ABSTRACT

Wet-chemical syntheses for quasi two-dimensional (2D) transition metal dichalcogenides (TMDs) have emerged as promising methods for straightforward solution-processing of these materials. However, photoluminescence properties of colloidal TMDs are virtually unexplored due to the typically non-emitting synthesis products. In this work, we demonstrate room temperature micro-photoluminescence spectroscopy on delicate ultrathin colloidal WS$_2$ nanosheets synthesized from WCl$_6$ and elemental sulfur in oleic acid and oleylamine at 320 °C for the first time. Both, mono- and multilayer photoluminescence is observed, revealing comparable characteristics to exfoliated TMD monolayers and underpinning the high quality of colloidal WS$_2$ nanosheets. In addition, a promising long-term air-stability of colloidal WS$_2$ nanosheets is observed and the control of their photodegradation under laser excitation is identified as a challenge for further advancing nanosheet monolayers. Our results render colloidal TMDs as easily synthesized and highly promising 2D semiconductors with optical properties fully competitive with conventionally fabricated ultrathin TMDs.

TOC
KEYWORDS Colloidal 2D transition metal dichalcogenides, TMDs, monolayer photoluminescence, photodegradation, air-stability.

Atomically thin TMDs with the chemical formula $\text{MX}_2$ ($\text{M} = \text{Mo, W}; \text{X} = \text{S, Se, Te}$) are at the forefront of a new generation of optically active 2D materials$^{1,2}$ that are promising candidates for single-photon emission, as ultra-fast transistors,$^3$ and for spin- or valleytronics$^{4-7}$. Optical characterization methods including low-temperature spectroscopy$^8$ have established a profound knowledge of the unique optoelectronic properties of TMDs that are dominated by the formation of long-living excitons with high binding energies in the order of hundreds of meV.$^9$ In conjunction with a direct band gap in the visible to near-infrared region of the optical spectrum$^{10}$, a large spin splitting induced by a strong spin-orbit coupling$^{11}$ and a valley-selective addressable supplemental degree of freedom$^{12,13}$, TMD monolayers have the potential to impact a wide spectrum of research fields.

Most of the current experimental findings were obtained using samples fabricated via exfoliation$^{14-16}$ or chemical vapor deposition (CVD)$^{17-19}$ since these methods yield monolayers of large lateral sizes and low defect concentration. However, as an additional alternative fabrication method wet-chemical synthesis methods for TMDs are becoming increasingly popular.$^{20-23}$ These colloidal TMDs represent solution-processable and scalable materials and – if the material thickness is controlled properly – bear a high potential as building blocks in TMD heterostructures and for numerous applications like photodetectors,$^{24}$ solar cells,$^{25}$ or polarized light emitting diodes.$^{26}$ Current research has shown that the approach is capable of producing various TMDs with single-to few-layer thickness and controlled lateral size.$^{27,28}$ Nevertheless, despite the huge synthetic progress, the optical properties of colloidal TMD mono- and few-layers prepared by colloidal methods have been sparsely studied$^{22,23,29}$ and photoluminescence (PL) in non-passivated ultrathin
nanosheets has not been shown up to now due to competing defect-induced non-radiative mechanisms. 

In this work we present the room temperature micro-photoluminescence ($\mu$-PL) spectroscopic characterization of wet-chemically synthesized WS$_2$ nanosheets, showing that WS$_2$ nanosheet mono- and multilayers exhibit similar optical quality like 2D WS$_2$ prepared by exfoliation or CVD and rendering the colloidal TMDs fully compatible with existing methods for the first time. In addition, close attention is paid to both, the promising long-term air-stability as well as to the occurring photodegradation process, which turns out to be the most challenging task for future detailed research. The findings in this work aim for the optimization of the optical properties of colloidal TMDs via a systematic investigation of their joint structural and $\mu$-PL properties.

Photoluminescent colloidal WS$_2$ nanosheets were synthesized by adjusting wet-chemical methods existing in literature for obtaining semiconducting WS$_2$ mono- and few layers.$^{20,30}$ Here, different modifications that are either semiconducting or metallic were obtained and exhibited no PL. We focused on synthetically advancing the PL properties of WS$_2$ nanosheets by obtaining the semiconducting phase. This included a better solubility of the tungsten precursor (WCl$_6$), which was achieved by dissolving WCl$_6$ in a mixture of oleylamine (OlAm) and oleic acid (OA). OlAm and OA form an oleylammonium species in an acid-base equilibrium$^{31}$ and can assemble as a lamellar tungsten precursor.$^{32}$ In contrast to previously described WS$_2$ nanosheet syntheses, elemental sulfur dissolved in OlAm was used as sulfur source. Elemental sulfur is less toxic than CS$_2$ or H$_2$S typically applied but likewise forms the alkylammonium polysulfide species that steadily releases the necessary H$_2$S at higher temperatures for the reaction.$^{33}$ By combining both precursor solutions and successively adding them to the OlAm and hexamethyldisilazane (HMDS) mixture at 320 °C, the sulfide species in situ forms H$_2$S, which reacts with the tungsten precursor.
yielding WS$_2$ nanosheets. A detailed description of the synthesis conditions and chemicals is found in the Supporting Information (SI).

