Scoccimarro 2000; Philcox et al. 2021) will prove useful in any higher-point NPCF analysis.

3.3 Edge Correction

In the analysis of real galaxy surveys, one does not have direct access to the galaxy overdensity field $\delta$. Instead, our observables are the set of $N_D$ galaxy positions $\{r_i\}$ (hereafter ‘data’), as well as a set of $N_R$ unclustered particles (hereafter ‘randoms’) $\{r_j\}$, with the randoms distributed according to the survey geometry and selection function. Mathematically, the associated random fields are given by

$$D(r) = \sum_{i=1}^{N_R} w_i^D \delta_D(r - r_i), \quad R(r) = \sum_{j=1}^{N_R} w_j^R \delta_D(r - r_j),$$

where $w_i^D$ and $w_j^R$ are data and random weights, with the latter normalized such that $\sum_i w_i^D = \sum_j w_j^R$. Averaging over the (Poissonian) sampling distribution, the data and random fields have expectations $\langle D(r) \rangle = n(r)\{1 + \delta(r)\}$, $\langle R(r) \rangle = n(r)$ where $n(r)$ is some background number density. This motivates the following estimator for the galaxy NPCF, based on Landy & Szalay (1993) and Szapudi & Szalay (1998):

$$\hat{\xi}(r_1, \ldots, r_{N-1}) = \frac{\int ds [D - R](s)[D - R](s + r_1) \cdots [D - R](s + r_{N-1})}{\int ds R(s)R(s + r_1) \cdots R(s + r_{N-1})},$$

(38)

defining the functions $N$ and $R$. In the shot-noise limit, this is simply an inverse-variance weighting (cf. Slepian & Eisenstein 2015). For a simple periodic-box geometry in the limit of infinite randoms, $R(r)$ takes the constant value $n$ everywhere, thus the denominator is trivial. Note that (38) applies also to gridded density fields with non-uniform geometry; in this case $N$ and $R$ are the multiplets of the gridded ‘data-minus-random’ and random density fields.

In general, we can expand each function appearing in (38) in the isotropic basis of §2, giving

$$\sum_{\Lambda} \hat{\xi}_\Lambda(R) P_{\Lambda}(\tilde{R}) = \sum_{\Lambda'N} N_{\Lambda'N}(R) P_{\Lambda'N}(\tilde{R}),$$

(39)

where we have denoted $\tilde{R} \equiv \{\tilde{r}_1, \ldots, \tilde{r}_{N-1}\}$ and $R \equiv \{r_1, \ldots, r_{N-1}\}$. Defining $f_{\Lambda}(R) = R_{\Lambda}(R)/R_0(R)$, we can write

$$\sum_{\Lambda'N} N_{\Lambda'N}(R) P_{\Lambda'N}(\tilde{R}) = \sum_{\Lambda'N} \hat{\xi}(\Lambda')(f_{\Lambda'}(R)P_{\Lambda'}(\tilde{R})) = \sum_{\Lambda'N} \hat{\xi}(\Lambda')(f_{\Lambda'}(R)) E(\Lambda') G^{\Lambda'\Lambda'N} P_{\Lambda'N}(\tilde{R}),$$

(40)

where we have expanded the product of two isotropic basis functions using (14). This uses the generalized Gaunt integrals $G^{\Lambda'\Lambda'N}$ defined in (15), with explicit low-order forms given in terms of Wigner $3-j$ and $9-j$ symbols in Appendix A. Invoking orthonormality (9), we can extract the $P_{\Lambda'N}(\tilde{R})$ basis coefficient as

$$\frac{N_{\Lambda'N}(R)}{R_0(R)} = \sum_{\Lambda} \hat{\xi}_{\Lambda} \left[ \sum_{\Lambda'} f_{\Lambda'}(R) E(\Lambda') G^{\Lambda'\Lambda'N} \right] = \sum_{\Lambda} \hat{\xi}_{\Lambda}(R) M_{\Lambda'\Lambda'N}(R).$$

(41)

In the second line we have noted that this is simply a linear combination (with radial-bin dependent) coupling matrix $M_{\Lambda'\Lambda'N}$; inverting yields the edge-corrected estimator for $\hat{\xi}_{\Lambda}$:

$$\hat{\xi}_{\Lambda}(r_1, \ldots, r_{N-1}) = \sum_{\Lambda'} M^{-1}_{\Lambda'\Lambda}(r_1, \ldots, r_{N-1}) N_{\Lambda'N}(r_1, \ldots, r_{N-1}) \frac{R_{\Lambda}(r_1, \ldots, r_{N-1})}{R_0(r_1, \ldots, r_{N-1})}.$$

(42)

writing out $R$ in full. This applies also to the binned statistic with the substitutions $N_{\Lambda}(R) \rightarrow N_{\Lambda}^B(R)$, $R_{\Lambda}(R) \rightarrow R_{\Lambda}^B(R)$, $\xi_{\Lambda}(R) \rightarrow \xi_{\Lambda}^B$, as can be seen from first rewriting (38) in binned form.

The meaning of (42) can be understood as follows. For a uniform periodic geometry (e.g., an $N$-body simulation or some gridded periodic data), $R(r_1, \ldots, r_{N-1})$ is independent of positions $r_i$, thus its only non-zero basis coefficient is

$$R_0(r_1, \ldots, r_{N-1}) = \frac{\hat{n}^N}{V} \int d\tilde{r}_1 \cdots d\tilde{r}_{N-1} \bar{P}_0(\tilde{r}_1, \ldots, \tilde{r}_{N-1}) = (4\pi)^{-N/2} \hat{n}^N.$$

(43)
Accelerate the estimates of the isotropic functions can be ignored. The power spectrum monopole and quadrupole in the presence of an anisotropic survey window. Here, we assume this effect to be small, such that the bias in our galaxy distribution can generate an isotropic NPCF, and ought to be removed via an anisotropic edge-correction equation. This is analogous to the mixing of spherical-harmonic-weighted sum of all secondary particles, the NPCF estimates. The latter is straightforward; the only complexity is in computation of the \( \sum_i f_i \). Assuming the Universe to be parity symmetric, these are unphysical. In disconnected mode, we estimate the Gaussian contribution to the 4PCF; this allows direct estimation of the purely non-Gaussian connected 4PCF, and will be discussed in Philcox et al. (prep).

An additional caveat concerns the choice of \( \sum_i f_i \), with \( \sum_j f_j \) being the infinite matrix equation (42) is straightforward to implement; one first measures the multiplets \( N_\Lambda \) and \( R_\Lambda \) using the estimators of (29) or (34), with \( \delta \) replaced by \( |D - R|/(r) \) or \( R/(r) \). Given the set of all measured multiplets, the matrix inversion is a straightforward operation, and may be done for each radial bin combination separately. In practice, \( M_{\Lambda\Lambda'}(R) \) is close to diagonal (cf. Fig. 4), thus truncation of the infinite matrix \( M_{\Lambda\Lambda'} \) at finite \( \ell_{\text{max}} \) is expected to yield an accurate estimate of \( \hat{\zeta}_{\Lambda}(R) \) for all multiplets those containing \( \ell \) near \( \ell_{\text{max}} \). We additionally note that \( G^{NN'\Lambda} \) is only non-zero if \( \sum_i \ell_i + \sum_j \ell_j + \sum_k \ell_k \ell_k' \) is even. This implies that a parity-odd NPCF can be sourced by a parity-even \( R \) and a parity-odd \( N \) or vice versa, whilst a parity-even NPCF requires both the data and random counts to have the same parity (cf. §3.1).

### 4 IMPLEMENTATION

Below, we discuss the implementation of the \( O(N^2) \) discrete NPCF estimator given in (34). Discussion of the gridded NPCF estimator (which is of use for hydrodynamic simulations and gridded cosmological simulations) will follow in future work, building upon the 3PCF code of Portillo et al. (2018). The discrete estimator is implemented within the code package, encore, publicly available at github.com/oliverphilcox/encore, and is loosely based on the isotropic 3PCF code of Slepian & Eisenstein (2015) and the hipster power spectrum estimator package of Philcox & Eisenstein (2020); encore is written in C++ and CUDA and includes routines for computing the NPCF counts using both parallelized CPU resources and GPUs, as well as computing the edge-corrections as in §3.3. Currently, the code supports computation of the isotropic 2-, 3-, 4-, 5- and 6-point functions for both odd- and even-parity multiplets. Higher \( N \) and \( \ell_{\text{max}} \) can be straightforwardly included, though we note that the \( C_M^\Lambda \) matrix becomes sizeable for large \( \ell_{\text{max}} \) (scaling as \( (1 + \ell_{\text{max}})^{N-1} (1 + 2\ell_{\text{max}})^{2N-6} \), cf. §3.2.3). The code can be run in various modes, as shown in Table 1 and discussed in greater detail below.

