(Dated: May 21, 2021)

By properly considering the propagation dynamics of the dipole field, we obtain the full magnetic dipolar interaction between two quantum dipoles for general situations. With the help of the Maxwell equation and the corresponding Green function, this result applies for general boundary conditions, and naturally unifies all the interaction terms between permanent dipoles, resonant or non-resonant transition dipoles, and even the counter-rotating interaction terms altogether. In particular, we study the dipolar interaction in a rectangular 3D cavity with discrete field modes. When the two dipoles are quite near to each other and far from the cavity boundary, their interaction simply returns the freespace result; when the distance between the two dipoles is comparable to their distance to the cavity boundary and the field mode wavelength, the dipole images and near-resonant cavity modes bring in significant changes to the freespace interaction. This approach also provides a general way to study the interaction mediated by other kinds of fields.

I. INTRODUCTION

The electric/magnetic dipolar interaction widely exists in many microscopic systems, such as the Josephson qubit interacting with the dielectric defects [1–4], the nitrogen-vacancy (NV) interacting with the nuclear spins around [5, 6], as well as the dipolar interactions in many chemical and biology molecular [7–9]. In principle, the electromagnetic interactions between particles are indirectly induced by their local interaction with the field. Thus, it is possible to engineer the dipolar interaction by properly controlling the mediating EM field [10–18].

But in literatures, the magnetic dipolar interaction between two quantum dipoles with distance \( R \) has three different descriptions:

1. **Direct exchange**: In freespace, the classical dipolar interaction between two static magnetic dipoles is (\( \hat{e}_R \) is the unit directional vector of the distance \( R \)) [19]
   \[
   V_0 = \frac{\mu_0}{4\pi R^3} \left[ \hat{m}_1 \cdot \hat{m}_2 - 3(\hat{m}_1 \cdot \hat{e}_R)(\hat{m}_2 \cdot \hat{e}_R) \right],
   \]
   thus the quantum dipolar interaction is usually obtained by simply replacing the classical dipole moments with quantum operators \( \hat{m}_i \). Here the mediation effect of the EM field is not explicit, and the frequencies of the quantum dipoles do not appear [5, 6, 20].

2. **Master equation correction**: The dynamics of two dipoles locally interacting with the EM field can be described by a Markovian master equation, where the system Hamiltonian contains an interaction correction \( \hat{V}_{12} = V(\omega) \hat{\tau}_1^+ \hat{\tau}_2^- + \text{h.c.} \), where \( \hat{\tau}_{1,2} \) are the transition operators, and [21–24]
   \[
   V(\omega) = \frac{\mu_0}{4\pi R^3} \left\{ \hat{m}_1 \cdot \hat{m}_2 \left[ (1 - \eta^2) \cos \eta + \eta \sin \eta \right] \right.
   \]
   \[ -3(\hat{m}_1 \cdot \hat{e}_R)(\hat{m}_2 \cdot \hat{e}_R) \left[ (1 - \frac{\eta^2}{3}) \cos \eta + \eta \sin \eta \right] \},
   \]
   Here \( \eta := \omega R / c \), and \( \omega \) is the transition frequency of the two resonant dipoles. The interaction strength \( \hat{V}(\omega) \) exhibits an oscillating decay with the distance \( R \), and returns the above Eq. (1) when \( \omega R / c \rightarrow 0 \). Due to the limited usage of the rotating-wave approximation (RWA) in the master equation derivation, this approach could only give the interaction term between two resonant transition dipoles, but cannot give the other interaction terms, e.g., those between non-resonant dipoles [25], permanent dipoles, and the counter rotating terms. Besides, this approach cannot be applied when the field modes are discrete, e.g., in an ideal lossless cavity.

