In this work we demonstrate spectral-temporal correlation measurements of the Hong-Ou-Mandel (HOM) interference effect with the use of a 3D (2 spatial + 1 time dimension) camera based spectrometer. This setup allows us to take, within seconds, spectral temporal correlation measurements on entangled photon sources with sub-nanometer spectral resolution and nanosecond timing resolution. Through post processing, we can observe the HOM behaviour for any number of spectral filters of any shape and width at any wavelength over the observable spectral range. Our setup also offers great versatility in that it is capable of operating at a wide spectral range from the visible to the near infrared and does not require a pulsed pump laser for timing purposes. This work offers the ability to gain large amounts of spectral and temporal information from a HOM interferometer quickly and efficiently and will be a very useful tool for many quantum technology applications and fundamental quantum optics research.

1. Introduction

The interference of two photons on a beamsplitter (BS), the Hong-Ou-Mandel (HOM) effect [1], is one of the most defining features of quantum mechanics and lies at the heart of many technology applications requiring multi-photon interference including quantum communications, quantum computing, quantum state engineering and precision measurements [2–10]. The characteristic signature of HOM interference is a ‘dip’ in two-fold coincidences in the output ports of the beamsplitter. It has become synonymous with HOM interference, but in reality this dip is only a single-mode representation of a far more complex multi-mode effect. Recent demonstrations of the HOM effect in spatial-temporal [11], and spectral-temporal [12–15] modes have revealed the complex multi-dimensional nature of HOM interference.

Here we use a two-photon spectrometer based on a novel photon-counting camera [16–18] to spectrally resolve the HOM effect with high spectro-temporal resolution. Each output port of the beamsplitter (BS) is spectrally binned into 256 pixels and coincident detection is performed in all $256 \times 256 = 65536$ joint spectral modes simultaneously as the arrival time between the photons is scanned. In this way, a full spectro-temporal characterization of the HOM effect can be performed within just a few minutes. Conventional single photon cameras, such as EMCCD and ICCD cameras, limited by their frame rate, will require hours if not days to perform the same measurement and are also prone to stability issues within the long data taking period. It is also well known that the shape and width of the HOM interference dip is closely related to the photon spectrum and type of spectral filter used to perform the experiment [19–21]. Conventionally, investigating the spectral response of HOM interference may require the use of many different spectral filters or the use of pulse shapers. However, with our system, all such spectral information can be obtained in just one data taking run. Through post-processing, we have the freedom to artificially add any number of spectral filters with any wavelength, bandwidth and shape so long it is within the spectral range of the spectrometer. Compared to using a fiber-based
spectrometer [12, 13], or a chirped fibre bragg grating [14, 22], our camera based spectrometer can operate in a much wider spectrum from around 200 nm to 900 nm depending on the spectral response of the image intensifier used. We are also not limited to analysing photon pairs generated from a pulsed laser pump source, often required for timing purposes, thus giving our system more versatility.

2. Theory

The spectral correlation between the photon pairs generated from SPDC can be displayed in a joint spectral intensity (JSI) plot. Theoretically this can be determined by multiplying the phase-matching function of the crystal and the pump envelope function. The phase matching function for a ppKTP crystal of length $L$ with Type-0 phase matching is given by

$$h(\omega_1, \omega_2) = \text{sinc}(L \Delta k(\omega_1, \omega_2))$$  \hspace{1cm} (1)

with

$$\Delta k(\omega_1, \omega_2) = \frac{1}{2\pi c} \left[ n_e(\omega_p)\omega_p - n_e(\omega_1)\omega_1 - n_e(\omega_2)\omega_2 \right] - \frac{1}{\Lambda_0}, \hspace{1cm} (2)$$

where $\omega_p$, $\omega_1$, and $\omega_2$ are the frequency of the pump and photon pairs respectively. $n_e(\omega)$ is the extraordinary refractive index of the crystal, $\Lambda_0$ is the grating period of the crystal and $c$ the speed of light in vacuum.

Assuming a Gaussian shaped pump, the pump envelope function is given by

$$\alpha(\omega_1, \omega_2) = \exp\left[-\frac{(\omega_p - \omega_1 - \omega_2)^2}{2\sigma_p^2}\right], \hspace{1cm} (3)$$

with $\sigma_p$ the pump bandwidth.