<thead>
<tr>
<th>TABLE 1. The various computation modes available in the encore NPCF package. These allow control over which statistics are computed, as well as architecture choices. Any combination of these can be used in tandem, except for openmp and cuda. In the allparity mode, we include contributions from odd-parity spectra, i.e. those with odd ( \sum_i \ell_i ). Assuming the Universe to be parity symmetric, these are unphysical. In disconnected mode, we estimate the Gaussian contribution to the 4PCF; this allows direct estimation of the purely non-Gaussian connected 4PCF, and will be discussed in Philcox et al. (prep).</th>

6 The naïve estimator is analogous to the window-convolved galaxy power spectrum estimator of Feldman et al. (1994), or the CMB pseudo-\( C_\ell \) estimator.
7 To estimate these, we simply repeat the procedure with a larger \( \ell_{\text{max}} \).
8 An additional caveat concerns anisotropy of the window function. Strictly speaking, couplings between the anisotropic window function and anisotropic galaxy distribution can generate an isotropic NPCF, and ought to be removed via an anisotropic edge-correction equation. This is analogous to the mixing of power spectrum monopole and quadrupole in the presence of an anisotropic survey window. Here, we assume this effect to be small, such that the bias in our estimates of the isotropic functions can be ignored.
9 www.sympy.org
**Algorithm 1** Overview of the main algorithm underlying computation of the $N$-point correlation functions. Given precomputed coupling coefficients $C_N^{\Lambda M}$ (5), this routine computes the correlation function estimates (with $N > 2$) from $N_g$ particles with angular momentum coefficients up to $\ell = \ell_{\text{max}}$ using $N_r$ radial bins with minimum (maximum) separation $r_{\text{min}}$ ($r_{\text{max}}$). This is the main procedure underlying the ENCORE code and implements the estimator of (34). For windowed data, this approach is applied to two datasets: a field of random particles (which define the window) and one of ‘data-minus-randoms’. These are combination via (42).

1: Load particle positions and weights from disk
2: Read-in precomputed coupling coefficients $C_N^{\Lambda M}$ defined in (5)
3: for primary particle $i = 1, \ldots, N_g$ do
4:   for secondary particle $j = 1, \ldots, N_g$ with $j \neq i$ do
5:     if $r_{\text{min}} < |\mathbf{r}_i - \mathbf{r}_j| < r_{\text{max}}$ then
6:       for $\ell \leq \ell_{\text{max}}$ do
7:         for $m = 0, \ldots, \ell$ do
8:           for $b = 1, \ldots, N_r$ do
9:             Accumulate the contribution to the harmonic coefficient $a^b_{\ell m}(s_i)$ using (32) (cf. Algorithm 2)
10:          end for
11:       end for
12:     end if
13:   end for
14: end for
15: Compute the NPCF contribution as the product of $(N - 1)$ harmonic coefficients at for each multiplet $\Lambda$ and set of bin indices $B$, summed over $\{m_i\}$ (cf. 34 & Algorithm 3).
16: end for
17: Save the NPCF counts to disk

use the approach of Slepian & Eisenstein (2015), whereupon spherical harmonics are obtained from their Cartesian representations. For each secondary particle $j$, we first define the unit separation vector $\mathbf{r}_j - \mathbf{s}_i = \hat{\Lambda} = (\Delta_x, \Delta_y, \Delta_z)$, and compute all (non-negative integer) powers $\Delta_x^p \Delta_y^q \Delta_z^r$ where $p + q + r \leq \ell_{\text{max}}$. These can be combined to form the spherical harmonics. In practice, we compute histograms of $\Delta_x^p \Delta_y^q \Delta_z^r$ for all required $j$ particles (skipping those with separations outside $[r_{\text{min}}, r_{\text{max}}]$), before combining these to form the harmonic coefficients. This requires $O(N_g^2)$ operations and a total of $(1 + \ell_{\text{max}})(2 + \ell_{\text{max}})(3 + \ell_{\text{max}})/6$ histograms per bin $b$.

As an example, consider $a^b_{\ell_{\text{max}}}(s_i)$. This requires the spherical harmonic $Y_{\ell_{\text{max}}}^2(\hat{\Lambda}) = (\Delta_x - i \Delta_y)\Delta_z$; to compute it, we first obtain the sum of $\Delta_x\Delta_z$ and $\Delta_y\Delta_x$ over all secondary galaxies within the bin $b$, then combine the sums and normalize to obtain $a^b_{\ell_{\text{max}}}(s_i)$. Pseudo-code for this procedure is shown in Algorithm 2. Due to the spherical harmonic conjugation symmetry, $a_{\ell - m} = \bar{a}_{\ell m}$, allowing us to compute only harmonic coefficients with $m \geq 0$.

**Algorithm 2** Procedure to calculate the $a^b_{\ell m}(s_i)$ harmonic coefficients (32) for a given primary particle (either a galaxy or random) at position $s_i$. The algorithm relies on two facts: (1) $a^b_{\ell m}(s_i)$ is a sum over spherical harmonics $Y_{\ell m}(\mathbf{r}_j - \mathbf{s}_i)$ for secondary $\mathbf{r}_j$ within bin $b$, and (2) the spherical harmonics can be written as a sum of products of their Cartesian components. In the first part of the algorithm, we accumulate histograms of all relevant unit powers (here denoted $f_{pqr}$), before transforming these into spherical harmonics. In practice, the first loop is implemented using custom Advanced Vector Extension (AVX) instruction sets (Slepian & Eisenstein 2015), and operates on sets of eight secondary particles simultaneously.

1: for secondary particle $j = 1, \ldots, N_g$ do
2:   Compute the unit separation vector ($\Delta_x, \Delta_y, \Delta_z = (s_i - r_j)/|s_i - r_j|$
3:   Find the radial bin $b$ corresponding to separation $|s_i - r_j|$
4:   Accumulate all combinations $f^b_{pqr} += w_j \Delta_x^p \Delta_y^q \Delta_z^r$ with $p + q + r \leq \ell_{\text{max}}$ for secondary weight $w_j$
5: end for
6: for $\ell = 0, \ldots, \ell_{\text{max}}$ do
7:   for $m = 0, \ldots, \ell$ do
8:     Construct $a^b_{\ell m}(s_i)$ as a weighted sum of $f^b_{pqr}$ coefficients
9:   end for
10: end for

Finally, we must combine the $a^b_{\ell m}(s_i)$ harmonic coefficients to form the NPCF contributions. This is done using (34), and must be performed $N_g$ times. In essence, this is just an outer product of $(N - 1)$ harmonic coefficients, summed over the $m_i$ indices and weighted by the coupling matrix $\mathfrak{E}(\Lambda) C_N^{\Lambda M}$. For large $N$, evaluation of this expression becomes expensive, since the dimensionality of $\Lambda$, $M$ and $B$ is large (cf. §3.2.1).

For each of element in $\zeta_B^B$ (of which there are at most $N_g(N_g - 1)(1 + \ell_{\text{max}})(1 + 2\ell_{\text{max}})^{N-1}$ for $N > 3$), we must sum over a maximum of $(1 + \ell_{\text{max}})^{N-2}$ $M$ combinations, requiring a large number of operations to be performed for each primary particle.
In practice, this may be expedited. Firstly, we omit any \( \Lambda \) contributions violating the triangle conditions, (e.g., for \( N > 3 \), we can enforce \([\ell_1 - \ell_2] \leq \ell_{12} \leq \ell_1 + \ell_2 \), and note that the \( C_{\Lambda}^{N} \) conditions require \( m_{N-1} = -m_1 - \ldots - m_{N-2} \), as well as \( m_{12} \leq \ell_{12}; \ |m_{123}| \leq \ell_{123} \) et cetera. Usually, we compute only correlators obeying \( \zeta(\vec{\mathbf{R}}) = \zeta(-\vec{\mathbf{R}}) \), i.e. those with \( E(\Lambda) = 1 \). These correspond to even \( \sum_i \ell_i \). Finally, we can use the conjugate symmetry of the harmonic coefficients to sum only terms with \( m_{N-1} \geq 0 \). This is detailed in Appendix B, and corresponds to rewriting the single-particle contribution to (34) as

\[
 w_i \sum_{m_1, \ldots, m_{N-1}} E(\Lambda) C_{\Lambda}^{N} a_{\ell_1m_1}(s_1) \ldots a_{\ell_{N-1}m_{N-1}}^{N-1}(s_{N-1}) = 2w_i \sum_{m_{1}+\ldots+m_{N-1} \geq 0} S(m_{N-1}) E(\Lambda) C_{\Lambda}^{N} \sum_{m_1} Q_{\Lambda} a_{\ell_1m_1}(s_1) \ldots a_{\ell_{N-1}m_{N-1}}^{N-1}(s_{N-1})
\]

where \( S(m) = 1/2 \) if \( m = 0 \) and unity else, and the operator \( Q_{\Lambda} \) returns the real-part if \( \Lambda \) is parity-even and \( i \) multiplied by the imaginary-part else. This reduces the number of terms that must be summed approximately by a factor of two, and makes manifest the reality of \( \xi_{\Lambda} \) for even-parity multiplets. Algorithm 3 gives an example of the full summation strategy for the 4PCF.