3. **Mode elimination**: Considering the two dipoles (frequency \( \omega_{1,2} \)) both interacting with one common field mode (frequency \( \nu \)), e.g., \( \hat{V} = \hat{a}^\dagger (g_1 \hat{\tau}_1^+ + g_2 \hat{\tau}_2^-) + \text{h.c.} \), the mediating field mode can be eliminated by the Fröhlich-Nakajima transform [10, 26–29], which gives \( \hat{V}_{12} \approx \tilde{\tau}_1^+ \tilde{\tau}_2^- + \text{h.c.} \), with (see Appendix A)
   \[
   \tilde{\beta} = \frac{1}{\sqrt{\omega_1 - \nu}} \left( g_1 g_2^\dagger + g_2 g_1^\dagger / \omega_2 - \nu \right). \]
   In more realistic cases, usually more field modes should be involved.

It is not quite clear to see how these approaches are connected with each other. In this paper, we make a general approach which unifies all the above results together in the same framework. The existence of one dipole would generate a dipole field propagating to the other one, and then the dipolar interaction is generated [30, 31]. The dynamics of this dipole field is given by the Maxwell equation and the corresponding Green function [14–16, 32, 33]. Based on this idea, we obtained the full dipolar interaction for two quantum magnetic dipoles for general boundary conditions. Our result naturally includes all the interaction terms between permanent dipoles, resonant or non-resonant transition dipoles, and even the counter-rotating interaction terms altogether.
II. DIPOLE FIELD PROPAGATION

We consider two magnetic dipoles are placed in the EM field. The Hamiltonian of each dipole is $\hat{H}_\alpha = \sum_u E_u^{(\alpha)} |u\rangle_\alpha \langle u|$, where $E_u^{(\alpha)}$ and $|u\rangle_\alpha$ are the eigen energy and the corresponding eigenstate of dipole-$\alpha$ ($\alpha = 1, 2$).

The two magnetic dipoles interacts with the EM field via their local interactions $V_\alpha = -\vec{m}_\alpha \cdot \vec{B}(r_\alpha)$, where $r_\alpha$ is the position of dipole-$\alpha$, and $\vec{m}_\alpha := \sum_{uv} \vec{m}_{uv} \hat{\alpha}_{uv} := \sum_{uv} \vec{m}_{uv} |u\rangle_\alpha \langle v|$ is the dipole operator, with $\vec{m}_{uv} := \langle u| \vec{m}_\alpha | v\rangle$ and $\hat{\alpha}_{uv} := |u\rangle_\alpha \langle v|$ (see Fig. 1). Usually, one dipole operator $\vec{m}_\alpha$ contains both nonzero permanent dipoles (the diagonal terms $\vec{m}_{uv} |u\rangle_\alpha \langle u|$) and transition dipoles (the off-diagonal terms $\vec{m}_{uv} |u\rangle_\alpha \langle v|$ with $u \neq v$) together [30].

The existence of one magnetic dipole changes the EM field dynamics, and when such field changes propagate to the other dipole, the interaction is generated between the two dipoles [30, 31]. Here we first consider the dipole field generated by dipole-1 interacting with dipole-2. Notice that, the quantized magnetic field $\vec{B}(r, t)$ also follows the Maxwell equation

$$\left[ \frac{1}{c^2} \partial_t^2 - \nabla^2 \right] \vec{B}(r, t) = \mu_0 \nabla \times \vec{j}_1(r, t),$$

which has the same form with the classical one [19], although the explicit form of the quantized field $\vec{B}(r, t)$ is not written down. Here $\vec{j}_1 := \nabla \times \dot{M}_1$ is the electric current density induced by dipole-1, and $\dot{M}_1(r, t) := \vec{m}_1(t) \delta (r - r_1)$ is the magnetization density.

The dynamics of the quantized field contains two contributions $\vec{B}(r, t) = \vec{B}_0(r, t) + \vec{B}_{d1}(r, t)$, where $\vec{B}_0(r, t)$ comes from the vacuum EM field, given by the homogeneous equation $[c^{-2} \partial_t^2 - \nabla^2] \vec{B}_0 = 0; \vec{B}_{d1}(r, t)$ is the dipole field generated by dipole-1, which can be given with the help of the tensor Green function [32, 34, 35].

$$\vec{B}_{d1}(r, t) = \mu_0 \int_{-\infty}^{\infty} dt' \int_V d^3r' \vec{G}_m(rt, r't') \cdot \vec{j}_1(r', t'),$$

$$\left[ \frac{1}{c^2} \partial_t^2 - \nabla^2 \right] \vec{G}_m(rt, r't') = \nabla \times \dot{\vec{\delta}}(r-r') \delta(t-t').$$

Here $\vec{r}'$ denotes the field (source) position in the Green function $\vec{G}_m(rt, r't')$.

