The Landau-Lifshitz equation governing magnetization dynamics is written in terms of the amplitudes of normal modes associated with the micromagnetic system’s appropriate ground state. This results in a system of nonlinear ordinary differential equations, the right-hand side of which can be expressed as the sum of a linear term and nonlinear terms with increasing order of nonlinearity (quadratic, cubic, etc.). The application of the method to nanostructured magnetic systems demonstrates that the accurate description of magnetization dynamics requires a limited number of normal modes, which results in a considerable improvement in computational speed. The proposed method can be used to obtain a reduced-order dynamical description of magnetic nanostructures which allows to adjust the accuracy between low-dimensional models, such as macrospin, and fully spatially discretized micromagnetic models. This new paradigm for micromagnetic simulations is tested for three problems relevant to the areas of spintronics and magnonics: directional spin-wave coupling in magnonic waveguides, high power ferromagnetic resonance in a magnetic nanodot, and injection-locking in spin-torque nano-oscillators. The case studies considered the validity of the proposed approach as a new systematic method to obtain an intermediate order dynamical model based on normal modes for the analysis of magnetic nanosystems. The time-consuming calculation of the normal modes has to be done only one time for the system. These modes can be used to optimize and predict the system response for all possible time varying external magnetic fields. This is of utmost importance for various applications where a fast and accurate system response is required, such as in electronic circuit simulation software where an accurate response of the magnetic device has to be predicted.

INTRODUCTION

Micromagnetism\(^1\),\(^2\),\(^3\) is the most effective theory to predict magnetization behaviour of systems, at micrometer and sub-micrometer length scales, relevant to magnetic information and communication technologies\(^4\), and to the related research areas of spintronics\(^5\) and magnonics\(^6\). A crucial role in the theory is played by the Landau-Lifshitz-Gilbert (LLG) equation\(^7\),\(^8\),\(^10\), the nonlinear partial differential equation governing magnetization dynamics, and its generalizations\(^9\),\(^11\),\(^12\). In most cases, LLG equation is solved numerically due to nonlinearities and nontrivial geometrical and physical features of micromagnetic systems\(^13\),\(^14\). This has given rise to the area of Computational Micromagnetics\(^15\)–\(^20\). There are special situations where the solutions of LLG can be obtained analytically. This is usually possible when the geometrical dimensions of the magnet are not much larger than the exchange length, a characteristic length below which magnetization is spatial uniform\(^21\), and the LLG dynamics can be described in a low-dimensional state space. This is the case of the macrospin model, in which magnetization is assumed to be spatially uniform, used in the studying of magnetization switching\(^22\),\(^23\), ferromagnetic resonance\(^24\),\(^25\), chaotic magnetization dynamics\(^26\) and noise induced transitions\(^27\) in magnetic nanosystems. Other special cases are those related to motion of domain walls or vortices which can be treated with the method of collective variables\(^29\),\(^28\), such as curling and buckling modes. Recently, also neuronal networks are utilized in order to predict magnetization dynamics, of systems that are trained with full micromagnetic simulations\(^30\) or with single domain simulations\(^31\). Except these notable cases, the solution of LLG is obtained by discretizing the body in a grid of small cells or finite elements, with linear dimensions smaller than the exchange length. The LLG equation is then reduced to a nonlinear many-body evolution problem in which the state variables are the magnetization vectors defined on the grid.

This paper presents a new computational micromagnetic approach that bridges the gap between low-dimensional modeling, such as the Stoner Wohlfarth model, and full spatial discretized LLG equation. It is a spectral method in which the degrees-of-freedom are not the magnetic moments associated with cells but the amplitudes of normal modes obtained by the linearized LLG equation around the reference (ground) state of the problem under-investigation\(^32\),\(^33\),\(^34\). Although the expression of LLG in terms of normal modes is mathematically equivalent to the original LLG, it turns out that in many situations of interest in the study of magnetic nanostructures, the confined nature of the problem leads to magnetization dynamics which can be described by a relatively small number of normal modes\(^35\). Thus, using the proposed spectral approach is possible to obtain reduced dimensionality numerical model, which can be solved more efficiently than usual fully discretized micromagnetic problems. The normal modes-based method is also related to spin-wave theory, in which the deviation of magnetization field from the ground state is decomposed into a sum of Fourier-like plane-waves\(^36\). This approach is very convenient for the theoretical analysis.
of linear waves propagation in extended magnonic structures\cite{37}. For confined structures, spin-wave theory is affected by the difficulty that plane-waves do not correctly take into account boundary conditions\cite{38,39}. Normal modes, on the other hand, are obtained by solving the appropriate eigenvalues problem which includes the correct boundary conditions\cite{34}. In addition, the normal mode formulation of LLG enables to naturally take into account nonlinear coupling between the modes. In this respect, the proposed approach allows extending the Suhl’s analysis for the bulk magnet of nonlinear coupling of spin-waves\cite{40,41} to the case of confined magnetic nanostructures.

We demonstrate the effectiveness of the proposed approach by studying nonlinear magnetization dynamics in three distinct magnetic structures which are relevant for applications in the emerging field of spintronics\cite{4}, namely: directional spin-wave mode coupling in a magnonic waveguide, high-power ferromagnetic resonance (FMR) in a rectangular magnetic nanodot, and synchronization in injection-locked spin-torque oscillator.

The paper is organized as follows. First, the normal modes-based nonlinear model is introduced in connection with the Landau-Lifshitz-Gilbert equation with Slonczewski spin-torque\cite{9} (LLGS). Then, it is shown that this model is able to make quantitative predictions on the aforementioned three magnetic systems using a small number of normal modes. These predictions are in very good agreement with full micromagnetic simulations. Finally, the advantages of the proposed model with respect to full micromagnetic simulations are discussed.

I. RESULTS

The main result of this work is the quantitative description of nonlinear magnetization dynamics in micromagnetic systems evolving around a given arbitrary (spatially inhomogeneous) ground state by using reduced-order models with incremental accuracy controlled by the number of involved degrees-of-freedom, whose role is played by selected magnetization normal modes (eigenmodes) \cite{34}. Such a description is mathematically formulated by the following system of coupled nonlinear ordinary differential equations, here and on called normal modes model (NMM):

\[ \dot{a}_h = \frac{j \omega_h}{1 + \alpha G} \left( b_h + \sum_i b_{hi}a_i + \sum_{i,j} c_{hij}a_i a_j + \sum_{i,j,k} d_{hijk}a_i a_j a_k + \sum_{i,j,k,l} e_{hijkl}a_i a_j a_k a_l + \sum_{i,j,k,l,m} f_{hijklm}a_i a_j a_k a_l a_m + \ldots \right) \]

(1)

where the unknowns are the complex amplitudes $a_h(t)$ of the normal modes $\phi_h$ and the coefficients (listed in table \[1\]) are derived in the section Methods starting from the Landau-Lifshitz-Gilbert equation including the Slonczewski spin transfer torque\cite{9} (LLGS). This model is conceptually equivalent to the LLGS equation in the continuum framework, but after discretization on a computational grid, it exploits the global interpolation power of spectral methods that are capable of reproducing complex spatial features of vector fields with a relatively small number of degrees-of-freedom, which here are given by the eigenmodes amplitudes $a_h$.