**Algorithm 3** Typical example of the summations required to compute the NPCF estimator, given the \( a_{\ell m}^{N} \) harmonic coefficients for radial bins \( b \) and angular momentum coefficients \( \ell, m \). Here, we give the pseudo-code for the parity-even \( N = 4 \) summations; higher orders proceed similarly. The 4PCF is parametrized by three angular momenta, \( \Lambda = \{ \ell_1, \ell_2, \ell_3 \} \) (obeying the conditions \([\ell_1 - \ell_2] \leq \ell_3 \leq \ell_1 + \ell_2 \) and \( \ell_1 \leq 0 \)) and three radial bins \( B = \{ b_1, b_2, b_3 \} \). Note that we store only bins with \( b_1 < b_2 < b_3 \); any other bins are either superfluous or contain zero-lag contributions. Here, we compute only even-parity multiplets, skipping any triplet with odd \( \ell_1 + \ell_2 + \ell_3 \), as indicated by the 'continue' statement. We further note that 'load' indicates that a quantity held in RAM is accessed and passed to the cache. \( S(m) \) is defined below (44).

1: for \( \ell_1 = 0, \ldots , \ell_{\text{max}} \) do
2: \hspace{1em} for \( \ell_2 = 0, \ldots , \ell_{\text{max}} \) do
3: \hspace{2em} for \( \ell_3 = [\ell_1 - \ell_2], \ldots , \min (\ell_1 + \ell_2, \ell_{\text{max}}) \) do
4: \hspace{3em} if \( \ell_1 + \ell_2 + \ell_3 \) is odd continue
5: \hspace{3em} for \( m_1 = -\ell_1, \ldots , \ell_1 \) do
6: \hspace{4em} for \( m_2 = -\ell_2, \ldots , \ell_2 \) do
7: \hspace{5em} \( m_3 = -m_1 - m_2 \)
8: \hspace{5em} if \( m_3 > \ell_3 \) or \( m_3 < 0 \) continue
9: \hspace{5em} Load coupling weight \( w_i(-1)^{\ell_1+\ell_2+\ell_3} C_{\ell_1m_1}^1 C_{\ell_2m_2}^2 C_{\ell_3m_3}^3 \)
10: \hspace{5em} for \( b_1 = 1, \ldots , N_r \) do
11: \hspace{6em} Load \( a_{\ell_1m_1}^{b_1} \) or, if \( m_1 < 0 \), \( (-1)^{m_1} a_{\ell_1-m_1}^{b_1} \)
12: \hspace{6em} for \( b_2 = b_1 + 1, \ldots , N_r \) do
13: \hspace{7em} Load \( a_{\ell_2m_2}^{b_2} \) or \( a_{\ell_2-m_2}^{b_2} \), if \( m_2 < 0 \)
14: \hspace{6em} for \( b_3 = b_2 + 1, \ldots , N_r \) do
15: \hspace{7em} Load \( a_{\ell_3m_3}^{b_3} \)
16: \hspace{6em} Accumulate 4PCF: \( \xi_{\ell_1 \ell_2 \ell_3}^{b_1 b_2 b_3} = 2S(m_3)w_i(-1)^{\ell_1+\ell_2+\ell_3} C_{\ell_1m_1}^1 C_{\ell_2m_2}^2 C_{\ell_3m_3}^3 \Re [a_{\ell_1m_1}^{b_1} a_{\ell_2m_2}^{b_2} a_{\ell_3m_3}^{b_3}] \)
17: \hspace{5em} end for
18: \hspace{4em} end for
19: \hspace{3em} end for

23: end for
24: end for

### 4.1.2 CPU Implementation

**ENCORE** provides a C++ implementation of the above routine. Whilst most of the code is straightforward, there are several points of note. Firstly, when computing the harmonic coefficients for each primary particle, we optionally employ custom Advanced Vector Extension (AVX) instruction sets to accumulate the necessary unit vector powers \( \Delta_{\hat{x}}^{\Lambda} \Delta_{\hat{y}}^{\Lambda} \Delta_{\hat{z}}^{\Lambda} \) (cf. §4.1.1). These were developed for the **ABACUS** simulation project (Metchnik 2009; Garrison et al. 2019, 2021) and used in the C++ implementation of the isotropic 3PCF algorithm of Slepian & Eisenstein (2015). Practically, this allows optimal vectorization, with eight secondary particles being analyzed simultaneously (assuming double precision). Whilst the \( a_{\ell m}^{N} \) computation is not rate-limiting at large \( N \), the addition of AVX instruction sets gives significant speed-boosts for the 3PCF (cf. §5.2).

Secondly, the code is (optionally) parallelized using OpenMP. For this, we distribute the iteration over \( N_g \) primary particles to as many threads as are available, parallelizing steps three to twelve of Algorithm 1. Each thread has its own value of the NPCF sum and weight functions, with the former then being combined at the conclusion of the algorithm. Only the list of particle positions is shared between threads. As shown in §5.2, the computation time scales as \( 1/N_{\text{threads}} \), for the higher-order functions, implying that the parallelization is almost perfect.
4.1.3 GPU Implementation

Given that the bulk of the NPCF algorithm requires simple additions and multiplications of harmonic coefficients, we expect that the performance can be significantly enhanced using Graphical Processing Units (GPUs). Modern GPUs contain thousands of individual processing cores, each of which is capable of handling ~1000 threads concurrently. Developers can take advantage of this by using platforms such as NVIDIA’s Compute Unified Device Architecture (CUDA) to design massively parallel algorithms, resulting in significant speed gains for algorithms that are limited by computational resources rather than memory access. The ENSCORE code includes GPU acceleration via CUDA, and it is found to be of significant use for the 5PCF and beyond (§5.3). Since the computation time of the algorithm is a strongly increasing function of $N$ (due to the larger dimensionality of $\Lambda$ and $B$), we focus on the step which is rate-limiting for the higher-point functions; combination of harmonic coefficients to form the NPCF summand. i.e. step 11 in Algorithm 1. Currently, we do not include a GPU implementation of the $a_{\ell m}^b$ estimation; this may be added in the future. We note also that the GPU code is not currently compatible with OpenMP, i.e. it should be run single-threaded.

To implement a GPU-based code, we must first consider what functions we wish each GPU thread to compute. Two options come to mind: (a) allow each thread to compute the $a_{\ell m}^b$ contribution from a single multiplet $\Lambda$, set of bin-indices $B$, summing over all choices of $M$, or (b) use a separate thread for each $M$ element. Option (b) allows a greater number of threads to be utilized, maximizing the GPU capabilities; further, each thread must perform the same number of operations. However, since multiple $M$ contribute to the same multiplet $\Lambda$, this requires careful consideration of memory access. CUDA requires thread blocks to be able to execute independently, in any order, and with many threads running simultaneously it is possible for a collision to occur during which two threads attempt to write to the same NPCF element at once, resulting in an undefined value. In order to avoid this error, the addition into the NPCF array $\zeta^b_{\Lambda}$ must be done atomically; i.e. only one thread can access a given NPCF element at once. This will lead to reduced performance. For option (a), each thread computes a different element of $\zeta^b_{\Lambda}$ thus there are no issues with atomicity, though the total number of threads utilized (equal to the dimension of the NPCF) is smaller. This approach does not achieve maximum parallelization if the dimension is small and the work per thread varies as a function of $\Lambda$.

In practice, we implement both approaches within ENSCORE for the 4PCF and 5PCF, and compare their performance in §5.3. Schematically, the action of the GPU-parallelized code is the following:

- For each primary position $i$, compute $a_{\ell m}^b$ on the CPU.
- Copy the $a_{\ell m}^b$ array to the GPU.
- For each multiplet $\Lambda$ and set of bin-indices $B$, compute the contribution to $\zeta^b$ on the GPU.
- After all primary particles have been processed, copy the result back to the CPU.