In the above dipole field $\vec{B}_{d1}(r, t)$, the dynamics of dipole-1 is contained in the current $\vec{j}_1(r, t) = \nabla \times [\vec{m}_1(t) \delta (r - r_1)]$. Here we make an approximation that during the field propagation time ($\sim R/c$), the dynamics of the dipole-1 can be regarded as only governed by its self-Hamiltonian $H_1$ and thus follows the unitary evolution, which gives $\vec{m}_1^{ab}(t') \approx \vec{m}_1^{ab}(t) \exp[-i\omega_1^{ab}(t'-t)]$, with $\hbar \omega_1^{ab} := E_2^{(ab)} - E_1^{(ab)}$ as the energy gap between these two levels [30, 31]. In most experiments with micro-/mesoscopic dipoles, the distance between different dipoles are within several microns, thus the propagation time for the their interactions ($R/c \lesssim 10^{-15}$ s) is much shorter than the decay time of each single dipole, which guarantees this approximation reliable. Then the dipole field (5) can be further obtained as

$$\vec{B}_{d1}(r, t) = \mu_0 \int_{-\infty}^{\infty} dt' \int_V d^3r' \vec{G}_m(rt, r't') \cdot \nabla \times [\vec{m}_1(t') \delta(r'-r_1)]$$

$$\simeq -\mu_0 \sum_{ab} \int_{-\infty}^{\infty} dt' \int_V d^3r' \vec{G}_m(rt, r't') \cdot \nabla \times [\vec{m}_1^{ab}(t) e^{-i \omega_1^{ab}(t'-t)} \delta(r'-r_1)]$$

$$= \mu_0 \sum_{ab} \vec{G}_m(r, r_1; \omega_1^{(1)}) \times \nabla_1 \cdot \vec{m}_1^{ab}(t).$$

(6)

Here $[\nabla \times \vec{G}]_{ij} := \epsilon_{jmn} \partial_n \vec{G}_{im}$ means the curl operation to the left, $\nabla' / \nabla_1$ is the derivative respect to $r'/r_1$, and

$$\vec{G}_m(r, r'; \omega) := \int_{-\infty}^{\infty} dt' \vec{G}_m(rt, r't') e^{-i \omega(t'-t)}$$

(7)
is just the Fourier transform of the Green function $G_m(r, r')$.

Therefore, the local interaction between dipole-2 (at position $r_2$) and the dipole field $\mathbf{B}_{d1}(r, t)$ naturally gives the DD interaction as the following symmetric form

$$
\dot{V}_{2-1} = -\mathbf{m}_2(t) \cdot \mathbf{B}_{d1}(r_2, t)
$$

(8)

$$
= \mu_0 \sum_{ab, uv} \mathbf{m}_{2uv} \cdot \mathbf{G}_m(r_2, r_1; \omega_{ab}^{(1)}) \times \nabla_1 \cdot \mathbf{m}_{1}^{ab}.
$$

(9)

Here $\mathbf{G}_A(r, r'; \omega)$ is introduced from $\mathbf{G}_m(r, r'; \omega) = \nabla \times \mathbf{G}_{A}(r, r'; \omega)$, which is just the Green function for the vector potential $\mathbf{B} = \nabla \times \mathbf{A}$. And $\mathbf{G}_A(r, r'; \omega)$ follows

$$\nabla^2 + (\omega/c)^2 \mathbf{G}_A(r, r'; \omega) = -\delta(r - r').$$

The interaction (8) is gauge independent, since the term $\nabla \times \mathbf{G}_A$ in $\dot{V}_{2-1}$ remains unchanged in gauge transformations. Besides, it is worth noting that the RWA is not needed throughout the above derivations.