Differently from what happens for micromagnetic simulations where the number of the degrees-of-freedom reflects that of elementary magnetized cells, the NMM involves a preliminary computation of magnetization eigenpairs $(\omega_h, \phi_h)$ by solving suitable generalized eigenvalue problem (see table \[1\] or eq. (12) in Methods) which depends exclusively on material and geometrical parameters and is performed only once for a given system under investigation. The special nature of the generalized eigenvalue problem allows the determination of a prescribed number of eigenmodes\cite{34} using Arnoldi-like iterative methods using classical computational routines adopted within micromagnetic codes in a large-scale fashion. It is worthwhile to remark that this preliminary computation is independent from external forcing terms in LLGS equation (e.g. microwave field, spin currents, etc.). By using eigenpairs $(\omega_h, \phi_h)$ along with computational routines for computing the micromagnetic effective field, all the coefficients appearing in eq. (1) can be also efficiently computed in the set-up phase. In the following, we show that eq. (1) considering a limited number of normal modes and terms is able to reproduce with quantitative accuracy the results of full micromagnetic simulations. Moreover, we show that this description allows the development of general analytical formulas for magnetization dynamics which can be instrumental in potential optimization and design of magnetic technologies. In the sequel, the NMM is applied to the study of three model-problems in nonlinear magnetization dynamics which span relevant applications in the world of spintronics: nonlinear spin-wave coupling in a magnonic waveguide, high-power ferromagnetic resonance in a rectangular magnetic nanodot, and synchronization in injection-locked spin-torque oscillator. The sketches of these devices with their dimensions are shown in fig. \[4\]. The results obtained by NMM are compared with full-scale micromagnetic simulations of the investigated systems.
Landau-Lifshitz-Gilbert-Slonczewski (LLGS) equation (in dimensionless form)

\[
\frac{\partial m}{\partial t} - \alpha_G m \times \frac{\partial m}{\partial t} = -m \times h_{\text{eff}}[m] - m \times h_{\text{rf}} + \beta m \times (m \times p)
\]

Effective field \(h_{\text{eff}}[m] = -C m + h_a\), \(C = -L_2 \nabla^2 + N + e_{an} e_{an} \otimes e_{an}\) (exchange, magnetostatic, anisotropy).

Micromagnetic equilibrium (ground state) \(m_0 \times h_{\text{eff}}[m_0] = 0\), in \(\Omega\), \(\frac{\partial m}{\partial n} = 0\) on \(\partial \Omega\).

Radio-frequency applied field \(h_{\text{rf}}(t)\), spin-torque intensity \(\beta\) with polarizer unit-vector \(p\).

A. Directional spin-wave mode coupling in Magnonic Waveguide

The first considered magnetic system is the magnonic waveguide shown in figure 2a). The analysis of such a system has been inspired from ref. 15, where a YIG magnonic waveguide has been studied and proposed as directional coupler to build a magnonic logic circuit. The material parameters used are: saturation magnetization \(M_s = 133 \text{kA/m}\), damping \(\alpha_G = 2 \times 10^{-4}\) and exchange stiffness \(A_{ex} = 3.5 \text{pJ/m}\). The micromagnetic equilibrium \(m_0\) is obtained by letting magnetization relax from a saturated state under a dc magnetic field of 50 mT applied along the same \(x\) direction.

The computation of normal modes \(\phi_h\) and related eigenfrequencies \(\omega_h\) provides in itself several insightful information, which are reported in fig 2a). One can see that the system exhibits modes with spatial distribution confined in a small region of the magnonic waveguide (e.g. mode labelled as 7) and modes which extend throughout the guide in different ways (e.g. modes 64, 73, 95). In particular, it is very interesting to notice that selected modes with distinct
eigenfrequencies extend differently across the upper and lower arms in the rightmost part of the waveguide. Specifically, there are modes, such as mode 73 (mode 95) extending only in the right upper (lower) arm of the structure, and modes such as #64 oscillating in both arms. These macro features are shared by several other modes associated with different eigenfrequencies (see Supplemental Material). From the knowledge of the eigenpairs \((\omega_h, \varphi_h)\), the dispersion curve of spin-waves propagating in the magnonic waveguide can be straightforwardly computed. The result is reported in in figure 2(b). In fact, for each \(\omega_h\) the two-dimensional Fast Fourier Transform (FFT) of the associated mode spatial distribution \(\varphi_h\) is computed in order to have its representation in the wavenumber domain \((k_x, k_y)\). Then, the peaks of the spectral magnitude along \(k_x\) for given each \(k_x\) is plotted. By inspecting figure 2(b), one can see that dominant spin-wave modes follow an approximately parabolic dispersion curve starting close to frequency values \(\sim 3.45 \text{ GHz}\). On one hand, this curve can qualitatively describe the oscillation pattern of spin-waves interpreted in terms of normal modes distribution, since confined (extended) spin-wave modes exhibit broad (narrow) spectra owing to Fourier Transform’s duality property. On the other hand, the diagram is instrumental for analyzing the working condition of the magnonic waveguide. For instance, one can see that propagating extended modes with positive group velocity (narrow spectrum) is possible for positive \(k_x\) starting from \(\omega/2\pi \sim 3.6 \text{ GHz}\) upwards. Viceversa, negative group velocities occur in the same range of frequencies, but for negative \(k_x\) values. By using this approach, the dispersion relation is readily obtained once eigenmodes and associated eigenfrequencies, such as those reported in figure 2(c), are computed. Moreover, this analysis immediately permits to reveal the presence of non-reciprocal propagation of spin waves \[14\]. This is a great advantage with respect to its evaluation via time-domain techniques based on long micromagnetic simulations.

In ref.\[15\], magnetization dynamics is excited in the magnonic waveguide by applying a microwave external field with a U-shaped antenna located in the initial part of the magnonic waveguide. Here we reproduce a similar scenario by applying a sinusoidal time-varying magnetic field, directed along the \(y\) direction, uniformly distributed in a region \(1 \mu\text{m-long}\) of the upper left arm of the waveguide. For weak amplitudes of the microwave field (in dimensionless units \(h_{rf} \ll \alpha_G\)), magnetization dynamics can be analyzed in the linear regime, where the NMM can be written as:

\[
\dot{a}_h = \frac{j\omega_h}{1 + \alpha^2_G} \left( b_h + \sum_i b_{hi} a_i \right),
\]

where \(b_h \approx - (\varphi_h, f_c) = B_h \cos(\omega_{rf} t)\), the terms \(b_{hi} = \delta_{hi} + b_{hi}^0 + b_{hi}^1\) with \(|b_{hi}^0/\alpha_G| \ll 1\) for \(h \neq i\), and \(|b_{hh}^0/\alpha_G| \sim \mathcal{O}(1)\). Moreover, all the terms \(|b_{hi}^1/\alpha_G| \ll 1\) and, since the excitation frequency is less than twice the value of the frequency corresponding to the first normal mode, parametric resonances can be excluded. This permits to consider a diagonal approximation of equations (2) where \(b_{hi} \approx \delta_{hi}(1 + b_{hi}^0)\). In this way, we can give a closed form expression for the normal modes dynamics as in the following equation:

\[
a_h = A_h \left( e^{j\frac{\tau_h}{2} (\cos \omega_{hf} t + j \sin \omega_{hf} t) + \frac{\omega_{rf}}{j \omega_h - 1/\tau_h} \sin \omega_{rf} t - \cos \omega_{rf} t} \right),
\]

\[
A_h = \frac{-\omega_h^2 B_h}{\omega_{rf} - \omega_h^2 - 2 j \omega_h/\tau_h}, \quad \tau_h = \left| b_{hh}^0 \right|^{-1} = (\alpha_G \omega_h^2 \| \varphi_h \|^2)^{-1}.
\]

where the initial condition \(a_h(0) = 0\) is assumed. The predictions of this formula in terms of \(|a_h(t)|\) are compared with the results of micromagnetic simulations\[15\] in figure 2(d), where the microwave field amplitude is \(\mu_0 H_{rf} = 10 \mu\text{T}\) and