The GPU kernels are launched a total of $N_g$ times. Due to the conditions on $\Lambda$, $B$ and $M$, it is non-trivial to relate the GPU thread index to the individual angular momentum and bin components; for this reason we first generate a look-up table for $\Lambda$, $B$ and (optionally) $M$, which is passed to the GPU on initialization. This additionally avoids any threads having to do only trivial work; for example we can ensure that any combinations that violate the triangle conditions are not included. Finally, we note that some commercially available GPUs are optimized for float-based calculations whilst others perform well using doubles. For this reason we consider three variants: (1) using double precision at all times (as for the CPU calculation), (2) using single precision only, and (3), using single precision for the $a_{\ell m}^b$ arrays, but adding to the NPCF as a double. The performance of each variant is compared in §5.3.

4.2 Reconstructing the Full NPCF

§4.1 presented a detailed discussion of how to compute the NPCF multiplets for a given set of input particles. We now consider the practicalities of computing the full geometry-corrected NPCF, as outlined in §3.3.

For this purpose, we require two fields: the data (galaxy positions), $D(r)$, and randoms (unclustered particles), $R(r)$ (cf. 37). The latter are used to compute the normalization term $\mathcal{R}_{\Lambda}^B$ appearing in (42); this requires a straightforward application of estimator (34). For the second term, $N_{\Lambda}^B$, we first compute a joint ‘data-minus-randoms’ field by combining the data and random catalogs together (following Slepian & Eisenstein 2015). Randoms are assigned negative weights and normalized such that the summed weight is zero. The multiplets of this field give $N_{\Lambda}^B$ directly.\(^{10}\)

In practice, the random catalog $R(r)$ contains many more particles than the data to minimize the inherent Poissonian errors. Slepian & Eisenstein (2015) and Keihanen et al. (2019) advocate splitting the random catalog into subsets, each of size $\sim 1.5 \times 2 \times$ that of the data, and co-adding the $N_{\Lambda}^B$ counts for each; if the computation time is quadratic in the number of particles, this minimizes the work required for a given

\(^{10}\) An additional method to compute $N_{\Lambda}^B$ is to expand the numerator of (38) into separate terms, each involving just data or randoms. Schematically, one writes

$$N_{\Lambda}^B = \left( D_R N_{\Lambda}^B \right) + \left( N^{N-1} R_{\Lambda}^B \right) + \cdots + \left( D R^{N-1} N_{\Lambda}^B \right),$$

where $\{X_1, X_2, \ldots, X_N\}_{\Lambda}^B$ are the multiplets of $N$ input fields $X_1, X_2, \ldots, X_N$. This is analogous to the standard procedure for the 2PCF computation (using $DD$, $DR$, and $RR$ counts), but somewhat inefficient here, since it requires significant recomputation.
level of Poisson noise.\footnote{For periodic-box geometries, it is possible to partially remove the dependence on random catalogs, as discussed in Pearson & Samushia (2019), Sosa Nuñez & Niz (2020) and Philcox (2021).} Whilst appropriate for the 3PCF, the runtime of \textsc{encore} when applied to higher-point statistics is usually found to scale linearly with the number of particles (cf.\S5.2), thus there is no gain to such a split. It is retained in \textsc{encore} for full generality however, leading to \~32 separate catalogs if one uses randoms with 50x the galaxy density. Given that the $a^b_{\ell m}$ contributions from the data must be included in each split, the approach is somewhat inefficient; to avoid this, we include the functionality to save and reload the histogrammed Cartesian powers of positively-weighted (data) particles. Finally, we note that, since the $\mathcal{R}_A^B$ counts use only positively weighted particles, their intrinsic noise is much reduced, thus it is sufficient to use only a single random partition for their computation.

Given the estimated $\mathcal{R}_A^B$ and $N^B_\Lambda$ quantities (averaged over the random subsets), we can compute the full edge-corrected NPCF via \eqref{eq:fullNPCF}. To form the coupling matrix $M_{\Lambda \Lambda'}$ we require the generalized Gaunt integrals of \eqref{eq:gaunt}; these involve Wigner 9-\textit{j} symbols and can be straightforwardly precomputed for a given $\Lambda$ and $\ell_{\text{max}}$ using the \textsc{python} \textsc{sympy} package. For simplicity, the entire edge-correction procedure is performed in \textsc{python}, and involves a matrix inversion for each radial bin combination $B$. In the case of a periodic box geometry, the edge-correction is trivial, and we use the analytic $\mathcal{R}_A^B$ functions of \eqref{eq:RAB}. To facilitate general use of the \textsc{encore} code, we provide a \textsc{bash} (or \textsc{slurm}) script to automate the entire process of computing raw NPCF multiplets and applying edge-correction, allowing for the full NPCF estimates to be obtained given the data and random particle positions.

5 RESULTS

We now present results from applying the NPCF estimators of \S3 to data, considering both scalings with computational resources and particle number density, as well as a demonstration of the edge-corrected 4PCF and 5PCF of realistic simulations.

5.1 Comparison to Brute-Force NPCF Estimators

Given the complexity of the \textsc{encore} algorithm (\S3 \& \S4), it is important to test whether the code returns accurate estimates of the $N$-point functions. For this purpose, we compared the NPCF multiplets output by \textsc{encore} to those computed via a brute-force approach. To form such estimates, we compute $\zeta_A^B$ directly, as a sum over $N_g$ particles weighted by the relevant basis function:

$$\zeta_A^B = \sum_{i_1, \ldots, i_N} \mathcal{P}_A^B (\mathbf{r}_{i_2} - \mathbf{r}_{i_1}, \ldots, \mathbf{r}_{i_N} - \mathbf{r}_{i_1}) \Theta^{b_1}(|r_{i_2} - r_{i_1}|) \cdots \Theta^{b_N}(|r_{i_N} - r_{i_1}|),$$

where $\mathbf{r}_i$ is the position vector of particle $i$, and $\Theta^{b}(r)$ are binary binning functions, as in \S3.2. This is simply the definition for the NPCF multiplets \eqref{eq:mult} for discrete data, with the addition of binning. Since it involves a sum over $N \Lambda$ particles, it has complexity $O(N^g_\Lambda \Lambda)$. To evaluate the angular basis functions, we use the Cartesian forms given in Cahn \& Slepian (2020, Appendix A); for example, $\mathcal{P}_{110}^g(g_1, g_2, g_3) = -\sqrt{3}(4\pi)^{-3/2}(f_1 \cdot f_2)$. This approach is prohibitively slow for large $N_g$, thus we use only $N_g = 20$ as a test case. In our case, the two approaches agreed to machine precision for all $\Lambda$ considered and $N$ in $\{3, 4, 5, 6\}$. Since this approach knows nothing about spherical harmonics or angular momenta, the precise agreement affords us confidence in the validity of \textsc{encore}.

5.2 Scalings

The algorithm described in \S4 contains two computationally intensive steps. These have the following scalings:

- **Computation of $a_{\ell m}^b(s)$**: This requires a count over all pairs of galaxies separated by distances within a spherical shell $[r_{\text{min}}, r_{\text{max}}]$; as such, the work scales as $N^g \times \bar{n} \left(r_{\text{max}}^3 - r_{\text{min}}^3 \right)$ for (galaxy or random) number density $\bar{n}$ and total number $N_g$, i.e. it is quadratic in the total number of particles if $\bar{n}$ is fixed. Computation of each count requires accumulation of $(1 + \ell_{\text{max}})(2 + \ell_{\text{max}})(3 + \ell_{\text{max}})/6$ powers of $\Delta^b_\Lambda \Delta^b_{\Lambda'} \Delta^c_\Sigma$ (cf.\S4.1), thus runtime is cubic in $\ell_{\text{max}}$ and linear in $N_r$. Note that this is independent of the NPCF order, $N$.

- **Accumulation of $\zeta_A^B$**: For each $\Lambda$ and $B$, we must sum over all $M$ indices for $(N - 1)$ harmonic coefficients. Since this must be performed for each primary position, computation time scales as $N^g \equiv \bar{n}V$. Restricting to bins with $b_1 < b_2 < \ldots < b_{N - 1}$, there are $(N - 1)!$ combinations contained in $B$, with $(N - 2)$ independent $M$ elements for each of $(2N - 5)$ choices for $\Lambda$ (cf.\S3.2.3). This implies the asymptotic scaling is of the form $\ell_{\text{max}}^{3N - 7} N^{N - 1} r^{-1}$, which is a strong function of $\ell_{\text{max}}$.

Given this, we expect the runtime of \textsc{encore} to scale as $N^2_\Lambda$ for dense samples at low $N$ (as found in Friesen et al. 2017), or $N^g_\Lambda$ for higher-point functions with fewer particles, or those with a large number of bins.