Therefore, once $\mathbf{G}_A(r, r'; \omega)$ is solved, the dipolar interaction $\dot{V}_{2-1}$ can be obtained from Eq.(8). The full dipolar interaction between the two magnetic dipoles also should involve the interaction between dipole-1 and the field induced from dipole-2, i.e.,

$$
\dot{V}_{1+2} = \frac{1}{2} [\dot{V}_{2-1} + \dot{V}_{1-2}]
$$

$$
= -\frac{1}{2} [\mathbf{m}_1 \cdot \mathbf{B}_{d1}(r_2) + \mathbf{m}_1 \cdot \mathbf{B}_{d2}(r_1)].
$$

(10)

In freespace, the Green equation (9) has an isotropic solution $\mathbf{G}_A(r_2, r_1; \omega \equiv ck) = (\cos kR/4\pi R) \mathbf{I}$, with $R \equiv |r_2 - r_1|$. Then Eq.(8) gives the dipolar interaction as $\dot{V}_{2-1} = \sum_{uv, ab} V_{2uv}^{ab} (\omega_{ab}^{(1)}) \mathbf{G}_{m}^{ab} |\omega_u|^{2} |u|^{2} \mathbf{r}_{uv}^{ab}$, where the interaction strength $V_{2uv}^{ab} (\omega_{ab}^{(1)})$ of each term is given by

$$
V_{2uv}^{ab} (\omega_{ab}^{(1)}) = \mu_0 \left[ \mathbf{m}_{2uv} \cdot \mathbf{m}_{1}^{ab} \right] \frac{\cos kR}{4\pi R}
$$

$$
= \mu_0 \left\{ \mathbf{m}_{2uv} \cdot \mathbf{m}_{1}^{ab} \left[ (1 - \eta^2) \cos \eta + \sin \eta \sin \eta \right] - 3(\mathbf{m}_{2uv} \cdot \mathbf{e}_R)(\mathbf{m}_{1}^{ab} \cdot \mathbf{e}_R) \left[ (1 - \eta^2) \cos \eta + \sin \eta \sin \eta \right] \right\}.
$$

(11)

III. THE DIPOLAR INTERACTION INSIDE A LOSSLESS CAVITY

Now we further consider the dipolar interaction between two dipoles inside a rectangular cavity, which is made of ideal conductors with no loss.

In this case, the field modes in the cavity are fully discrete. The above discussions about the dipole field propagation still holds, and the cavity boundary condition is naturally included in the tensor Green function $\hat{\mathbf{G}}_A(r, r'; \omega)$ from Eq. (9), i.e.,

$$
\hat{n} \times \hat{\mathbf{G}}_A(r, r'; \omega) = 0, \quad \nabla \cdot \hat{\mathbf{G}}_A(r, r'; \omega) = 0
$$

(12)

for $\mathbf{r}$ on the conductor plane [34, 35]. Here the Green function can be written as $\hat{\mathbf{G}}_A = G_A^x \hat{x} \hat{x} + G_A^y \hat{y} \hat{y} + G_A^z \hat{z} \hat{z}$, and the above boundary condition indicates $G_A^\sigma = 0$ on the sidewalls and $\partial_\sigma G_A^\sigma = 0$ on the end caps with respect to direction-$\sigma$ (for $\sigma = x, y, z$).

The Green function $\hat{\mathbf{G}}_A(r, r'; \omega)$ has the following solution of mode expansion

$$
G_A^\sigma(r, r'; \omega) = \sum_k \frac{A_k^\sigma(r) A_k^\sigma(r')}{k^2 - (\omega/c)^2},
$$