FIG. 1: Sketch of the micromagnetic systems under investigation with the NMM: a) magnonic waveguide, b) rectangular nanodot and c) spintronic oscillator.
FIG. 2: Normal mode analysis for the magnonic waveguide shown in fig. 1(a). (a) Plots of mode amplitude $||\varphi||^2$, normalized in the range $(0, 1)$, for different spatial distributions of normal modes. In order from the top: confined mode, double arm mode, upper arm mode and lower arm mode respectively. The color scale is the same as for (b). (b) Dispersion curve. (c) Normal modes frequencies resulting from the solution of the eigenvalue problem (12). Blue filled dots are the frequencies values corresponding to the normal modes plotted in (a). (d) Comparison between the prediction of equation (3) and micromagnetic simulations for linear magnetization dynamics. (e) Power transmitted by the waveguide in the linear regime as a function of the excitation frequency. The red line indicates the power transmitted on the lower arm while the blue line the power transmitted on the upper arm. (f) Comparison of the power transmitted by the waveguide as a function of the microwave field amplitude, computed with the NMM and by micromagnetic simulations. The colors are coherent to (e). Solid and dashed lines refer to NMM integrated with 5 and 20 modes respectively. Filled circles refer to micromagnetic simulation results.

its frequency $f$ is equal to mode 95 frequency $f_{95} = 3.946$ GHz, which only extends in the lower arm of the waveguide (see the bottom of fig. 2(a)). This situation is useful to elucidate general properties of the NMM. In fact, when $f = f_h$, the denominator of the term $|A_h|$ in equation (3) is minimized and the amplitude $|a_h(t)| = (1/2)\omega rf\tau_h |B_h|(1 - e^{-t/\tau_h})$ has the typical aspect of first-order linear dynamical systems forced response. The maximum amplitude that is reached in steady-state conditions is proportional to $\tau_h \sim O(1/\alpha G)$ and to $b_h$. The latter coefficient $b_h$ has a very important meaning in that it quantifies the strength of the coupling between the spatial distribution of the $h$-th mode and the excitation field, as it can be inferred from its expression (see table I and section Methods). From the knowledge of the desired mode profile to excite, by using the latter formula, one can accordingly tune the external microwave field direction and localization in order to maximize the excitation of the selected mode. These considerations are independent from the particular mode considered here and, therefore, hold in general for modes with different spatial distributions.

Thus, in the linear regime (low microwave power), there is twofold selection mechanism for magnetization oscilla-
ations: i) selection due to the excitation field spatial distribution; ii) selection due to the excitation field frequency. This mechanism can be used to interpret the results reported in ref. [45] where, depending on the frequency, magnetization oscillations were observed to occur either in one arm (upper or lower) or in both. Indeed, if one considers a situation where the coupling of the first kind (frequency) is of the same order of magnitude for modes in a given frequency range, then the coupling of the second kind (spatial distribution) can be essential to produce larger magnetization oscillations in one arm (e.g. the lower one) rather than in the other (e.g. upper) arm. Such a difference can be quantitatively appreciated by introducing the following expression for the waveguide output power:

\[ P_{up} = \frac{\int_{T=0}^{T=\Omega_{rf}} \| \delta m_\perp \|^2 d\Omega d\tau}{\int_{T=0}^{T=\Omega_{rf}} \| \delta m_\parallel \|^2 d\Omega d\tau + \int_{T=0}^{T=\Omega_{low}} \| \delta m_\perp \|^2 d\Omega d\tau}, \quad P_{lw} = 1 - P_{up}, \tag{4} \]

where \( \Omega_{up(\text{low})} \) indicate the final 1 \( \mu \)m-long part of the upper (lower) arm, where magnetization oscillation is expressed in terms of the normal modes as \( \delta m_k(r,t) = \sum a_k(t) \varphi_k(r) \) (see the section Methods) and \( T \) is the period of the excitation field. The time-average is computed starting at \( t = 1000 \) ns when the transients are reasonably extinguished (see figure 2(d)). In figure 2(c), the dependence of excitation field frequency on the relative power in each arm is plotted according to equation (4). One can easily see that, in the considered frequency range, there are multiple transitions of output power from the lower to the upper arm (and vice-versa) with different efficiency. In the linear regime, as it is expected from the above discussion according to equation (4) and to the linear dependence of steady-state normal modes amplitudes on the microwave field magnitude (see eq. (3)), the field frequency is the only parameter able to switch the output power between upper and lower arms. By increasing the microwave power, it is experimentally shown in ref. [45] that the switching of output power between arms can be achieved as function of the microwave field amplitude, as a consequence of nonlinearity. In order to analyze this effect with the NMM, we consider eq. (1) truncated at the summation involving the product of four modes amplitudes, while considering five normal modes (modes 58-62) whose frequencies \( \{f_{58}, f_{59}, f_{60}, f_{61}, f_{62}\} = \{3.6168, 3.6186, 3.6226, 3.6267, 3.6322 \text{ GHz} \} \) are centered around the chosen microwave field frequency \( f = 3.618 \) GHz. In the linear regime, for such frequency, the relative power exhibits a sharp transition of output power between the arms (high sensitivity in frequency) and, therefore, it is expected that by inducing a nonlinear frequency shift, one can observe similar power switching between the waveguide arms. The NMM eq. (1) with the above five modes is integrated for 1000 ns with different amplitudes of the excitation field. As a result of these computations, the relative power is evaluated as a function of the microwave amplitude according to equation (4) and plotted using solid lines in figure 2(f). The diagram shows a dependence of the relative power on the microwave field amplitude which is very similar to the one reported in ref. [45]. In the same figure, the results of full micromagnetic simulations are shown (filled dots). The agreement is quantitative and improves as far as the field amplitude increases. The NMM predicts a power switching field value (upper arm output power equals lower arm’s one) \( \sim 170 \mu \)T, while from micromagnetic simulations we have \( \sim 70 \mu \)T. It is expected that this discrepancy can be reduced by increasing the number of modes considered in the integration of the NMM. In fig. 2(f), the power vs microwave amplitude curves obtained from the NMM integrated with 20 modes (modes 41-60) are also plotted (dashed lines), which confirm the expected improvement of the agreement with micromagnetic simulations. We observe that, despite the limited number of modes considered, this analysis is in good agreement with micromagnetic simulations when the magnetization dynamics is in nonlinear regime and driven by moderate microwave field amplitudes \( \mu_0 H_{zf} \sim 0.1 \text{ mT} \). As soon as the field amplitudes is increased to \( \mu_0 H_{zf} \sim 1 \text{ mT} \), the number of modes involved in the nonlinear dynamics grows dramatically with the microwave field power, leading to a chaotic regime.

A systematic analysis of which modes are dominant in weakly nonlinear conditions is a topic of great interest for dimensionality reduction of nonlinear magnetization dynamics in magnonic systems and will be the focus of future investigation based on the NMM.

### B. High-power ferromagnetic resonance in rectangular magnetic nanodot

In this section, the magnetic system considered is a rectangular thin-film with dimensions \( L_x = 100 \text{ nm}, L_y = 50 \text{ nm} \) and \( L_z = 3 \text{ nm} \). The material parameters are \( M_s = 800000 \text{ A/m}, \alpha_C = 0.02, \) \( l_{ex} = 5.69 \text{ nm} \). The micromagnetic equilibrium is a quasi-uniform S-state along the \( x \) direction obtained by relaxing a spatially-homogeneous magnetization slightly tilted in the transverse direction \( y \). The rectangular nanodot magnetized at remanence is excited by a spatially-uniform and sinusoidally time-varying magnetic field applied along the \( y \) direction with given amplitude and frequency to probe the steady-state response of magnetization oscillations. This situation is investigated with the NMM and compared with micromagnetic simulations performed by changing amplitude and frequency of the driving field as it is done in experiments to characterize the nonlinear FMR frequency response of the magnetic system. The NMM considered for the analysis of the above situation is obtained retaining the summation terms involving
FIG. 3: Normal mode analysis for the rectangular nanodot shown in fig.1-(b). (a) Plots of the function $\|\varphi\|^2$, normalized in the range $(0, 1)$, for the first 4 normal modes. (b,c,d) Steady-state oscillation amplitude of spatially-averaged magnetization $y$-component for three microwave field amplitudes: (b) $h_{\text{rf}} = 1$ mT, (c) $h_{\text{rf}} = 1.5$ mT, (d) $h_{\text{rf}} = 2$ mT. Solid lines refer to NMM, filled dots are the result of micromagnetic simulations. Blue (red) color refers to increasing (decreasing) frequency.