To test the above, we compute the parity-even NPCF for a synthetic box of galaxies at different mean densities $\bar{n}$. We use a cubic box with $L_{\text{box}} = 1500h^{-1}\text{Mpc}$, populated with randomly placed galaxies of varying number density from one-tenth to ten times that of BOSS CMASS (Alam et al. 2015; cf.\S5.4). The pair counts are computed on a 16-core machine in periodic mode (cf.\Tab.1), using $\ell_{\text{max}} \in \{10, 10, 5, 3\}$ for $N \in \{3, 4, 5, 6\}$ respectively. The maximum multipole is varied between samples to keep the dimensionality of the statistics reasonable, but the number of radial bins is fixed to $N_r = 10$; here, the dimensionality of $B$ and $\Lambda$ is $\{46, 123, 215, 259\}$.
Figure 1. Scaling of the encore code with the mean number density of the sample, when run in 3PCF, 4PCF, 5PCF and 6PCF mode with 10 radial bins. As described in §5.2, the galaxy sample is simply a set of uniformly distributed points in a periodic box. The scaling is close to quadratic (linear) with number density and hence particle number $N_g$ for the 3PCF (4PCF and above), as expected. The dotted (dashed) lines show quadratic (linear) relationships, anchored through the highest number-density sample. Note that the maximum multipole, $\ell_{\text{max}}$, is varied to keep the dimensionality of the output reasonable; its value is indicated by the caption in each case. All calculations are performed on sixteen 2.4 GHz Intel Skylake CPUs, parallelized using OpenMP. We show only results computable within 16 hours of wall-clock time.

and $\{6, 381, 1211, 1558\}$ respectively, incorporating all triangle and binning conditions. The total dimension is the product of these, i.e. approximately $\{280, 4.7 \times 10^4, 2.6 \times 10^5, 4.0 \times 10^5\}$ elements respectively. The run-times, $T$, of encore for each setup are shown in Fig. 1.

Notably, the four and higher-point algorithms follow closely a $T \sim N_g^2$ scaling (noting that $N_g \propto \bar{n}$, since $V$ is fixed). The 3PCF exhibits a quadratic scaling $N_g^2$ at high $\bar{n}$, though is closer to linear for low density samples. Given the above discussion on the limiting steps of each algorithm, this is as expected. Furthermore, the low-$\bar{n}$ plateau of the 3PCF is due to other processes from Algorithm 1 that become important, such as the loading of galaxies and coupling weights into memory and the particle neighbor searches. At much larger $\bar{n}$, we may expect the 4PCF to scale as $N_g^2$, as it becomes limited by the same processes as for the 3PCF. Due to the prohibitive $N_g^{N-1} \ell_{\text{max}}^{3N-7}$ scaling of the $\bar{\xi}_\ell^B$ accumulation step, the quadratic scaling is unlikely to occur for higher-point functions at any reasonable $\bar{n}$.

It is also useful to quantify how well the encore algorithm can be parallelized. To this end, we rerun the analysis used to create Fig. 1 at $\bar{n} \approx 1.5 \times 10^{-4} h^3 \text{Mpc}^{-3}$, but on a varying number of CPU threads. The results are shown in Fig. 2 and the conclusion is straightforward; the algorithm exhibits almost perfect scaling with the number of cores. This is as expected; as discussed in §4.1.2, the OpenMP implementation parallelizes the sum over all primary particles, each of which is independent (and holds its own copy of the NPCF sum), except for look-ups in the shared particle grid. We note that the code does not currently include Message Passing Interface (MPI) parallelization; whilst this could lead to further speed boosts and distribute the work across multiple nodes, it is expected that a more useful application of these resources would be to compute separate $N_A$ counts (cf.42), or the NPCF estimates of different simulations. Fig. 2 may also be used to examine the dependence of the runtime on $\ell_{\text{max}}$. The ratio of $\ell_{\text{max}} = 10$ to $\ell_{\text{max}} = 5$ takes the values $1.9 \pm 0.1, 11.5 \pm 1.1$ for the 3PCF and 4PCF; this is somewhat better than the scalings discussed above, indicating the asymptotic limit (i.e. the scalings for $\ell_{\text{max}} \gg 1$) has not yet been reached.

5.3 GPU Testing

We now consider the test encore’s GPU implementation. As in §4.1.3, GPUs are currently used to expedite the accumulation of the $\bar{\xi}_\ell^B$ arrays for each primary particle, given $d_{\ell m}^B(s_i)$ coefficients computed on the CPU. Two approaches are possible: (a) each GPU thread can sum over all $M$ for a given $\Lambda$ and $B$, or (b) each GPU thread can compute contributions from a single set of coefficients $M$ (requiring atomic memory access). To test these, we use the same setup as §5.2, except with $\bar{n}$ fixed to the lowest value of $1.5 \times 10^{-5} h^3 \text{Mpc}^{-3}$ for speed (recalling that the higher-point functions scale linearly with $\bar{n}$). The 4PCF and 5PCF are then computed both on the CPU and GPU, using an Nvidia P100 chip for the latter, and the runtimes are shown in Tab. 2.

For the 4PCF at $\ell_{\text{max}} = 5$, computation is far faster for the 16-core CPU code than for the GPU-accelerated version. This occurs since the GPU code uses only a single CPU to compute the $d_{\ell m}^B$ harmonic coefficients, which become rate-limiting for low $N$ and $\ell_{\text{max}}$. Testing the GPU implementation against such a parallelized CPU code is a reasonable test however, given that GPUs are currently a scarcer resource for most high performance computing systems, though this is subject to change. For $\ell_{\text{max}} = 10$, we find a slight preference for the GPU code, which is much increased if one considers the 5PCF. Indeed, the GPU implementation is able to provide speed-ups of $O(8\times)$ for the latter case.
On newer GPU chips such as the A100 series,\textsuperscript{12} we expect the performance to increase significantly. This is possible since the primary particle loops entering Algorithm 3 are distributed across a large number of threads. For the P100 chip used herein, we have 3584 \texttt{CUDA} cores, each with up to 2048 threads, allowing a maximum of \( \sim 7.3 \times 10^6 \) threads to be run in parallel. The A100 chip has 6912 \texttt{CUDA} cores and, moreover, as each individual core is faster, Nvidia claims an order of magnitude speed-up for HPC applications.\textsuperscript{13}

Table 2 also allows us to compare the different GPU modes discussed in \S 4.1.3. For the 4PCF test-cases, we find comparable runtimes between cases (a) and (b). Case (a) uses a much smaller number of tasks of unequal length (8 280 or 45 720 for \( \ell_{\text{max}} = 5 \) or 10), whilst case (b) launches a far greater number of tasks (135 120 or 2 499 480 respectively), but requires atomic memory access (to ensure that no two threads access the same memory location concurrently). Whilst the first case does not come close to fully utilizing the GPU resources (since the number of tasks launched is significantly below the number that can be simultaneously performed on the GPU), atomic addition does not have to be performed, compensating for the inefficiency. In fact, the degree of similarity suggests that memory access of the NPCF array is the main limiting factor in this case. For the 5PCF, we note a different story; case (a) is \( \sim 2 - 3 \times \) faster than case (b), even though the number of tasks is much reduced (295 260 instead of 29 606 430, cf. \S 3.2.3). This is unsurprising since the 5PCF array is of much higher dimension than the 4PCF, thus we utilize a good fraction of the available GPU threads in case (a), while in case (b) we vastly exceed maximum parallelization; \textit{i.e.}, the number of tasks is larger than the maximum number of threads that can be processed in parallel. Above this threshold, we cease to realize additional speed gains so the difference in number of parallel threads is not large enough to overcome the speed penalty of atomicity.