(13)

where $\{A_k^\sigma(r)\}$ is a set of orthonormal eigenfunctions for $[\nabla^2 + \mathbf{k}^2]\mathbf{K}_k(r) = 0$, with $\mathbf{k}$ indexing the field.
modes (see Appendix B). Then the dipolar interaction can be further obtained [from Eq. (8)] as
\[ V_{2\rightarrow 1}^{uv,ab}(\omega) = \sum_k \frac{c^2 \Omega_{uv,ab}^2 / \omega}{\omega - c^2 k^2} \sum_{|k| \leq 1} \frac{c^2 \Omega_{uv,ab}^2 / \omega}{\omega - c^2 k^2}, \] (14)
where \( \Omega_{uv,ab}^{\alpha} \) is the interaction strength returning the result (3) in the mode elimination approach (see Appendix A). How-

tever, it turns out the above summation series converges too slowly, since the density of state of the field modes also increases as \( \sim k^2 \), which is in the same scale with the denominator \( \omega^2 - c^2 k^2 \). As a result, only counting the near-resonant terms is not enough to give a precise evaluation for the dipolar interaction.

On the other hand, \( G_A^\omega(r, r'; \omega = \pm k) \) also can be written in the form of image expansion (Fig. 1), but that is also inefficient for numerical estimations. This problem can be solved by the improved Ewald expansion [34, 35], that is, with the help of \( \text{erf}(x) + \text{erfc}(x) = 1 \), the Green function is separated as \( G_A^\omega(r, r'; \omega) = G_{A1}^\omega(r, r'; \omega) \) and \( G_{A2}^\omega(r, r'; \omega) \), which further gives (see more details in Refs. [34, 35])

\[ G_{A1}^\omega = \sum_{ijklrst} (-1)^{r+s+t-q} \cos \frac{k R_{ijl, rst}}{4 \pi} \cdot \text{erf}(K_c R_{ijl, rst}), \]
\[ G_{A2}^\omega = \sum_{ijklrst} (-1)^{r+s+t-q} \cos \frac{k R_{ijl, rst}}{4 \pi} \cdot \text{erfc}(K_c R_{ijl, rst}) \]
\[ = \sum_{mnp} \mathcal{K}_{mnp}(r) \mathcal{K}_{mnp}(r') \cdot \Gamma(K_c)(k, k_{mnp}). \] (15)

Here \( k_{mnp} = |\mathbf{m}/L_x, \mathbf{n}/L_y, \mathbf{p}/L_z| \) is the field mode index with \( k_{mnp} := |\mathbf{k}| \) and \( m, n, p \in \mathbb{Z}^+ \), \( R_{ijl, rst} := |r - R_{ijl, rst}| \) is the distance between the field point \( r \) and the image of \( r' \equiv (x', y', z') \) at

\[ R_{ijl, rst} = [2i L_x + (-1)^s x'] \hat{x} + [2j L_y + (-1)^t y'] \hat{y} \]
\[ + [2l L_z + (-1)^z z'] \hat{z}, \] (16)
with \( i, j, l \in \mathbb{Z}, r, s, t = 0, 1, \) and \( q_{x,y,z} = r, s, t \). The function \( \Gamma(K_c)(k, k_{mnp}) \) provides a fast-converging cutoff,

\[ \Gamma(K_c)(k, k_{mnp}) = \frac{1}{2k_{mnp}} \left[ \frac{e^{-(k+k_{mnp})^2 / 4k_c^2}}{k_{mnp} + k} + \frac{e^{-(k-k_{mnp})^2 / 4k_c^2}}{k_{mnp} - k} \right]. \]

Here \( K_c \) is a free parameter [usually set as \( K_c = \sqrt{\pi/(2V^{1/3})} \)].

Now both the above \( G_{A1}^\omega \) and \( G_{A2}^\omega \) converge rapidly without counting too many images. When \( K_c \to 0 \), the Green function \( G_A^\omega(r, r'; \omega) \) gives the form of image expansion, and when \( K_c \to \infty \), \( G_A^\omega(r, r'; \omega) \) returns the form of mode expansion (13). In this sense, we say \( G_{A1}^\omega \) and \( G_{A2}^\omega \) indicate the contributions from the images and mode-propagation respectively. Then the dipolar interaction strength can be further obtained from Eqs. (8, 10).