The comparison of the results of the NMM and micromagnetic simulations has been done in terms of average magnetization component. In particular, from the $y$-component of the spatially-averaged magnetization vector, the amplitude of steady-state oscillation has been considered. In fig.3 such a comparison is shown for three amplitudes of the microwave field: (d) $\mu_0H_{\text{rf}} = 1$ mT, (e) $\mu_0H_{\text{rf}} = 1.5$ mT and (f) $\mu_0H_{\text{rf}} = 2$ mT. First, one can clearly see that there is quantitative agreement between the NMM and full micromagnetic simulations. Second, it is apparent that, as far as the microwave amplitude is increased, more and more pronounced hysteresis in frequency response of magnetization oscillation appears, which is a strong evidence of nonlinear FMR. These results point out the capability of NMM of capturing strongly nonlinear magnetization dynamics with a very small number of degrees-of-freedom. It is worthwhile remarking that, for uniformly magnetized nanoparticles, nonlinear FMR is amenable of analytical treatment in terms of bifurcation theory. Interestingly, despite the magnetic thin-film is almost uniformly magnetized, the frequency response exhibit multiple peaks ($\sim 3.2$ GHz and $\sim 4$ GHz), which is the fingerprint of coexisting resonances. The resonance peaks are located at frequency values close to those of the first and second normal modes. From fig.3(a,b), one can see that such modes have a similar amplitude spatial distribution and, according to what has been discussed in the previous section for the linear regime, they can couple with the external microwave field by matching the spatial distribution and the frequency. When the system is driven in nonlinear conditions by increasing the microwave amplitude, the interpretation of the hysteretic behavior of the frequency response is rather complex to infer from
micromagnetic simulations, whereas it becomes remarkably simple in terms of normal modes. On the other hand, the uniform mode (macrospin) theory is not able to describe the observed dynamics, while the NMM with 5 degrees-of-freedom leads to quantitative estimation, providing also a way to extend the low-dimensional analysis of nonlinear magnetization oscillations to magnetic system non uniformly magnetized.

By further increasing the field amplitude, the deviation of NMM from micromagnetic computations increases. This is due to the small number (five) of normal modes adopted to describe the magnetization dynamics. In particular, as far as the microwave amplitude is increased, a larger number of modes is required in eq. (1) for the correct description of the dynamics. The proposed NMM provides a class of low-dimensional dynamical models with increasing accuracy and predictive power comparable to full-scale micromagnetics.

C. Synchronization in injection-locked Spin-Torque Oscillator

In this section, the phase-locking of magnetization self-oscillations with an external microwave current is investigated for a spin transfer-torque nano-oscillator (STNO). The magnetic system under investigation is a thin disk with diameter $D = 100$ nm and thickness $d = 12$ nm. The material parameters are $M_s = 800000$ A/m, $\alpha_C = 0.02$, $l_{ex} = 5.69$ nm. The micromagnetic equilibrium is obtained by relaxing magnetization under a spatially-uniform dc magnetic field $H_b = 0.8 M_s$ along the out-of-plane $z$-direction which is the symmetry axis of the disk. This produces a quasi-uniform magnetization aligned with the $z$ axis. In fig. 4(e), three normal modes computed around this equilibrium state are reported. Magnetization dynamics is excited in the STNO by injecting a spin-polarized current in the perpendicular direction with dc+ac components, expressed in dimensionless form as: $\beta = \beta_{dc} + \beta_{ac} \cos(\omega_r t)$. The current value in dimensional units, can be obtained with the following expression: $J = \beta \lambda_p / (2\eta) \ A/m^2$, where $J_p = e \gamma M_z^2 L_z / (g\mu_B)$ with $\gamma$ the absolute value of the gyromagnetic ratio, $e$ is the absolute value of the electron charge, $g$ is the Landé factor, and $\mu_B$ is the Bohr magneton. The coefficient $\eta$ is the polarization factor, and is assumed to be $\eta = 0.1$ [57]. The ac current amplitude is much smaller than the dc one. The spin-polarizer of the electric current is directed 45 degrees off the out-of-plane $z$ axis. In this situation, the dc spin-polarized current excites magnetization self-oscillations while the weak ac current is used to synchronize such oscillations with the external excitation, which is referred to as injection-locking. This is realized by slowly varying the ac excitation frequency back and forth in a range centered around the unperturbed self-oscillations (free running) frequency. In addition, for sufficiently large ac excitation, hysteretic synchronization in injection-locking is expected. Here we analyze such a complex nonlinear phenomenon by using the proposed NMM with five normal modes.

In fig. 4 the comparison of (normalized) power spectrograms of the $y$ component of the spatially-averaged magnetization vector, obtained from the NMM (see fig. 4(a,c) and micromagnetic simulations [55] (see fig. 4(b,d)), are reported. The dc spin polarized current value is $I_{dc} = 29.34$ MA/cm$^2$, while the ac current is $I_{ac} = 7.33$ MA/cm$^2$ for fig. 4(a,b) and $I_{ac} = 11.73$ MA/cm$^2$ for fig. 4(c,d). In dimensionless units, they correspond to $\beta_{dc} = 0.2 \alpha_C$ and $\beta_{ac} = 0.05 \alpha_C$, $0.08 \alpha_C$, respectively. The free-running magnetization self-oscillation frequency is $\sim 4$ GHz and the excitation frequency is linearly varied upwards and downwards in the range $1 \sim 6$ GHz with a rate of change $\pm 0.01$ GHz/ns. No significant variation of the results for lower rate is observed. In order to outline the synchronization mechanism, we consider the spectrogram reported in fig. 4(a). The simulated experiment starts from an unsynchronized state (US) oscillating at the unperturbed self-oscillation frequency (USF). Then, the excitation frequency is increased from 1 to 6 GHz. White arrows in the figure panels help understanding the synchronization process. In fact, magnetization oscillation frequency coincides with the free-running frequency before approaching a value of $\sim 4$ GHz. In this condition, the oscillation gets phase-locked in a synchronized state (SS) which is kept until the excitation frequency value reaches around 5 GHz, after which magnetization oscillations frequency drops at the USF. This abrupt change of frequency in terms of oscillating states correspond to the transition SS$\rightarrow$US. At this point, similar considerations hold for the reverse experiment where the excitation frequency is decreased back to 1 GHz (with with same rate 0.01 GHz/ns), but the synchronization band is different with respect to the forward experiment and the transition SS$\rightarrow$US corresponds to an upward jump. From these diagrams, the hysteretic nature of the synchronization process can be immediately recognized. Indeed, for excitation frequency ranges (phase-locking bands) there is coexistence of SS and US. The actual observed magnetization regime depends on the past history of the dynamics.

Hysteretic synchronization of magnetization oscillations in a STNO has been theoretically investigated in previous works where the magnetization field distribution in the free layer of the STNO was spatially-uniform [46] and in a vortex state [47, 48]. In both cases, the magnetization dynamics was described by models with 2 degrees-of-freedom (collective variables). For the STNO considered in this paper, the above approaches cannot be used to obtain quantitative predictions because the magnetization state is neither spatially-uniform nor in a vortex state. Nevertheless, even in this intermediate situation, the NMM is able to provide a low-dimensional dynamical model with predictive power comparable with full-scale micromagnetic simulations. In this respect, fig. 4(e) reports three of the five normal
FIG. 4: Normal mode analysis for the spintronic oscillator shown in fig.1-(c). Comparison of the spectrograms obtained for two distinct ac current values, of the in plane component of the average magnetization vector: (a,c) NMM and (b,d) micromagnetic simulations. (e) Plots of the function $\| \varphi \|^2$, normalized in the range $(0, 1)$, for the 3 normal modes (out of the 5 considered in the integration of the NMM) mainly involved in the synchronization dynamics.