Finally the JSI is given by

$$\Phi(\omega_1, \omega_2) = |\alpha(\omega_1, \omega_2)h(\omega_1, \omega_2)|^2. \hspace{1cm} (4)$$

Now with an expression for the JSI we can use it to calculate the shape of the HOM dip. As shown in [1, 19], the intensity correlation function for the HOM interference with multi-spectral modes is given by

$$G^{(2)}(t_1, t_2, \Delta z) \propto \left| \int d\omega_1 d\omega_2 \Phi(\omega_1, \omega_2) \left( T e^{i\omega_1 \Delta z/c} - R e^{i\omega_2 \Delta z/c} \right) e^{-i\omega_1 t_1 - i\omega_2 t_2} \right|^2. \hspace{1cm} (5)$$

with $\Delta z$ the path length difference, $T$ and $R$ the transmissivity and reflectivity of the BS.

Since the detector timing resolution is much longer than the coherence time of the SPDC photons, which is approximately the inverse of the spectral filter bandwidth, the two photon coincidence count is then proportional to the time average of $G^{(2)}(t_1, t_2)$

$$N_c(\Delta z) \propto \int_0^\infty dt_1 dt_2 G^{(2)}(t_1, t_2, \Delta z)$$

$$\propto \left| \int d\omega_1 d\omega_2 \Phi(\omega_1, \omega_2) \left( T e^{i\omega_1 \Delta z/c} - R e^{i\omega_2 \Delta z/c} \right) \right|^2. \hspace{1cm} (6)$$

A useful observation here is the absolute square of the integrand in Eq. 6,

$$\left| \Phi(\omega_1, \omega_2) \left( T e^{i\omega_1 \Delta z/c} - R e^{i\omega_2 \Delta z/c} \right) \right|^2, \hspace{1cm} (7)$$
will be the JSI measured between the two output ports of the BS in HOM interference. Oscillations in the intensity will be observed with a frequency of \(2\Delta z/c\).

When spectral filters with spectral shape of \(f(\omega)\) are placed in the system, a small modification is required in the JSI, \(\Phi(\omega_1, \omega_2) \to \Phi'(\omega_1, \omega_2)\), where

\[
\Phi'(\omega_1, \omega_2) = f(\omega_1)f(\omega_2)\Phi(\omega_1, \omega_2).
\]  

3. Experimental Setup

Fig. 1. (a) Time and wavelength correlated photon pairs are generated through SPDC by a 405.5 nm CW laser pumping a nonlinear ppKTP crystal. A long-pass (LP) spectral filter is used to filter out the pump laser. The generated signal and idler photons are then sent on different paths and undergo HOM interference at a 50:50 BS before being coupled into single-mode (SM) optical fibers. A motorized translational stage is used to control the arrival time difference between the two photons at the BS. The photons are vertically displaced upon exiting their respective fibers and they are diffracted off a diffraction grating which decomposes the photons into their spectral compositions. The diffracted photons are then focused by a lens onto the 3D camera. (b) Image of the twin beam spectrum captured on the camera.

The experimental setup is shown in Fig. 1(a). A 200 mW, 405.5 nm continuous wave (CW) laser is used to pump a 1 mm long Type-0 periodically poled potassium titanyl phosphate (ppKTP) crystal to generate photon pairs through the process of SPDC. A 10 cm focal length lens is placed after the crystal to collimate the SPDC beam. The photon pairs are then split into separate paths using a D-shaped mirror and are then sent into a 50:50 BS (actual T:R ratio is 57:43) to undergo HOM interference. The difference in arrival time between the photon pairs at the BS is adjusted through a motorized delay line constructed in one of the paths. Upon exiting the BS, the photons are coupled into single mode optical fibers which are then fed into the customized spectrometer [23–25].