Figure 1 shows TEM images of WS$_2$ mono- and multilayers. The overview TEM image (Figure 1A) demonstrates that the nanosheets form a flower-like morphology with overall lateral dimensions of a few micrometers. Figure 1B shows a high-resolution TEM (HR-TEM) image of a
flat lying domain of a single WS$_2$ nanosheet, revealing its crystallinity. In addition, the hexagonal layout supports the presence of the semiconducting 2$H$ phase. Figure 1C depicts interlayer distances in WS$_2$ nanosheets visible by nanosheets stacked on their edges. Statistical analysis of these distances carves out two major cases shown in Figure 1D: 1) layers are 0.73 ± 0.06 nm apart, or 2) they exhibit a less defined spacing of 2.4 ± 0.4 nm. These distances correlate well with the theoretical tungsten-to-tungsten layer distance in the bulk material of 0.62 nm$^{34}$ and an interim ligand layer of several nanometers due to a ligand template effect, respectively.$^{35}$ As shown in Figure 1E, monolayers and few-layers of up to 5 stacked sheets were found via TEM. Therefore, both mono- and multilayer features can be expected in the PL measurements. Absorption spectra of WS$_2$ nanosheets exhibit a negligible background absorption at 750 nm (1.65 eV), which is attributed to small amounts of the metallic WS$_2$ phase.$^{30}$ However, distinct absorption features are present for the A-, B- and C-exciton at 612 nm (2.03 eV), 521 nm (2.38 eV), and 441 nm (2.81 eV), as is shown in Figure 1F, and confirm the predominant semiconducting character of WS$_2$ nanosheets.$^{20}$ A detailed evaluation of the A-excitonic feature is shown in Figure S1 and reveals a small shoulder at 633 nm (1.96 eV) in the differentiated absorption spectrum. The presence of these two absorption energies is attributed to mono- and few layers as has been shown for CVD samples before$^{36}$ and as is validated by the TEM images.

In contrast to absorption measurements, PL characterization is substantially more influenced by defects present in the nanosheets,$^8$ which can reduce the PL efficiency by the stimulation of different types of non-radiative recombination.$^{37-40}$ Up to now, typical colloidal TMDs exhibit a high number of chalcogen vacancies leading to a lack of PL in the samples and hindering their unambiguous optical investigation.$^{29}$ Based on the essential importance of PL measurements for future research and for underpinning the high structural quality of colloidal TMDs shown here, we
apply highly sensitive $\mu$-PL spectroscopy for a systematic investigation of the optical properties of WS$_2$ nanosheets. The employed confocal microscope setup is schematically shown in Figure S2 in the SI. It contains, *inter alia*, a high working distance objective (NA = 0.45), motorized translation stages and a nitrogen-cooled CCD array, allowing spatially resolved, highly sensitive measurements with excitation and detection spot sizes in the range of 1-2 $\mu$m.

All $\mu$-PL measurements were performed at a temperature of 25 °C. Two samples were prepared by drop casting a solution with three different concentrations of the WS$_2$ nanosheets on a standard broadband dielectric mirror substrate. Sample 1 was assembled instantaneously into a microcryostat while sample 2 was stored for six months under ambient conditions in a container without a desiccant for the validation of the air-stability.

We find $\mu$-PL of 2D-colloidal WS$_2$ mono- and multilayers, underpinning the high quality of single ultrathin WS$_2$ layers. Figure 2 shows $\mu$-PL measurements of WS$_2$ nanosheets illustrating the different aspects of the measured monolayer PL. Spectra of different positions on (position 2-4) and next to (position 1) the measured PL feature (Figure 2A) can be clearly assigned to a WS$_2$ monolayer due to the narrow linewidth and matching emission energy of the spectral features alongside with a drastic increase of the PL intensity.$^{10,41,42}$ All spectra were obtained by acquiring two PL spectra at each position which were subsequently filtered, averaged and subtracted with a background noise spectrum. The corresponding pixel of the positions are highlighted in the PL map (see Figure 2B) showing the integrated spectra. We find an elongated shape of the monolayer feature with a spatial diameter below 5 $\mu$m, which can be identified as well in the microscope image of the sample (Figure S3).