II. DISCUSSION

The generality of the proposed approach based on the description of nonlinear magnetization dynamics in terms of the normal modes associated with a micromagnetic equilibrium has been established by a quantitative reproduction of the results of micromagnetic simulations for three different systems of great interest for magnetic technologies, subject to different external excitations (magnetic fields and spin-polarized currents). The main advantage of using such a model is twofold. One one hand, it allows to study the nonlinear magnetization dynamics with a strongly reduced number of degrees-of-freedom with respect to full micromagnetic simulations. For instance, the analysis of the magnonic waveguide in section I A required discretization on $N = N_x \times N_y \times N_z = 650 \times 62 \times 1 = 40300$ computational cells ($3N \sim 10^5$ degrees-of-freedom), while the NMM allowed quantitative and increasingly accurate description of the relevant features of the nonlinear dynamics with $N = 5$ and $N = 20$ normal modes. Moreover, since normal modes are independent from the external (forcing) excitation, the NMM can be used to perform fast engineering and optimization of microwave external fields and/or spin current on the basis of the desired feature (e.g. output power switch from upper to lower arms of the waveguide), which conversely would require repeating very long micromagnetic simulations (thousands nanoseconds to reach the steady-state) as far as the excitation is changed. On the other hand, the NMM is a nonlinear system of ordinary differential equations which is much more manageable with analytical techniques. Indeed, in the case of linear magnetization dynamics, we have derived the expressions governing the time evolution of modes and then of the magnetization field. Such formulas are independent from the
magnetic system considered. Indeed, they have been derived independently from the magnetic equilibrium or the normal modes spatial profile. When nonlinear mode coupling is considered in the dynamics, the NMM includes a large number of terms involving products of 2, 3,... normal modes amplitudes. These terms becomes more and more important as far as the magnetic state deviates by a large angle from the equilibrium configuration. A systematic study of what are the dominant modes in magnetization dynamics is an open question, as well as an a-priori estimate of the number of modes required to guarantee a prescribed accuracy. Nevertheless, there are many situations relevant for the design of magnetic technologies, such as those analyzed in this paper, where the magnetization is driven far from the equilibrium into a nonlinear steady-state regime depending on amplitude, spatial distribution and time-variation of the external excitation. We have demonstrated that, in these conditions, the NMM can quantitatively describe nonlinear magnetization dynamics by using a small number of modes, becoming a powerful alternative tool to full-scale micromagnetic simulations. In addition, the NMM allows to define a hierarchy of models which differ by the number of normal modes considered and type of nonlinear mode coupling (product of multiple modes amplitudes). In conclusion, we believe that the proposed model will change the current perspective of computational micromagnetics.

III. METHODS

A. Normal Modes Formulation - conservative dynamics in the linear regime

In this section a brief review of the formulation of normal modes in micromagnetic systems is given. For detailed and rigorous statement, the reader can refer to ref.\[34\].

Let us consider a magnetic body occupying the region $\Omega$, which magnetization field is indicated as $\mathbf{M}(\mathbf{r}, t)$. For a given temperature, well below the Curie’s one of the material, the fundamental micromagnetic constraint $|\mathbf{M}(\mathbf{r}, t)| = M_s(T)$ is assumed, where $M_s(T)$ is the saturation magnetization of the material at temperature $T$. Introducing the magnetization unit vector $\mathbf{m}(\mathbf{r}, t)$, the micromagnetic constraint can be rewritten as:

$$m^2(\mathbf{r}, t) = 1.$$ (5)

In terms of energy, the magnetic state is characterized by the Gibbs-Landau free energy functional, which in dimensionless unit can be written as:

$$g_L(\mathbf{m}; \mathbf{h}_a) = \frac{G_L(\mathbf{M}; H_s)}{\mu_0 M_s^2 V_\Omega} = \frac{1}{V_\Omega} \int_{\Omega} \left[ \frac{l^2}{2} (\nabla \mathbf{m})^2 - \frac{1}{2} \mathbf{h}_m[\mathbf{m}] \cdot \mathbf{m} + \kappa_{\text{an}} [1 - (\mathbf{m} \cdot \mathbf{e}_{\text{an}})^2] - \mathbf{h}_a \cdot \mathbf{m} \right] dV,$$ (6)

where $\mu_0$ is the vacuum magnetic permeability, $V_\Omega$ is the volume of the magnetic body, $l_e = \sqrt{2A/(\mu_0 M_s^2)}$ is the exchange length, $A$ the exchange stiffness of the material, $\kappa_{\text{an}}, \mathbf{e}_{\text{an}}$ the anisotropy constant and direction, $\mathbf{h}_a$ applied magnetic field and $\mathbf{h}_m[\mathbf{m}]$ the magnetostatic field, expressed by the following expression:

$$h_m[\mathbf{m}] = -\nabla \nabla \cdot \frac{1}{4\pi} \int_{\Omega} \frac{\mathbf{m}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} dV_{\mathbf{r}'}.$$ (7)

The free energy description, allows us to derive the equations governing the magnetic equilibria. Indeed, by means thermodynamic arguments, it is possible to justify that the micromagnetic equilibria of the magnetic body subject to the action of static magnetic field, can be found by minimizing the Gibbs-Landau free energy functional \[6\] under the constraint expressed by Eq.\[5\]. As a result of such a procedure the following set of equations known as Brown’s equations [1], are derived:

$$\mathbf{m}_0 \times \mathbf{h}_{\text{eff}}[\mathbf{m}_0] = 0 \text{ in } \Omega, \quad \frac{\partial \mathbf{m}_0}{\partial t} = \mathbf{0} \text{ on } \partial \Omega,$$ (8)

where $\mathbf{n}$ is the outward normal to the boundary of the magnetic body $\partial \Omega$, and

$$h_{\text{eff}}[\mathbf{m}] = -\frac{\delta g_L}{\delta \mathbf{m}} = -\mathcal{C} \mathbf{m} + \mathbf{h}_a = l^2_{\text{ex}} \nabla^2 \mathbf{m} + h_m[\mathbf{m}] + 2\kappa_{\text{an}}(\mathbf{m} \cdot \mathbf{e}_{\text{an}})\mathbf{e}_{\text{an}} + \mathbf{h}_a,$$ (9)

is the effective field, given by the Fréchet functional derivative with respect to the magnetization distribution of the free energy functional. In the formula above, the effective field is decomposed as a sum of a linear operator $\mathcal{C}$ acting on the magnetization field, plus the external applied field.
When the equilibrium is perturbed, the magnetization dynamics occurs. Let us consider conservative magnetization dynamics described by the conservative Landau-Lifshitz equation \[ \frac{\partial m}{\partial t} = -m \times h_{\text{eff}}[m], \] 
which in dimensionless unit reads as:

\[ \frac{\partial m}{\partial t} = -m \times h_{\text{eff}}[m], \tag{10} \]

where the dimensionless time \( t = \gamma M_s t' \), with \( \gamma \) the absolute value of the gyromagnetic factor and \( t' \) the time expressed in dimensional unit. The magnetization field can be always decomposed as \( m = m_0 + \delta m \), where \( \delta m(r,t) \) is an other vector field. Let us consider an initial perturbation \( \delta m(r) = \delta m_\perp(r) \) belonging in each point to the perpendicular plane to the equilibrium direction \( m_0 \). Such plane will be referred as tangent plane to \( m_0 \) and indicated with the symbol \( \mathcal{T}M(m_0) \). When such perturbation in modulus is small enough such that: \( \|m_0 + \delta m_\perp\| \approx 1 \), in other terms \( \|\delta m_\perp\|^2 \approx 0 \), the dynamics can be described by the linearized form of equation (10) around the equilibrium \( m_0 \), expressed as follows:

\[ \frac{\partial \delta m_\perp}{\partial t} = m_0 \times (C + h_0) \delta m_\perp = m_0 \times A_{0\perp} \delta m_\perp, \tag{11} \]

where \( A_{0\perp} = \mathcal{P}_{m_0}(C + h_0 \mathcal{I}) \), with \( \mathcal{P}_{m_0} = \mathcal{I} - m_0 \otimes m_0 \) the projection operator onto the tangent space \( \mathcal{T}M(m_0) \), \( \mathcal{I} \) the identity operator and \( h_0 = m_0 \cdot h_{\text{eff}}[m_0] \). By using the phasor notation \( \delta m_\perp(r,t) = \varphi(r) e^{j\omega t} \), equation (11) can be written as the following generalized eigenvalue problem:

\[ A_{0\perp} \varphi = \omega B_0 \varphi, \tag{12} \]

where \( B_0 \varphi = -jm_0 \times \varphi \). As mentioned at the beginning of this section, this problem has been studied with great details in ref[34]. The summary of the main properties, which will be extensively used in the next sections are the following:

1. The eigenvalues \( \omega \) are real.
2. If the pair \( (\omega_k, \varphi_k) \) is solution to the problem (12), then the pair \( (-\omega_k, \varphi_k^*) \) is solution to it too, where \( \varphi_k^* \) is the complex conjugated vector of \( \varphi_k \).
3. The spectrum \( \{\omega_k\}_{k\in\mathbb{Z}} \) is discrete (the essential spectrum is at infinity), with \( \omega_{-k} = -\omega_k \).
4. The set of eigenvectors \( \{\varphi_k\}_{k\in\mathbb{Z}} \) constitute a basis of the tangent space \( \mathcal{T}M(m_0) \), with \( \varphi_{-k} = \varphi_k^* \).
5. The eigenvectors of different and non degenerate eigenvalues are \( A_{0\perp} \)-orthogonal.

In more details, property 4 implies that:

\[ \delta m_\perp(r,t) = \sum_{k=-\infty}^{\infty} a_k(t) \varphi_k(r), \tag{13} \]

while property 5 can be specified as follows:

\[ (\varphi_h, \varphi_k)_{A_{0\perp}} = (\varphi_h, A_{0\perp} \varphi_k) = \frac{1}{|\Omega|} \int_{\Omega} \varphi_h^* \cdot A_{0\perp} \varphi_k \ d\Omega = \delta_{hk}, \]

with \( |\Omega| \) the volume of the region \( \Omega \) occupied by th emagnetic body. It is useful to remark that due to the self adjointness of the operator \( A_{0\perp} \), the equation above can be rewritten as:

\[ (\varphi_h, \varphi_k)_{A_{0\perp}} = (A_{0\perp} \varphi_h, \varphi_k) = j\omega_h (m_0 \times \varphi_h, \varphi_k) = \delta_{hk}. \tag{15} \]

At this point, let us derive the equation governing the time evolution of the normal modes amplitudes \( a_k(t) \). This task can be accomplished by projecting equation (11) in the normal modes basis. Such projection can be obtained by replacing equation (13) in equation (11) and using the orthogonality of the eigenvectors (14) as follows:

\[ \begin{align*}
 (\varphi_h, \frac{\partial \delta m_\perp}{\partial t})_{A_{0\perp}} &= \sum_k (\varphi_h, \varphi_k)_{A_{0\perp}} \dot{a}_k = \dot{a}_h, \\
 (\varphi_h, m_0 \times A_{0\perp} \delta m_\perp)_{A_{0\perp}} &= \sum_k (\varphi_h, m_0 \times A_{0\perp} \varphi_k)_{A_{0\perp}} a_k = \sum_k j\omega_k (\varphi_h, \varphi_k)_{A_{0\perp}} a_k = j\omega_h a_h. 
\end{align*} \tag{16} \]

Therefore, the micromagnetic dynamics is described by the following system of equations where the unknows functions are the normal modes amplitudes:

\[ \dot{a}_h = j\omega_h a_h, \tag{17} \]

which evolve independently according to the following law: \( a_h(t) = a_{h0} e^{j\omega_h(t-t_0)} \), where \( a_{h0} = a_h(t = t_0) \) being \( t_0 \) the initial time of integration.
When the perturbation to the equilibrium state brings the magnetization dynamics out of the linear regime, the assumption of Section III A $||m_0 + \delta m|| \sim 1$ does not hold any longer and hence eq. (17) describing the normal modes amplitude evolution is not valid anymore. In the following, we arrive to a new system of ordinary differential equations which generalizes equation (17) for nonlinear magnetization dynamics. As a first step we decompose the magnetization field according to the following formula:

$$m(r, t) = m_0(r) + \delta m(r, t) = m_0(r) + \delta m_0(r, t) + \delta m_{\perp}(r, t),$$

where for each point $r \in \Omega$, $\delta m_0(r, t) = \delta m_0(r, t) m_0(r)$ is the projection of $\delta m(r, t)$ along the equilibrium direction given by $m_0(r)$, and $\delta m_{\perp}(r, t)$ is the component of $\delta m(r, t)$ in the tangent space $T\mathcal{M}(m_0)$. Then, plugging equation (18) into equation (10), we obtain the following expressions:

$$\frac{\partial \delta m_{\perp}}{\partial t} = m_0 \times (C + h_0) \delta m + \delta m \times C \delta m,$$

which can be exploded in the following equation:

$$m_0 \frac{\partial \delta m_0}{\partial t} + \frac{\partial \delta m_{\perp}}{\partial t} = m_0 \times A_{0, \perp} \delta m_{\perp} + m_0 \times C \delta m_0 + \delta m_0 \times C \delta m_0 +$$

$$+ \delta m_{\perp} \times C \delta m_0 + \delta m_0 \times C \delta m_{\perp} + m_0 \times C \delta m_{\perp} + m_0 \times C \delta m_{\perp},$$

where we use the fact that $m_0 \times h_0 \delta m = m_0 \times h_0 \delta m_{\perp}$. Decomposing the operator $C$ as follows:

$$C = C_{\perp} + C_0, \quad C_{\perp} = \mathcal{P}_{m_0} C,$$

equation (20) is decomposed in the following system of coupled equations:

$$\frac{\partial \delta m_{\perp}}{\partial t} = m_0 \times A_{0, \perp} \delta m_{\perp} + m_0 \times C_{\perp} \delta m_0 + \delta m_0 \times C_{\perp} \delta m_0 +$$

$$+ \delta m_{\perp} \times C_{\perp} \delta m_0 + \delta m_{\perp} \times C_{\perp} \delta m_{\perp} +$$

$$+ m_0 \times C_{\perp} \delta m_{\perp}.$$

Up to this point, we have simply rewritten the conservative Landau-Lifshitz equation in the reference frame given by the unit vector $m_0$ and the tangent plane $T\mathcal{M}(m_0)$. The system of ordinary differential equations (odes), where the unknown functions are the normal modes amplitudes could be obtained by applying property 5 to the first of equations (22). However, the occurrence of terms including $\delta m_0$ couples the projected equation with the second of equations (22). This bottleneck can be avoided if we can express the variation $\delta m_0$ in function of the normal modes amplitudes and the eigenvectors $\{\varphi(r)\}_{k}$. Such relation exists as a consequence of the fundamental micromagnetic constraint imposed on equation (18). Therefore substituting eq. (18) in eq. (22), we obtain the following expressions:

$$\delta m_0^2 + 2\delta m_0 + \delta m_{\perp}^2 = 0 \Leftrightarrow \delta m_0 = -1 \pm \sqrt{1 - \delta m_{\perp}^2}.$$