We finally comment on the dependence of computation-time on precision (cf. \S 4.1.3). Most consumer-grade GPUs are optimized for float-based calculations, thus one might naively expect a significant performance increase when lower precision is used in the GPU kernels; indeed

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
\textbf{Mode} & \textbf{Wall-clock time (4PCF, \( \ell_{\text{max}} = 5 \))} & \textbf{Wall-clock time (4PCF, \( \ell_{\text{max}} = 10 \))} & \textbf{Wall-clock time (5PCF, \( \ell_{\text{max}} = 5 \))} \\
\hline
CPU (16-core) & 4.8 & 58.8 & 741.8 \\
GPU-a (double) & 31.1 & 41.5 & 86.1 \\
GPU-a (float) & 21.9 & 38.4 & 74.3 \\
GPU-a (mixed) & 22.0 & 38.6 & 77.2 \\
GPU-b (double) & 30.1 & 43.3 & 177.7 \\
GPU-b (float) & 23.9 & 42.7 & 202.8 \\
GPU-b (mixed) & 30.6 & 41.2 & 159.6 \\
\hline
\end{tabular}
\caption{Runtimes of the \textsc{encore} GPU code for the 4PCF and 5PCF using \( N_r = 10 \) radial bins and \( \ell_{\text{max}} = 5 \) or 10. In each case, we use a synthetic dataset containing \( 5 \times 10^4 \) uniformly distributed particles in a periodic box of side-length \( L = 1500h^{-1}\text{Mpc} \) (corresponding to one-tenth of the BOSS CMASS density), and count pairs of particles up to \( r_{\text{max}} = 200h^{-1}\text{Mpc} \). All computations are performed on a single P100 Nvidia GPU coupled with an Intel Xeon Broadwell CPU. We give results for each of the GPU modes detailed in \S 4.1.3; these vary whether the \( M \) summation is distributed across threads and what level of precision is used for intermediate calculations. For comparison, we give also the timings from the CPU code using a 16-core Intel Skylake node, parallelized using \texttt{OpenMP}. All times are reported in seconds.}
\end{table}

\begin{figure}
\centering
\includegraphics[width=\textwidth]{scaling.png}
\caption{Strong scaling of the \textsc{encore} code: dependence of runtime, \( T \), on the number of CPU cores on a single node, for the test cases considered in Fig. 1, fixing \( \tilde{n} \approx 1.5 \times 10^{-4} \). Dashed lines indicate linear relationships, and are calibrated at the single-CPU time. Results are shown for \( N = 3 \) and \( N = 4 \) with two choices of \( \ell_{\text{max}} \). The code exhibits close-to-ideal parallelization, as shown by the linear trends. This extends also to higher order. As expected, the runtime increases significantly when \( \ell_{\text{max}} \), and thus the number of multiplets \( \Lambda \), is increased. The 3PCF results deviate slightly from the linear relationship when using 32 CPUs; this occurs since we become limited by other processes such as data loading.
}
\end{figure}
this was found in preliminary testing on commercially-available GeForce GTX 1660 architectures where ‘float’ mode was found to be ~8x faster than ‘double’ mode. However, many research-grade data center GPUs are optimized for double-precision calculations. We observe this in practice, as we do not find a particularly large improvement in efficiency on the Nvidia P100 GPUs; at most the runtime decreases by ~30%, though this depends on the precise kernel. We caution that reducing the precision of the GPU calculation necessarily leads to errors in the final result; for the 4PCF in ‘float’ (‘mixed’) mode, the average fractional error is ~3 × 10⁻³ (1 × 10⁻⁵), increasing to ~2 × 10⁻² (7 × 10⁻⁵) for the 5PCF.

5.4 Application to Mock Catalogs

Finally, we apply the NPCF estimators of this work to realistic simulations of galaxy surveys. Here, we use a set of 10 MultiDark-Patchy mocks (Kitaura et al. 2016; Rodríguez-Torres et al. 2016) constructed for the Baryon Oscillation Spectroscopic Survey (BOSS) (Dawson et al., 2013), using the twelfth data release (DR12) of SDSS-III (Eisenstein et al. 2011; Alam et al. 2015). Presentation of the full BOSS 4PCFs will follow in Philcox et al. (prep). The MultiDark-Patchy mocks are constructed using approximate gravity solvers, calibrated to an N-body simulation (Klypin et al. 2015). Here, we use the northern Galactic cap (NGC) CMASS sample (hereafter CMASS-N), containing ~6 × 10⁵ galaxies with mean density $\bar{n} \sim 1.5 \times 10^{-4} h^3$ Mpc⁻³ at an effective redshift of $z_{\text{eff}} = 0.57$. To use the NPCF estimator of (38), we require also the random field $R(r)$; for this we use a public random catalog, containing 50 times the galaxy density. As in §4.2, this is split into 32 disjoint subsets, enhancing the computational efficiency for small $N$.

To give insight into the performance of the algorithm on real data, we first consider the runtime of the various sections of the NPCF computation in Algorithm 1 for a single ‘data-minus-random’ chunk. This is performed for both the 3PCF and 4PCF in 10 linearly-spaced radial bins up to $r_{\text{max}} = 200 h^{-1}$ Mpc, using $\ell_{\text{max}} = 5$ or 10 and skipping any odd-parity modes. This gives a total of 270 (495) correlation function components for the $\ell_{\text{max}} = 5$ (10) 3PCF, and 13, 320 (80, 520) for the 4PCF, as in §3.2.3. The code is run on a 16-core node with a 2.4 GHz Intel Skylake processor (without GPU acceleration), and requires a wall-clock time of 36 s to compute both the 3PCF and 4PCF multipoles up to $\ell_{\text{max}} = 5$, or 291 s with $\ell_{\text{max}} = 10$.

Fig. 3 shows the timing breakdown for the above samples. We immediately note that the computation time is dominated by the two processes highlighted in §4.1.1: estimation of $d^b_{\ell m}(s_i)$ at each primary particle position and their combination (summing over $M$) to form the $N_A^B$ basis coefficients. For the 3PCF, the former is rate-limiting (as in Slepian & Eisenstein, 2015), whilst for the 4PCF, the bin-summations start to become important, particularly as $\ell_{\text{max}}$ (and thus the number of $m$ indices) increases (cf. §5.2). Indeed, for moments beyond the 4PCF, virtually all computation time is spent in this procedure, thus the algorithm is expected to scale linearly with $N_g$, as found in Fig. 1. In practice, much of the time is spent loading the various harmonic coefficients elements into memory, rather than performing the actual addition into the NPCF sum itself. For $\ell_{\text{max}} = 10$, and $N_g = 10$, we have 660 complex elements in $d^b_{\ell m}(s_i)$, with a total size of 10.3 kB in double precision. This can comfortably fit within the 64 kB L1 cache of the Intel Skylake processors, which allows for the fastest memory access (though this is not true for the much larger NPCF array).

Next, we consider estimation of the NPCFs themselves, including edge-correction. Here, we will present only the isotropic 4PCF and 5PCF, given that the 3PCF has been presented elsewhere (e.g., Slepian & Eisenstein, 2017b). As before, we use $N_g = 10$, but restrict to $\ell_{\text{max}} = 5$ ($\ell_{\text{max}} = 3$) for the 4PCF (5PCF) to keep computation times reasonable. This leads to 69 (204) unique multiplets $\Lambda$ and 120 (210) bin combinations $B$ for the 4PCF (5PCF), giving a total of 8, 280 (42, 840) elements. Whilst this is certainly large, it is still much smaller than the number of galaxies in the survey, which is a practical upper-limit to the number of useful bins, if all are independent. As in §4.2, we compute and average $N^B_A$ for all 32 data-minus-random splits as well as the normalization $\mathcal{R}^B_A$ for a single chunk, before forming the edge-correction matrix $M_{\Lambda\Lambda'}^B$ of (41) and solving for $\zeta_{\ell m}$ using (42). Using the CPU code on 16 Skylake cores, each split requires ~1 (4) CPU-hours for the 4PCF (5PCF) computation, thus the entire statistic can be estimated in ~30 (120) CPU-hours. The short computation time means that, in a real analysis, many mocks can be analyzed within the confines of standard computational allocations. Furthermore, estimating the 4PCF multiplets requires only twice as much computation time as estimating the 3PCF, for the same $\ell_{\text{max}}$.

The edge-correction matrices, $M_{\Lambda\Lambda'}^B$ (41), corresponding to the above scenarios are shown in Fig. 4. The coupling matrix is a function of bin $B$; as expected, the coupling strength increases with the radial bin value since the CMASS survey window function is smooth except on the largest scales. For this reason we plot only the final radial bin. In both the 4PCF and 5PCF, the off-diagonals couple between different angular momenta are small, at most 7% (5%) for the 4PCF (5PCF), consistent with that found for the 3PCF in Slepian & Eisenstein (2015). Whilst Fig. 4 shows a matrix with non-trivial structure, almost all the largest couplings are found in closely separated multiplets $\Lambda$ and $\Lambda''$, i.e. those with $|\ell_i - \ell_j| \leq 1$. This motivates the earlier statement (§3.3) that, by measuring all multiplets up to some $\ell_{\text{max}}$, we obtain accurate NPCF measurements up to $(\ell_{\text{max}} - 1)$.