The PL spectrum of the colloidal WS$_2$ is composed of three contributions (Figure 2C), each described by an asymmetric hyperbolic secant function.$^{43}$ We assign the nearly constant offset in
this energy range to multilayer PL and the

**Figure 2.** Monolayer PL of colloidal WS$_2$ nanosheets: [A] Averaged PL spectra at different positions *on* (position 2 to 4) and *next to* (position 1) the monolayer. [B] Related spatial map of the integrated PL intensity with a lateral step size of 1.5 µm. [C] Result of spectral fitting with an asymmetric hyperbolic secant function with narrow PL ($X_1$) at ~1.97 eV associated to localized excitons or trions and PL ($X_2$) associated to neutral excitons. [D] Comparison of the normalized monolayer PL signal of position 3 with the PL spectrum of an exfoliated WS$_2$ monolayer. For reasons of clarity, the offset of the colloidal PL signal was subtracted.
transition $X_2$ to the neutral exciton. The dominating narrow PL peak at $\sim 1.97$ eV ($X$) might be induced by localized excitons\textsuperscript{44} or by trions obtained by an electron surplus due to the sulfur vacancies in colloidal WS\textsubscript{2} nanosheets.\textsuperscript{45–49}

When comparing the normalized spectra of the colloidal WS\textsubscript{2} monolayer PL at position 3 with the PL of a state-of-the-art hBN-encapsulated exfoliated WS\textsubscript{2} monolayer (sample 3, see Figure 2D), both samples exhibit similar properties in general with colloidal WS\textsubscript{2} nanosheets showing only a fourfold lower PL intensity as the compared exfoliated sample. Surprisingly, the PL features of colloidal WS\textsubscript{2} nanosheets are much stronger pronounced than the exfoliated monolayer. Taking into account the long-standing experience in the field of the exfoliation fabrication method\textsuperscript{8}, our results show the overall promising optical properties of the wet-chemically synthesized TMDs.

We find colloidal WS\textsubscript{2} nanosheet monolayers to be quite degradation sensitive (potentially visible in the two successively taken PL spectra of position 4, see Figure S4), which could be, e.g., attributed to an optically triggered oxidation process.

In conjunction with the absorption and TEM measurements of the colloidal WS\textsubscript{2} nanosheets, a considerable number of features was found in the $\mu$-PL measurement, which can be assigned to few-layer structures due to significantly lower PL intensities and broader widths.\textsuperscript{10,42} These multilayer features are present either as separate structures or as an extended agglomerate of two or more features with overall lateral dimensions of up to tens of $\mu$m. Both, a typical coarse and detailed PL map of a separated multilayer PL feature is represented in Figure 3A. In agreement with the findings of the TEM images in Figure 1, the separated multilayer feature has an approximately circular shape with an overall diameter of less than $5\mu$m. The associated broad PL spectrum is illustrated in Figure 3B, consisting of multiple spectra for different central wavelengths of the spectrometer and providing an expected width of several hundred of meVs due to the
influence of the indirect band-gap transition.\textsuperscript{10,42} In addition, a direct relation between the microscope images and the PL maps of the multilayer features was observed (Figure 3C and Figure 3D). An exemplary PL map and microscope image of an extended agglomerate of colloidal WS\textsubscript{2} nanosheets is shown in Figure 3F and Figure S5, underpinning this relation.

For a deeper insight into the origin of the multilayer PL, the PL intensity \( I \) was measured in dependence of the laser excitation \( P \) (Figure 3F) and is fitted using a standard power function \( I(P) \sim P^k \). It reveals a nearly linear dependence (\( k \sim 0.91 \pm 0.01 \)), which is expected for the radiative recombination of excitons and trions. Several mechanisms can explain the small deviation including the defect-induced formation of bound excitons and phonon side-band emission.\textsuperscript{50,51} The understanding of the intensity dependence of the PL enables a quantitative analysis of previously observed critical photodegradation and aging processes as well as of general PL characteristics like the dependence on the solution concentration. The \( \mu \)-PL measurements reveal clear photodegradation under laser excitation in colloidal WS\textsubscript{2} nanosheets, which is an important challenge to overcome for the future technical applicability as well as for the unambiguous research output of such materials. In this work, suitable multilayer features were initially localized with PL maps and exposed to the laser in a controlled manner. The measured PL signal was filtered and averaged. During the whole process the background noise and the excitation power were monitored to correct fluctuations with the known intensity-dependence of the PL (Figure S7). A typical exponential decrease of the PL intensity is shown in Figure 3G. Here, the laser excitation intensity of \( \sim1.9 \times 10^4 \text{ W cm}^{-2} \) induces a significant drop of the averaged PL intensity below 50\% of the initial value within ten minutes. This decrease of the PL intensity is also directly visible in the PL spectra shown in Figure S8. In addition, no regeneration process of the optical properties can be observed since the integrated PL remains constant after stopping the
exposure for around 35 minutes shown in the red area of Figure 3G. This indicates that the photodegradation process is correlated with a structural change of the wet-synthesized multilayer feature. Further investigations revealed that the photodegradation is affected by the laser excitation power and the position (Figure S9).