IV. NUMERICAL RESULTS

Based on the above discussions, we consider the dipolar interaction \( V_{2\rightarrow 1}^{cav} \) between two magnetic dipoles inside a rectangular 3D cavity with \( L_{x,y,z} \equiv L \) in different situations and show the numerical results in Fig. 2.

In Fig. 2(a, b), dipole-1 (red) is placed at the center of the cavity, dipole-2 (green) moves from the center to the boundary \( (r_2 = r_1 + R) \) with \( 0 < R < L/2 \), and both dipoles are oriented at the z-direction. As mentioned above, the full interaction contains the contributions from the field propagations in both way, namely, \( V_{cav}^{2\rightarrow 1} = V_{cav}^{2\rightarrow 1} + V_{cav}^{2\rightarrow 1} \), and clearly these two contributions \( V_{cav}^{2\rightarrow 1} \) and \( V_{cav}^{2\rightarrow 1} \) [Fig. 2(a, b)] are not exactly the same with each other.

As a comparison, the dipolar interactions in freespace with the same conditions are also presented [Eqs. (1, 2), see the green and blue lines]. Since here we choose the dipole frequency as \( \omega/c = 20 \), in the regime \( \omega R/c > 1 \), the interaction \( V_{cav}^{2\rightarrow 1} \) exhibits significant oscillations with the distance \( R \). When the distance between the two dipoles is quite small (in the regime \( \omega R/c < 0 \)), \( V_{cav}^{2\rightarrow 1} \) just returns the static dipolar interaction in freespace (1) with the power law dependence \( \sim R^{-3} \) [see the log-log scale inset in Fig. 2(a)]. That means, when the two dipoles are far from the conductor boundary, their interaction well returns the freespace situation [36], and this is also consistent with the situation in classical electrodynamics.

Accordingly, we consider the situation that the two dipoles are placed near the conductor plane. In Fig. 2(c), dipole-1 is set near the bottom center \( r_1 = (0.5 L_x, 0.5 L_y, 0.01 L_z) \), and still dipole-2 moves away...
All the conditions are the same with (a) except the interaction at bottom to top, with (e) All the conditions are the same with (d) except the positions are the same with (c). (f) Both the two dipoles move from the bottom to the top, with $r_1 = (0.5L_x, 0.5L_y, 0.01L_z)$. (g) All the conditions are the same with (f) except $d$ are oriented at $z$-direction. The reason is, the dipole field $\mathbf{B}_{d2}(r)$ generated from dipole-1 should follow the boundary condition near the conductor plane during its propagation, thus $\mathbf{B}_{d2}(r)$ tends to be parallel with the conductor plane. Therefore, since here dipole-2 is perpendicular to the conductor plane, their local interaction $-\mathbf{m}_2 \cdot \mathbf{B}_{d1}(r_2)$ tends to vanish to zero [Eq. (8)].

Similar comparison is also made for two dipoles oriented in $x$-direction [Fig. 2(d, e)]. Since here the two dipoles are parallel to the conductor plane, there is no suppressing behavior as Fig. 2(c) when the dipoles are placed near the cavity bottom, and the interactions $V_{2c-1}^{\text{cav}}$ in Fig. 2(d, e) look similar to each other.

To see this mechanism more clearly, we consider the distance between the two dipoles is fixed as $r_2 = r_1 + R \hat{e}_x$ with $R \approx 0.1L$, and they both move from the cavity bottom to the top $|r_1| = (0.5L_x, 0.5L_y, d)$ with $0 < d < L_z$ [Fig. 2(f)], and clearly the interaction $V_{2c-1}^{\text{cav}}$ approaches zero when the two dipoles (in $z$-direction) approach the top and bottom boundaries. The contributions from the dipole images and mode-mediation are also presented respectively [from $G_{A1}^2$ and $G_{A2}^2$ in Eq. (15)], comparing with the freespace interaction strength, which is a constant due to the fixed distance. But if dipole-2 is oriented in $x$-direction, $V_{2c-1}^{\text{cav}}$ would remain nonzero at the boundaries $d \to 0, L_z$ [Fig. 2(g)].