If the magnetization dynamics occurs around the equilibrium $m_0$, then the + sign has to be selected. Indeed, when $\delta m_{\perp} = 0$ such choice produces $\delta m_0 = 0$. The right hand side of equation (23) can be expanded in Taylor series as follows:

$$\delta m_0 = -\frac{1}{2} \delta m_{\perp}^2 - \frac{3}{4!} \delta m_{\perp}^4 + \ldots,$$

where considering only the first term of the expansion and expressing $\delta m_{\perp}$ in function of the normal modes, we obtain the following equation:

$$\delta m_0(r, t) \approx -\frac{1}{2} \sum_{i, j = -\infty}^{+\infty} \varphi_i(r) \cdot \varphi_j(r) a_i(t) a_j(t) \approx -\frac{1}{2} \sum_{i, j = -\infty}^{+\infty} \psi_{ij}(r) a_i(t) a_j(t).$$

This equation represents an approximation which will be referred to as parabolic approximation. It is quite accurate when $\delta m_0 < 0.2$ which corresponds to $\delta m_{\perp} < 0.6$. We will discover in the following that this range is more than
Gilbert equation [10], which in dimensionless unit reads as:

\[
(\varphi_h, \delta m_0 \times C \delta m_0)_{A_0} = j\omega_h (\varphi_h, C \delta m_0) = -\frac{j\omega_h}{2} \sum_{i,j} (\varphi_h, C \psi_{ij} m_0) a_i a_j ,
\]

\[
(\varphi_h, \delta m_0 \times C \delta m_0)_{A_0} = \frac{j\omega_h}{4} \sum_{i,j,k,l} (\varphi_h, \psi_{kl} C \psi_{ij} m_0) a_i a_j a_k a_l ,
\]

\[
(\varphi_h, \delta m_0 \times C \delta m_\perp)_{A_0} = -\frac{j\omega_h}{2} \sum_{i,j,k} (\varphi_h, \psi_j C \varphi_i) a_i a_j a_k ,
\]

\[
(\varphi_h, \delta m_\perp \times C \delta m_0)_{A_0} = - j\omega_h (\varphi_h, m_0 \cdot C \delta m_\perp \delta m_\perp) = \frac{j\omega_h}{2} \sum_{i,j,k} (\varphi_h, m_0 \cdot C \psi_{jk} m_0 \varphi_i) a_i a_j a_k ,
\]

\[
(\varphi_h, \delta m_\perp \times C \delta m_\perp)_{A_0} = - j\omega_h (\varphi_h, m_0 \cdot C \delta m_\perp \delta m_\perp) = -j\omega_h \sum_{i,j} (\varphi_h, m_0 \cdot C \varphi_j \varphi_i) a_i a_j .
\]

Putting equations (16) and (26) together, we arrive to the following system of ODEs in the normal modes amplitudes:

\[
\dot{a}_h = j\omega_h a_h + j\omega_h \sum_{i,j} c_{hij} a_i a_j + \frac{j\omega_h}{2} \sum_{i,j,k} d_{hijk} a_i a_j a_k + \frac{j\omega_h}{4} \sum_{i,j,k,l} e_{hijkl} a_i a_j a_k a_l ,
\]

where:

\[
c_{hij} = -\frac{1}{2} (\varphi_h, C \psi_{ij} m_0) - (\varphi_h, m_0 \cdot C \varphi_j \varphi_i) ,
\]

\[
d_{hijk} = - (\varphi_h, \psi_{jk} C \varphi_i) + (\varphi_h, m_0 \cdot C \psi_{jk} m_0 \varphi_i) ,
\]

\[
e_{hijkl} = (\varphi_h, \psi_{kl} C \psi_{ij} m_0) .
\]

Then we arrived to an equivalent formulation of the conservative Landau-Lifshitz equation in terms of the normal modes amplitudes. The only approximation used, as discussed previously, is the parabolic approximation expressed in equation (25).

C. Damped Dynamics - non linear regime

When damping effect is included, the magnetization dynamics is assumed to be described by the Landau-Lifshitz-Gilbert equation [10], which in dimensionless unit reads as:

\[
\frac{\partial m}{\partial t} - \alpha_G m \times \frac{\partial m}{\partial t} = -m \times h_{\text{eff}}[m] ,
\]

where \(\alpha_G \sim 10^{-2}\) is the Gilbert damping. This equation can be putted in the canonical form \(\dot{x} = f(x; t)\), obtaining the Landau-Lifshitz equation [10]:

\[
(1 + \alpha_G^2) \frac{\partial m}{\partial t} = -m \times h_{\text{eff}}[m] - \alpha_G m \times (m \times h_{\text{eff}}[m]) .
\]

In order to include damping effects in the normal modes dynamics, we project the Landau-Lifshitz equation in the tangent space \(T_{M}(m_0)\) as follows:

\[
(1 + \alpha_G^2) \frac{\partial \delta m_\perp}{\partial t} = m_0 \times A_{0\perp} \delta m_\perp + m_0 \times C_\perp \delta m_0 + \delta m_0 \times C_\perp \delta m_0 + \delta m_0 \times C_\perp \delta m_\perp +
\]

\[
\delta m_\perp \times C_0 \delta m_0 + \delta m_\perp \times C_0 \delta m_\perp - \alpha_G m \times (m \times h_{\text{eff}}[m])_\perp ,
\]

where according to equations (18) and (21), we have:

\[
m \times (m \times h_{\text{eff}}[m])_\perp = m \cdot h_{\text{eff}}[m] \delta m_\perp + C_\perp (\delta m_\perp + \delta m_0) ,
\]
with:

\[ m \cdot h_{\text{eff}}[m] = (1 + \delta m_0) (h_0 - m_0 \cdot C(\delta m_\perp + \delta m_0)) - \delta m_\perp \cdot C(\delta m_\perp + \delta m_0). \]  

(33)

Putting the two equations above together, we arrive to the following equation:

\[ m \times (m \times h_{\text{eff}}[m])|_\perp = A_0 \perp \delta m_\perp + h_0 \delta m_0 \delta m_\perp + C_\perp \delta m_0 - (1 + \delta m_0) m_0 \cdot C(\delta m_\perp + \delta m_0) \delta m_\perp + - \delta m_\perp \cdot C(\delta m_\perp + \delta m_0) \delta m_\perp, \]

(34)

from which, similarly as we did in equations (26), we can derive the projection of the damping torque in the normal modes basis expressed by the following terms:

\[
\begin{align*}
(\varphi_h, A_0 \perp \delta m_\perp)_{A_0 \perp} &= \omega_h \sum_\ell \omega_i (\varphi_h, \varphi_i) a_i, \\
(\varphi_h, h_0 \delta m_0 \delta m_\perp)_{A_0 \perp} &= \frac{j \omega h}{2} \sum_{i,j,k} (m_0 \times \varphi_h, h_0 \psi_{jk} \varphi_i) a_i a_j a_k, \\
(\varphi_h, C_\perp \delta m_0)_{A_0 \perp} &= \frac{j \omega h}{2} \sum_{i,j} (m_0 \times \varphi_h, C \psi_{ij} m_0) a_i a_j, \\
(\varphi_h, -(1 + \delta m_0) m_0 \cdot C \delta m_\perp \delta m_\perp)_{A_0 \perp} &= -j \omega h \sum_{i,j} (m_0 \times \varphi_h, m_0 \cdot C \varphi_j \varphi_i) a_i a_j + \\
&+ \frac{j \omega h}{2} \sum_{i,j,k,l} (m_0 \times \varphi_h, \psi_{kl} m_0 \cdot C \varphi_j \varphi_i) a_i a_j a_k a_l, \\
(\varphi_h, -m_0 \cdot C \delta m_0 \delta m_\perp)_{A_0 \perp} &= \frac{j \omega h}{2} \sum_{i,j,k} (m_0 \times \varphi_h, m_0 \cdot C \psi_{jk} m_0 \varphi_l) a_i a_j a_k, \\
(\varphi_h, -\delta m_0 m_0 \cdot C \delta m_0 \delta m_\perp)_{A_0 \perp} &= -j \omega h \sum_{i,j,k,l,m} (m_0 \times \varphi_h, \psi_{lm} m_0 \cdot C \psi_{jk} m_0 \varphi_l) a_i a_j a_k a_m, \\
(\varphi_h, -\delta m_\perp \cdot C \delta m_\perp \delta m_\perp)_{A_0 \perp} &= -j \omega h \sum_{i,j,k} (m_0 \times \varphi_h, C \varphi_j \varphi_i) a_i a_j a_k, \\
(\varphi_h, -\delta m_\perp \cdot C \delta m_0 \delta m_\perp)_{A_0 \perp} &= \frac{j \omega h}{2} \sum_{i,j,k,l} (m_0 \times \varphi_h, \psi_{kl} \varphi_i \cdot C \psi_{jk} m_0 \varphi_l) a_i a_j a_k a_l.
\end{align*}
\]