Within the spectrometer, the exit of the fibers are set at a slightly different height with respect to each other and the two beams are diffracted off a diffraction grating with the first diffraction
order focused onto the 3D camera (TPX3CAM [26]) using a 2 inch diameter, 10 cm focal length lens. The two beams are made to not propagate perfectly in parallel so to prevent the lens from focusing both spectra onto the same strip on the camera. The timing and spectral information of the photons are registered by the 3D camera from which we are able to deduce the temporal and spectral correlations between the photons. Single photon sensitivity of the 3D camera is provided by the attached image intensifier which has a quantum efficiency of approximately 20% in the spectral range of 500-850 nm [27]. A raw image of the twin beam spectrum captured on the camera is seen in Fig. 1(b).

As a single photon is converted into a flash of light by the image intensifier, a cluster of pixels will often be illuminated on the camera. Such a cluster has to be regrouped into a single event through a detection and centroiding algorithm [16]. After this correction, a spectral resolution of approximately 0.7 nm is obtained over a spectral range of 770-854 nm. Due to the signal strength (photon flux) dependence of the camera’s discrimination threshold crossover time [16, 28], a timing correction must also be performed, after which a timing resolution of approximately 6 ns is achieved.

4. Results

![Normalized Coincidence Counts](image)

Fig. 2. (a) A typical JSI measured after the BS at a path length difference of $\Delta z = 0.048$ mm. (b) Cross-section along the bright central band of the experimentally measured JSI as a function of the path length difference $\Delta z$ with $\lambda_1 - \lambda_2 = 0$ the degenerate wavelength. The cross-section of (a) highlighted by the red line. The corresponding theoretical JSI are shown in (c) and (d). A total of 151 JSI slices were taken in (b) between $\Delta z = -0.3$ mm and 0.3 mm, the data acquisition time is 10 seconds with a total of $\sim 10^4$ coincidence events for each JSI slice. Note that the coincidence counts here are not the total coincidence $N_c(\Delta z)$ given by Eq. 6 but the coincidence for each wavelength pair given by Eq. 7.

Experimentally, through looking for time correlated events between the two spectral bands seen in Fig. 1(b) and then by recording the two corresponding x-pixel/wavelength of the correlated
photons, a JSI plot can be made. A typical JSI experimentally measured after the BS at a path
length difference of $\Delta z = 0.048$ mm is shown in Fig. 2(a). The cross-section along the bright
central band of the experimentally measured JSI as a function of $\Delta z$ is shown in Fig. 2(b). We see
fast oscillations in the coincidence rate when away from $\Delta z = 0$ and no coincidences at $\Delta z = 0$.
The corresponding theoretical JSI, calculated from the integrand of Eq. 7, are shown in Fig. 2(c)
and (d). Very Good agreement is seen between the experimental results and theory.

In order to calculate the theoretical JSI, we first calculated the phase matching function (Eq. 1
and 2) with $\lambda_p = 2\pi c/\omega_p = 405.5$ nm, $\Lambda_0 = 3.425$ $\mu$m and $L = 1$ mm. $n_e(\omega)$ is obtained using
the Sellmeier equation given in [29] for a temperature of 24°C. The pump envelope function
(Eq. 4) is determined using a pump bandwidth $\sigma_p$ of 1 nm.

![Graph showing normalized coincidence counts vs path length difference](image)

Fig. 3. (a) The HOM interference dip for top-hat shaped spectral filters centered on the
degenerate wavelength of 811 nm with a bandwidth of 40 nm (black), 7 nm (blue)
and 3 nm (red). Circles are experimental data and the corresponding solid line with the
same color is the predicted shape based on theoretical calculation. (b)-(d) highlights
the corresponding region in the full JSI for the various filter bandwidth. The displayed
JSI is taken at path length difference of $\Delta z = 0.3$ mm.

Since the measured JSI in fig. 2 contains all the coincidence events across the full measurable
spectrum of the spectrometer, one can through post-processing, place virtual spectral filters
over the measured JSI to look at the changes in coincidence events in any spectral region of
interest. In Fig. 3, we show the HOM dip for top-hat shaped spectral filters of various bandwidth
(3, 7 and 40 nm) centered on the degenerate wavelength of 811 nm extracted from the HOM
dip scan data taken with no physical spectral filters used. The shape of the HOM dip between
theoretical calculation (through Eqs. 6 and 8 using a BS T:R ratio of 57:43) and experimental
data is shown in Fig. 3(a). Fig. 3(c)-(d) highlights the corresponding region in the full JSI, taken at $\Delta z = 0.3$ mm, for the various filter bandwidth. The experimental dip did not fully reach the theoretical minimum is due to imperfections in the optics alignment.