The influence from the conductor boundary also can be understood from the demonstration in Fig. 1. When dipole-1 is placed near the conductor plane, the dipole field felt by dipole-2 comes from both dipole-1 and its image. In the bulk regime far from the boundaries [see Fig. 2(f, g)], the interaction strength exhibits significant oscillations varying with positions, which comes from the spatial distribution of the mediating modes, especially the ones nearly resonant with the dipole frequency.
V. DISCUSSIONS

By properly considering the propagation of the dipole field, we obtain the full magnetic dipolar interaction which includes all the interaction terms between permanent dipoles, resonant or non-resonant transition dipoles, and even the counter-rotating interaction terms altogether. The result applies for general boundary conditions, which already have been enclosed in the tensor Green function $\tilde{G}_A(r, r'; \omega)$, and this is also consistent with the classical Maxwell equation. In particular, we show the interaction for the dipolar interaction in a rectangular 3D cavity, and how it is connected with previous results under certain conditions.

From the above results, it is worth noticing that the dipolar interaction exhibits significant dependence of three typical lengths, i.e., the distance $R$ between the two dipoles, the distance $d$ between the dipoles to the cavity boundaries, and the wavelength $\lambda$ of the field modes nearly resonant with the dipole frequencies.

For example, the NV centers ($\omega_{NV} \simeq 2.88\, \text{GHz}$) in a nano-diamond interact with the $^{13}$C nuclear spins ($\omega_c \sim 1\, \text{MHz}$) around through the magnetic dipolar interaction [5, 6, 20]. If the nano-diamond is placed in the center of a 3D cavity whose base frequency is $\sim 1\, \text{GHz}$ with the size $\sim 10\, \text{cm}$ [37], the magnetic dipolar interaction between the NV centers and the nuclear spins around should be almost the same as the static dipolar interaction (1) in freespace, since these magnetic dipoles are too far away from the cavity boundaries [Fig. 2(a)]. If the nano-diamond is placed quite near to the cavity boundary, or quite close to a metallic STM tip, their dipolar interactions would be significantly changed.

On the other hand, considering some cold atoms are placed in an optical cavity (usually $\sim 100\, \mu\text{m}$), the distance $R$ between the flying atoms, their distance to the cavity boundaries $d$, and the cavity mode wavelength $\lambda$ would be comparable [38–43]. In this case, the dipolar interaction in the cavity would have a complicated position dependence as shown in Fig. 2.

Throughout the discussion, the dynamics of the mediating dipole field is simply described by the Maxwell equation and the corresponding Green function. Thus, by properly changing to some other field equations, this approach can be generalized to study the interaction mediated by other kinds of fields, such as the exciton-polariton or phonon field [15, 24, 44, 45].

In the above discussions about the cavity situation, we only focus on the ideal conductors, and realistic situations may involve more physical effects. For example, near the metal surface, the surface plasmon induced by the electron density oscillation would influence the EM field nearby, and that would bring in extra changes to our above discussions [16, 24]. In principle, the interaction induced by these extra fields also can be considered by the approach in this paper.

Acknowledgments - S.-W. Li appreciates quite much for the helpful discussion with N. Wu, D. Xu, and B. Zhang in BIT. This study is supported by NSCF of China (Grant No. 11905007), Beijing Institute of Technology Research Fund Program for Young Scholars.

Appendix A: The effective interaction mediated by one field mode

We consider two dipoles both interact with one common field mode, and the Hamiltonian of the three body system is $\hat{H} = \hat{H}_0 + \hat{V}$, where

$$\hat{H}_0 = \omega_1 \hat{\tau}_1^+ \hat{\tau}_1^- + \omega_2 \hat{\tau}_2^+ \hat{\tau}_2^- + \nu \hat{a} \hat{\dot{a}},$$

$$\hat{V} = g_1 \hat{\tau}_1^+ \hat{a} + g_2 \hat{\tau}_2^+ \hat{a} + \text{h.c.} \quad (A1)$$