Finally, we come to the NPCF measurements themselves. Given that the statistic dimensionality is large, we here plot only a selection of $\Lambda$ multiplets, but include all radial bins, collapsed into one-dimension. Fig. 5 shows the measured 4PCF multiplets for the mean of 10 MultiDark-Patchy mocks, and we immediately note that there is a strong signal in some components, particularly $\Lambda = \{0,0,0\}, \{0,3,3\}$ and $\{2,0,2\}$, but a much weaker one in others, e.g., $\Lambda = \{3,3,2\}$. It is important to stress that the trends in Fig. 5 do not indicate a strong detection of non-Gaussianity; we must remember that the 4PCF contains both a disconnected contribution (from the product of two 2PCFs) and a connected component, as in (25). The former is sourced by Gaussian statistics, and would be present even in the absence of non-Gaussianity; before binning, this information is fully degenerate with the 2PCF. For an isotropic Gaussian universe, the disconnected term contributes only to multiplets of the form $\Lambda = \{0,\ell,\ell\}$ and permutations (Philcox et al. prep), thus the non-zero elements of $\Lambda = \{1,1,2\}$ observed at small
radius give evidence for violations of isotropy or Gaussianity; here they are primarily an indication of redshift-space distortions. This will be discussed in depth in Philcox et al. (prep), alongside a modified estimators that entirely remove the Gaussian contribution.

Fig. 6 shows the analogous results for a selection of 5PCF multiplets. Again we note that some multiplets show a strong signal whilst others are noise-dominated; in contrast to the 4PCF, the disconnected term now involves the product of a 2PCF and 3PCF, thus Fig. 6 does represent a robust detection of non-Gaussianity, albeit primarily in the 3PCF. A modified estimator may be derived to compute the connected-only 5PCF, as for the 4PCF. Analysis of the exact 5PCF shapes is beyond the scope of this work. However, we note a general trend of decreasing amplitude as the central bin values, $\bar{r}$, increase. Since late-time non-Gaussianity is usually concentrated on small scales, this is as expected.

6 SUMMARY

Correlation functions form the cornerstone of modern cosmology, and their efficient computation is a task of utmost importance for the analysis of current and future galaxy surveys. In this work, we have presented new algorithms for the estimation of the isotropic $N$-point correlation functions (NPCFs) for arbitrary order $N$. Making use of recently developed isotropic basis functions (Cahn & Slepian 2020), the estimator can
be written in factorizable form and has complexity $O(N_g^2)$ for $N_g$ particles. Furthermore, the output statistics are geometry-corrected and form a natural split into parity-even and parity-odd modes. The approach may be additionally generalized to homogeneous and isotropic spaces of arbitrary dimension, as discussed in our companion work (Philcox & Slepian prep).

We provide a public code, encore\textsuperscript{14}, with which the isotropic 3PCF, 4PCF, 5PCF and 6PCF can be efficiently computed. The algorithm performs two major steps; a weighted pair-count over galaxies to compute $\ell m$ harmonic coefficients in radial bins $b$ for angular momentum coefficients $\ell, m$, and a summation over the $m$ indices of $(N-1)$ such harmonic coefficients to form the NPCF. Whilst the former scales as $N_g^2$, the latter has $O(N_g)$ complexity, and is often found to be rate-limiting for $N > 3$, particularly if the number of bins is large. In many cases, our estimator scales linearly with the number of galaxies. We have provided detailed discussion of the encore code, including its implementation in C++ and CUDA, with the latter allowing for GPU acceleration. Furthermore, results for the 4PCF and 5PCF of realistic mock catalogs have been presented; these are amongst the first of their kind. The efficiency of our approach allows them to be quickly estimated; each required $\sim 30$ (150) CPU-hours in our test. Such methods will allow information to be extracted from the higher-point functions from upcoming surveys such as DESI and Euclid.

A number of avenues present themselves for future work. These include:

- **Theory Model**: To place constraints on cosmology from the NPCFs, we require a robust theory model. Whilst straightforward for the Gaussian contributions, the non-Gaussian pieces are more difficult to treat and must be modeled perturbatively or with simulations.

- **Covariance**: Due to the increase in complexity of the basis functions as $N$ increases, the covariance matrices of the NPCF statistics are non-trivial, even in the isotropic and Gaussian limit. However, computing analytic covariances is of importance since the statistics are high-dimensional, prohibiting a full mock-based covariance. The Gaussian covariances will be presented in Hou et al. (prep).

- **Connected Estimators**: For $N > 3$, the NPCFs contain both disconnected and connected contributions (cf. §3.1). The former simply repeats information from the lower-point functions, and is not cosmologically relevant. Analyses of the higher-point functions must either model or subtract the disconnected pieces. A connected-only 4PCF estimator will be presented in Philcox et al. (prep).

- **Application to Data**: The techniques developed in this work allow computation of the edge-corrected NPCFs of survey data. Coupled with the connected-only estimator and Gaussian covariance matrices, this will allow the first estimation of the non-Gaussian higher-point functions from data. Furthermore, consideration of the parity-odd multiplets provides a test for parity-violation in the late Universe. Application to the BOSS galaxy survey will be considered in Philcox et al. (prep).

- **Gridded Estimator**: Whilst the efficient estimator developed in §3 applies to both gridded and discrete density fields, only the latter

\textsuperscript{14} github.com/oliverphilcox/encore

Figure 4. Edge-correction matrices $M_{\Lambda\Lambda'}^B$, for the 4PCF and 5PCF analyses of realistic \textsc{MultiDark-Patchy} simulations. As described in §3.3, these matrices give the couplings between multiplets due to the non-uniform survey geometry and are independent of the data itself. The horizontal and vertical axes give the indices of the $\Lambda$ and the $\Lambda'$ multiplets respectively, each of which specifies the angular momentum coefficients $\ell_1, \ell_2, \ldots, \ell_{N-1}$. These are arranged in ascending order with the last element of $\Lambda$ varied first, and we omit any multiplets that do not satisfy the triangle conditions or are parity-odd, i.e. the first few terms are $\Lambda = \{0, 0, 0\}, \{0, 1, 1\}, \{0, 2, 2\}, \ldots \{1, 0, 1\}, \{1, 1, 0\} \ldots$ for the 4PCF. We show the matrices corresponding to the largest radial bin, since this contains the largest-amplitude correlations; the mean radius in each dimension is shown in the caption. The maximal off-diagonal coupling (in the $\Lambda - \Lambda'$ plane) ranges from 0.007 to 0.06 (0.009 to 0.05) for the 4PCF (5PCF). The edge-correction matrices are normalized by $(4\pi)^{(N-1)/2}$ with the unit matrix subtracted, such that all values would be zero for a periodic box geometry. Note that the couplings between multiplets are small in all cases, and further, that, for any given $\ell_{\text{max}}$, we do not find significant couplings between any multiplets with $|\ell_i - \ell_j| > 1$. 

\begin{align*}
(\hat{r}_1, \hat{r}_2, \hat{r}_3) = (150, 170, 190) \, h^{-1}\text{Mpc} \\
(\hat{r}_1, \hat{r}_2, \hat{r}_3, \hat{r}_4) = (130, 150, 170, 190) \, h^{-1}\text{Mpc}
\end{align*}
Figure 5. Edge-corrected 4PCF multiplets $\zeta_{\Lambda}^B$ measured from 10 MultiDark-Patchy simulations for five choices of the multiplet index $\Lambda = (\ell_1, \ell_2, \ell_3)$. We show the mean value (solid lines), and 1σ errors (shaded regions) in all cases. For each $\Lambda$, there are 120 choices of radial bin indices $B = (b_1, b_2, b_3)$; the top panel shows the linearly-averaged value of the radial bin, $\bar{r}$, corresponding to each. Succeeding panels show the individual multiplet estimates (normalizing by $\bar{r}_1 \bar{r}_2 \bar{r}_3$), with the value of $\Lambda$ shown in the caption. Using $\ell_{\text{max}} = 5$, there are 69 such multiplets, of which only five are shown. The 'sawtooth' pattern of the 4PCF multiplets occurs due to the non-smooth variation in radial bins; a consequence of plotting a high-dimensional statistic in 1D. We note that the 4PCF contains both disconnected (Gaussian) and disconnected (non-Gaussian) contributions (cf. §3.1), thus much of this result is simply a detection of the 2PCF. All results are computed using 10 radial bins in the range $[0, 200] h^{-1} \text{Mpc}$ on a 16-core Intel Skylake machine. To compute and edge-correct the 4PCF in all multiplets $\Lambda$ and bins $B$ for ten simulations, a total of 284 CPU-hours was required.
Figure 6. As Fig. 5 but for the 5PCF. As before, the first panel shows the bin-centers for each of the 210 radial bin combinations $B = \{b_1, b_2, b_3, b_4\}$, whilst the remaining plots give the measured multiplets $\zeta^B_{\Lambda}$ with $\Lambda = (\ell_1, \ell_2, (\ell_1 \ell_2), \ell_3, \ell_4)$. Restricting to $\ell_{\text{max}} = 3$, there are 204 such multiplets. As for the 4PCF, the signal is dominated by the disconnected contribution, here sourced by the product of a 2PCF and 3PCF. The total runtime for all 10 5PCF estimates was 1488 CPU-hours.
is included in enCORE. Developing a gridded estimator (possible via FFTs) will allow fast analysis of high-density data and application to other contexts such as hydrodynamical simulations. This can be built upon the code of Portillo et al. (2018), which presented a gridded 3PCF estimator for analysis of the turbulent ISM.