At this point, we are ready to generalize the system of odes (27) including damping terms. In this respect, we have:

\[
(1 + \alpha_2^G) \dot{a}_h = j \omega h \sum_i b_i a_i + j \omega h \sum_{i,j} c_{ij} a_i a_j + \frac{j \omega h}{2} \sum_{i,j,k} d_{ijk} a_i a_j a_k + \\
\frac{j \omega h}{4} \sum_{i,j,k,l} e_{ijkl} a_i a_j a_k a_l + \frac{j \omega h}{4} \sum_{i,j,k,l,m} f_{ijklm} a_i a_j a_k a_m,
\]

(36)

where:

\[
\begin{align*}
b_{hi} &= \delta_{hi} + j \alpha_2 G b_{hi}^\alpha, \\
c_{hi} &= c_{hi}^0 - \alpha_2 G c_{hi}^\alpha, \\
d_{hijk} &= d_{hijk}^0 - \alpha_2 G d_{hijk}^\alpha, \\
e_{hijkl} &= e_{hijkl}^0 - \alpha_2 G e_{hijkl}^\alpha, \\
f_{hijklm} &= -\alpha_2 G f_{hijklm}^\alpha,
\end{align*}
\]

(37)

with \( b_{hi}^\alpha, c_{hi}^\alpha, d_{hijk}^\alpha, e_{hijkl}^\alpha, f_{hijklm}^\alpha \) the coefficients taken from equation (35) which multiply the product of 1, 2, 3, 4 and 5 normal modes amplitudes respectively.

D. Forced Dynamics - non linear regime

The last step for the study of magnetization dynamics in the framework of normal modes, is the inclusion in the model of the excitation terms. Two different kinds of excitation will be considered: magnetic field and spin polarized
current. In general no restriction on spatial distribution and time dependence is putted. Moreover, the spin transfer torque term will be assumed of the Slonczewski type. In this respect, the equation describing the magnetization is the following:

$$\frac{\partial m}{\partial t} - \alpha_G m \times \frac{\partial m}{\partial t} = -m \times h_{\text{eff}}[m] - m \times h_{rf} + \beta m \times (m \times p),$$  \hspace{1cm} (38)

where $h_{rf}$ is the normalized microwave magnetic field and $(\beta, p)$ is the pair identifying the normalized amplitude and the polarization unit vector of the spin current. As we did in the previous section, it is useful to rewrite equation (38) in canonical form as follows:

$$(1 + \alpha_G^2) \frac{\partial m}{\partial t} = -m \times h_{\text{eff}}[m] - \alpha_G m \times (m \times h_{\text{eff}}[m]) - m \times f_c - m \times (m \times f_d),$$

where $f_c = h_{rf} + \alpha_G \beta p$ and $f_d = \alpha_G h_{rf} - \beta p$. At this point, we can derive the several terms to be included in the system of (40). In order, the terms due to $f_c$ are expressed in the following:

$$m \times f_c = (1 + \delta m_0) m_0 \times f_c + \delta m_\perp \times f_c,$$

$$\langle \varphi_h, (1 + \delta m_0) m_0 \times f_c \rangle_{\varphi_0 \perp} = j\omega_h \langle \varphi_h, f_c \rangle - \frac{j\omega_h}{2} \sum_{i,j} (\varphi_h, \psi_{ij} f_c) a_i a_j,$$

$$\langle \varphi_h, \delta m_\perp \times f_c \rangle_{\varphi_0 \perp} = -j\omega_h \sum_i (\varphi_h, m_0 \cdot f_c \varphi_i) a_i,$$

while the terms due to $f_d$ are expressed by the following ones:

$$m \times (m \times f_d) \Big|_{\varphi_0 \perp} = (1 + \delta m_0) m_0 \times f_d \delta m_\perp + \delta m_\perp \cdot f_d \delta m_\perp + m_0 \times (m_0 \times f_d),$$

$$\langle \varphi_h, (1 + \delta m_0) m_0 \cdot f_d \delta m_\perp \rangle_{\varphi_0 \perp} = j\omega_h \sum_i (m_0 \times \varphi_h, m_0 \cdot f_d \varphi_i) a_i - \frac{j\omega_h}{2} \sum_{i,j,k} (m_0 \times \varphi_h, \psi_{ij} m_0 \cdot f_d \varphi_i) a_i a_j a_k,$$

$$\langle \varphi_h, \delta m_\perp \cdot f_d \delta m_\perp \rangle_{\varphi_0 \perp} = j\omega_h \sum_{i,j} (m_0 \times \varphi_h, \varphi_j \cdot f_d \varphi_i) a_i a_j,$$

$$\langle \varphi_h, m_0 \times (m_0 \times f_d) \rangle_{\varphi_0 \perp} = j\omega_h \langle \varphi_h, m_0 \times f_d \rangle.$$

Once that the terms due to the driving force of the magnetization dynamics are projected into the normal modes framework, we arrive to the following model:

$$(1 + \alpha_G^2) a_h = j\omega_h b_h + j\omega_h \sum_i b_{hi} a_i + j\omega_h \sum_{i,j} c_{hij} a_i a_j + \frac{j\omega_h}{2} \sum_{i,j,k} d_{hijk} a_i a_j a_k + \frac{j\omega_h}{4} \sum_{i,j,k,l} e_{hijkl} a_i a_j a_k a_l + \sum_{i,j,k,l,m} f_{hijklm} a_i a_j a_k a_l a_m,$$

$$\hspace{1cm} (42)$$

where:

$$b_h = \alpha_G b_h^f,$$

$$b_{hi} = \delta_h + j\alpha_G b_{hi}^0 + \alpha_G b_{hi}^f,$$

$$c_{hij} = c_{hij}^0 - \alpha_G c_{hij}^0 + \alpha_G c_{hij}^f,$$

$$d_{hijk} = d_{hijk}^0 - \alpha_G d_{hijk}^0 + \alpha_G d_{hijk}^f,$$

$$e_{hijkl} = e_{hijkl}^0 - \alpha_G e_{hijkl}^0 + \alpha_G e_{hijkl}^f,$$

$$f_{hijklm} = -\alpha_G f_{hijklm},$$

$$\hspace{1cm} (43)$$

with $b_h^f, b_{hi}^f, c_{hij}^f, d_{hijk}^f$ the coefficients taken from equation (40) and (41) which multiply the product of 0 (pure additive), 1, 2, and 3 normal modes amplitudes respectively.

**ACKNOWLEDGEMENTS**

The financial support of the FWF project I 4917 and the support from the Christian Doppler Laboratory ”Advanced Magnetic Sensing and Materials” and the commercial Partner Infineon is acknowledged.
AUTHOR CONTRIBUTIONS

M.d’A., D.S. and C.S. planned the study. S.P. and M.d’A. developed the formalism of the normal modes-based model and the numerical simulation code with consultation from D.S and F.B. All authors discussed the results and wrote the manuscript.