The Fröhlish-Nakajima canonical transformation gives an effective Hamiltonian [26, 27],

$$\hat{H}_{\text{eff}} = e^{-\frac{\hat{S}}{2}} \hat{H} e^{\frac{\hat{S}}{2}} = \hat{H} + \frac{1}{2} [\hat{H}, [\hat{H}, \hat{S}]] + \ldots \approx \hat{H}_0 + \frac{1}{2} [\hat{V}, \hat{S}]$$

(A2)

where the first order is eliminated $\hat{V} + [\hat{H}_0, \hat{S}] \equiv 0$ by properly setting $\hat{S} := \hat{A} \tau_1^+ \hat{a} + \hat{B} \tau_2^+ \hat{a} + \text{h.c.}$, and that gives

$$[\hat{H}_0, \hat{S}] = (\omega_1 - \nu)(\hat{A} \hat{\tau}_1^+ \hat{a} + \text{h.c.}) + (\omega_2 - \nu)(\hat{B} \hat{\tau}_2^+ \hat{a} + \text{h.c.}), \Rightarrow A = \frac{g_1}{\nu - \omega_1}, \quad B = \frac{g_2}{\nu - \omega_2}. \quad (A3)$$

Therefore, the effective interaction becomes

$$\hat{V}_{\text{eff}} = \frac{1}{2} [\hat{V}, \hat{S}] = (\hat{\beta} \hat{\tau}_1^+ \hat{\tau}_2^- + \text{h.c.}) + \sum_{\alpha=1,2} \tilde{\xi}_\alpha \hat{\tau}_\alpha^+ \hat{a} + \frac{1}{2} \hat{a}^\dagger \hat{a},$$

$$\hat{\beta} = \frac{1}{2} \left[ \frac{g_1 g_2^*}{\omega_1 - \nu} + \frac{g_2 g_1^*}{\omega_2 - \nu} \right], \quad \tilde{\xi}_\alpha = \frac{|g_\alpha|^2}{\omega_\alpha - \nu}. \quad (A4)$$

The first term in $\hat{V}_{\text{eff}}$ eliminates the mediating field mode and gives the interchange interaction between the two dipoles as shown in Eq. (3), while the second term can be regarded as a correction to the self-Hamiltonian $\omega_\alpha \hat{\tau}_\alpha^+ \hat{\tau}_\alpha^-$ which depends on the mode state.

Appendix B: Eigen modes in the rectangular cavity

Here we show the eigen modes of the cavity field given by $[\nabla^2 + k^2] \hat{A}_k(r) = 0$ in the rectangular region $x, y, z \in [0, L_{x,y,z}]$. The boundary condition requires $\hat{n} \times \hat{A}_k(r) = 0, \nabla \cdot \hat{A}_k(r) = 0$ for $r$ on the boundary planes. Denoting the vector eigen modes as $\hat{A}_k(r) := (\hat{A}_{mnp}^x, \hat{A}_{mnp}^y, \hat{A}_{mnp}^z)$,
the eigen modes reads [34, 35]

\[
A_{mnp}(r) = \sqrt{\frac{4(2 - \delta_{m0})}{V}} \cos \frac{m\pi}{L_x} x \sin \frac{n\pi}{L_y} y \sin \frac{p\pi}{L_z} z,
\]

\[
A_{mnp}(r) = \sqrt{\frac{4(2 - \delta_{m0})}{V}} \sin \frac{m\pi}{L_x} x \cos \frac{n\pi}{L_y} y \sin \frac{p\pi}{L_z} z,
\]

\[
A_{mnp}(r) = \sqrt{\frac{4(2 - \delta_{m0})}{V}} \sin \frac{m\pi}{L_x} x \sin \frac{n\pi}{L_y} y \cos \frac{p\pi}{L_z} z,
\]

where \(k_{mnp} = (m\pi/L_x, n\pi/L_y, p\pi/L_z)\) and \(m, n, p \in \mathbb{Z}_+^3\). Here \(A_{mnp}(r)\) are normalized as \(\int_A A_{mnp}^*(r) A_{q}^*(r) d^3r = \delta_{mq}\delta_{kq}\).