- **Anisotropic NPCFs**: Whilst we have focused only on the isotropic case in this work, anisotropic NPCFs also contain information. We expect a similar approach to allow estimation of these statistics, using a generalized angular momentum basis. This is briefly discussed in Philcox & Slepian (prep).

- **CMB Estimators**: A similar prescription to the above may be used to compute \( N \)-point functions on the 2-sphere. This will allow estimation of CMB \( N \)-point functions from \( N_{\text{pix}} \) pixels in \( O(N_{\text{pix}}^2) \) time, and is detailed in Philcox & Slepian (prep).

To close, we briefly reflect on the justification for measuring higher-order NPCFs, and possible alternatives. As is well-known, the process of density field reconstruction (e.g., Monaco & Efstathiou 1999; Mohayaee et al. 2006; Eisenstein et al. 2007; Noh et al. 2009) shifts information from the high-point functions back to the 2PCF (Schmittfull et al. 2015) by reducing long-wavelength displacements. Given that it has become customary for survey analysis pipelines to implement BAO reconstruction (e.g., Padmanabhan et al. 2012; Beutler et al. 2017a; Vargas-Magaña et al. 2018; Philcox et al. 2020), one must ask whether there remains any utility in the unreconstructed higher-point functions. As shown in Samushia et al. (2021), the information on parameters affecting the evolution of matter from its initial conditions, may be better measured by the combination of late-time NPCFs than the initial power spectrum (and hence reconstructed 2PCF). This occurs since these parameters appear in the forward model, rather than the initial conditions. In essence, our argument is that the combination of the reconstructed 2PCF with unreconstructed NPCFs of higher order provides more information, particularly on parameters such as the dark energy density, than either one alone.

Ours is not the only way to proceed. An alternative approach involves forward-modeling the entire density field from its initial conditions to today (Jasche & Wandelt 2013; Leclercq et al. 2019; Seljak et al. 2017; Feng et al. 2018; Horowitz et al. 2019), including the possibility of field-level inference (Schmittfull et al. 2019, 2020; Schmidt et al. 2020; Cabass & Schmidt 2020; Schmidt 2021). Such approaches naturally capture information present both in the initial conditions and the forward model, and are a promising new way to perform inference. That said, analysis of this kind is computationally expensive due to the high dimensionality of the problem and necessity to run a large number of forward-model simulations to perform any parameter inference, though various tricks are used to expedite this. In contrast, the more classical approach of measuring the NPCFs allows fasts inference once the summary statistics have been computed and stored. Indeed, any new cosmological model can be tested without remeasuring any statistics, unlike in the forward-modeling framework. With the methods discussed in this work, including higher-order statistics in future analyses, such as those of DESI, Roman, and Euclid, has become an attainable goal.

**DATA AVAILABILITY**

The data underlying this article will be shared on reasonable request to the corresponding author. The enCORE code is available at github.com/oliverphilcox/encore and the MultiDark-Patchy mocks can be downloaded from data.sdss.org/sas/dr12/boss/lss/.

**ACKNOWLEDGMENTS**

The authors are pleased to acknowledge that the work reported on in this paper was substantially performed using the Princeton Research Computing resources at Princeton University which is consortium of groups led by the Princeton Institute for Computational Science and Engineering (PICSciE) and Office of Information Technology’s Research Computing.

**APPENDIX A: GENERALIZED GAUNT INTEGRALS**

We give the explicit forms of the generalized Gaunt integrals (15) used to construct the edge-correction equations in §3.3. The forms at arbitrary order can be constructed following Cahn & Slepian (2020, §6).

For \( N = 3 \), \( \Lambda = \{\ell, \ell'\} \), giving

\[
G^{\Lambda \Lambda \Lambda'} = \frac{1}{4\pi} \sqrt{2(2\ell + 1)(2\ell' + 1)(2\ell'' + 1)} \binom{\ell}{0} \binom{\ell'}{0} \binom{\ell''}{0}^2 ,
\]

(\text{A1})
which is just a rescaled version of the integral of three Legendre polynomials, viz. (17). For \( N = 4 \), \( \Lambda = \{ \ell_1, \ell_2, \ell_3 \} \), leading to

\[
\mathcal{G}^{\Lambda \Lambda \Lambda^*} = \frac{1}{(4\pi)^{3/2}} \left[ \sum_{\ell = 1}^{3} \sqrt{(2\ell + 1)(2\ell' + 1)(2\ell'' + 1)} \left( \begin{array}{ccc}
\ell_i & \ell_i' & \ell_i'' \\
0 & 0 & 0
\end{array} \right) \right] \times \left( \begin{array}{ccc}
\ell_1 & \ell_1' & \ell_1'' \\
\ell_2 & \ell_2' & \ell_2'' \\
\ell_3 & \ell_3' & \ell_3''
\end{array} \right),
\]

(A2)

where the \( 3 \times 3 \) matrix is a Wigner 9-\( j \) symbol (e.g., NIST DLMF, §34.6). Finally for \( N = 5 \), \( \Lambda = \{ \ell_1, \ell_2, (\ell_12), \ell_3, \ell_4 \} \), and we obtain

\[
\mathcal{G}^{\Lambda \Lambda \Lambda^*} = \frac{1}{(4\pi)^{4/2}} \left[ \sum_{\ell = 1}^{4} \sqrt{(2\ell + 1)(2\ell' + 1)(2\ell'' + 1)} \left( \begin{array}{ccc}
\ell_i & \ell_i' & \ell_i'' \\
0 & 0 & 0
\end{array} \right) \right] \times \left( \begin{array}{ccc}
\ell_1 & \ell_1' & \ell_1'' \\
\ell_2 & \ell_2' & \ell_2'' \\
\ell_3 & \ell_3' & \ell_3'' \\
\ell_4 & \ell_4' & \ell_4''
\end{array} \right),
\]

(A3)

now depending on two 9-\( j \) symbols.

**APPENDIX B: SIMPLIFICATION OF THE M SUMMATIONS**

Below, we outline a simplification of the \( M \) index summations necessary for the NPCF estimators. This reduces the computational requirements by a factor close to two. First, consider the summand of (34), which must be computed at the location of each primary particle:

\[
\mathcal{H}^B_\Lambda (s_i) = \sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i).
\]

(B1)

As noted in §2.3, the coupling coefficients \( C_M^\Lambda \) impose \( m_1 + \ldots + m_N = 0 \); this allows (B1) to be written as a sum of three pieces:

\[
\mathcal{H}^B_\Lambda (s_i) = \left( \sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i) \right) + \left( \sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i) \right)
\]

(B2)

Taking the final term and redefining \( m_i \to -m_i \), we find

\[
\sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i) = \sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i)
\]

(B3)

where we have used (6) and noted that \( Y_{\ell-m} (\hat{r}) = (-1)^m Y_{\ell} (\hat{r}) \), thus \( a_{\ell, m}^b (s_i) = (-1)^m a_{\ell, m}^b (s_i) \). The factor \( \prod_{j=1}^{N-1} (-1)^m = 1 \) by the summation rules. Combining (B3) with the first term in (B2) yields

\[
\left( \sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i) \right) = 2 \sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i),
\]

(B4)

defining the operator

\[
\mathcal{Q}_\Lambda [f] = \begin{cases} 
\text{Re} [f] & \text{if } E(\Lambda) = +1 \\
\text{Im} [f] & \text{if } E(\Lambda) = -1.
\end{cases}
\]

(B5)

Similarly, the second term in (B2) gives

\[
\sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i) = \sum_{m_1, \ldots, m_N = 0} E(\Lambda) C_M^\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i),
\]

(B6)

relabeling \( m_i \to -m_i \) and simplifying. Averaging the two yields the equivalent of (B4) but without the factor of 2. In concert, we obtain

\[
\mathcal{H}^B_\Lambda (s_i) = 2 \sum_{m_1, \ldots, m_N = 0} S(m_N) E(\Lambda) C_M^\Lambda \mathcal{Q}_\Lambda \prod_{j=1}^{N-1} a_{\ell_j m_j}(s_i),
\]

(B7)

where \( S(m) = 1/2 \) if \( m = 0 \) and unity else. This leads to a significant reduction in computation time and additionally makes manifest the notion that even-parity \( E(\Lambda) = +1 \) multiplets are real and odd-parity \( E(\Lambda) = -1 \) multiplets are imaginary.