Fig. 4. HOM interference dips for (a) a Gaussian shaped 811/5 nm spectral filter, (b) an absolute value Sinc function shaped 811/5 nm spectral filter, (c) dual band top-hat shaped filters centred on 805/2 nm and 817/2 nm and (d) quad band top-hat shaped filters centred on 799/1 nm, 801/1 nm 821.3/1 nm and 823.4/1 nm. Circles are experimental data and the solid line is the predicted shape based on theoretical calculation. The corresponding shape of the spectral filters are shown in the insets.

Of course, one is also free to choose the shape and number of spectral filters to be placed and this is demonstrated in Fig. 4. Fig. 4(a) and (b) shows the HOM dip scan of a Gaussian and an absolute value Sinc function shaped 811/5 nm spectral filter, where a Gaussian and triangular shaped HOM dip are observed. A dual band top-hat filter centered at 805/2 nm and 817.1/2 nm is used in Fig. 4(c) where oscillations are seen in the HOM dip. Finally, in Fig. 4(d), a quad band top-hat shaped shaped filters centred on 799/1 nm, 801/1 nm 821.3/1 nm and 823.4/1 nm is shown, in which the combination of narrow filters and small central wavelength difference results in a beating pattern in the HOM dip oscillation.

It is also possible to observe photon bunching events in HOM from the same data set by looking for coincidences in the spectrum of the same beam instead of between the two beams [18, 30]. However, due to the requirement to correct for clustering of events caused by the image intensifier, as discussed in the previous section, coincidence events that occur approximately in a 10 pixel
radius around the degenerate wavelength of 811 nm will all be regrouped into a single event. This results in the inability to obtain an accurate HOM ‘peak’ for single band spectral filters centered around the degenerate wavelength of 811 nm. However, for non-degenerate wavelengths, as seen in Fig. 5, accurate HOM interference shape for bunching events can still be obtained.

![Graph showing HOM interference for bunching (blue) and anti-bunching (red) events with dual band top-hat shaped filters centred on 805/2 nm and 817/2 nm. Circles are experimental data and the corresponding solid line with the same color is the predicted shape based on theoretical calculation. The bunching events shown are the sum of all bunching events from both output channels.](image)

Circles are experimental data and the corresponding solid line with the same color is the predicted shape based on theoretical calculation. The bunching events shown are the sum of all bunching events from both output channels.

### 5. Discussion

In this work we demonstrated measurement of the spectral and temporal correlations in HOM interference using a camera based spectrometer. The spectral response to HOM interference for the full operating spectrum of the spectrometer, between 770-854 nm, is obtained with a spectral resolution of 0.7 nm. From this, the HOM interference behaviour at any specific spectral region/s within the measured spectrum can be extracted. Thus, with this spectrometer, full spectral and temporal correlation data, with sub-nanometer spectral and nanosecond temporal resolution, can be obtained within seconds and a full HOM dip/peak scan can be performed in minutes. The system is also versatile in that it can be used with SPDC sources pumped by any type of laser and can work in any wavelength that an image intensifier is sensitive in. All these technical improvements combined, especially in speed, opens up a whole new avenue on what is practicable in quantum technology applications and experiments. Some examples include spectral multiplexing in quantum repeaters, obtaining spectral information of targets through a single shot measurement in quantum sensing and swiftly characterizing spectral-temporal properties of single photon sources.

Improvements to the spectral resolution can be achieved with a better designed spectrometer and through predicting the initial position of the photon through a centroiding algorithm and subdividing each camera pixel, thus giving a higher spatial resolution to the camera than the physical number of pixels [31]. The temporal resolution can also be improved to sub-nanoseconds with the use of a trigger signal from the multi-channel plates of the image intensifier [32] or, as proposed in the same work, using of a streaking tube in place of the image intensifier. The measurement speed is only limited by the photon pair production rate and the overall detection efficiency of the system, a brighter source and more efficient optical elements (mostly the diffraction grating) will further improve the overall measurement speed.