**Figure 3.** Multilayer PL of colloidal WS$_2$ nanosheets: [A] Coarse (step size of 2 µm) and detailed (step size of 0.5 µm) map of the integrated PL spectra of a separated multilayer feature. [B] Complementary broad PL spectrum. [C] Enlarged microscope image of separated WS$_2$ multilayer features in the high concentration area of the aged sample revealing the direct relation with the associated PL map [D]. [E] Excitation power dependence of the multilayer PL intensity showing nearly linear behavior. The related PL spectra are shown in Figure S6. [F] PL map of an extended assembly of colloidal WS$_2$ nanosheets and [G] photodegradation induced decrease of the multilayer PL intensity.
In general, the laser induced exponential decrease of the PL with decay times in the range of 3 ± 0.3 to 13.7 ± 1.2 minutes (Table S1) is in good agreement with earlier reported photodegradation processes in exfoliated or CVD grown TMDs. We assume that the photodegradation of colloidal WS\textsubscript{2} nanosheets is driven by a photoinduced oxidation process as well that induces chemisorption or etching of the structure. Additional work is required to prevent the degradation process with a promising approach being the formation of colloidal TMD heterostructures. Both lateral and stacked TMD heterostructures, like hBN supported TMD heterostructures, as well as core-crown geometries can tailor the optoelectronic properties to prevent photodegradation.

Degradations of the optical properties of TMDs appear primarily under elevated conditions such as the discussed laser exposure, but were observed also under ambient conditions due to environmental aging processes. The air-stability of colloidal TMDs is analyzed by comparing the directly investigated (new) sample 1 with the six months aged sample 2. Critical PL characteristics of both samples are summarized in dependence of the concentration at drop-casting in Table S2, including the number of multilayers per 100 µm\textsuperscript{2} and the averaged PL intensity. The aged sample shows overall comparable characteristics, thereby implying a remarkable air-stability compared to other encapsulation-free TMDs. Despite of the exposure to air a significant PL signal is measurable and even a higher number of more separated multilayer features is detected as outlined in the SI. The latter might be introduced either by normal variations in the fabrication process or by stress-induced reformations, which have been observed before in WS\textsubscript{2}. In addition, an interference effect (Figure S11) was detected in both samples. The SI includes further investigations revealing that the interference might be introduced by the WS\textsubscript{2} nanosheets themselves as has been observed before in 2D materials.
The concentration dependence of the PL signal was evaluated in the aged sample based on the more uniform distribution of the multilayer features, visible in the microscope images (Figure S12) and typical PL maps (Figure S13). PL multilayer features were identified in the PL maps and the related PL intensity was subsequently determined under consideration of the excitation power. Figure 4 shows that the formation of larger WS$_2$ nanosheet assemblies with increasing sample concentration leads to a shift to PL features with higher averaged intensities. We assume this to be caused either by a higher probability to find an emitting feature or by a higher number of emitting features as is evident from the spacing of the layers in the TEM analysis (see Figure 1). At last the formation of a shielding layer of “dried” OlAm and OA ligands, directly visible in the microscope images, might increase the PL intensity comparable to an encapsulation with hBN. Our findings verify that it is possible to optimize the PL characteristics by dilution of the WS$_2$ nanosheet solutions and provide a highly promising starting point for future PL studies.

Figure 4. Quantitative analysis of the WS$_2$ nanosheet multilayer PL (aged sample) for high, medium and low concentrations. Details are given in Table S2 and corresponding PL maps are shown in Figure S13. The specified mean values of the PL intensity were obtained by averaging the multilayer PL intensities of each concentration.
In conclusion, we have shown mono- and multilayer room temperature $\mu$-PL of colloidal 2D WS$_2$ for the first time, underpinning the high synthetic quality of single ultrathin WS$_2$ nanosheets and revealing comparable characteristics to exfoliated WS$_2$ monolayers. Challenges for further advancing colloidal WS$_2$ nanosheet monolayers include the control of their initial photodegradation under laser excitation and are currently under investigation. The observed long-term stability of the colloidal samples under ambient conditions finally advances colloidal WS$_2$ nanosheets as straightforward-to-synthesize and highly promising optical materials into a competitive level with conventionally produced 2D-TMDs.

Methods:

Chemicals

Oleylamine (70 %, technical grade) was acquired from Sigma-Aldrich and was degassed under vacuum for 6 h at 120 °C and stored under nitrogen. All other chemicals were used as received without further purification and stored under nitrogen. Tungsten(VI) chloride (WCl₆, 99%), and hexane (anhydrous) were purchased from Alfa Aesar. WCl₆ was stored at –25 °C. Sulfur (99.98%) and oleic acid (≥ 99%) were obtained from Sigma-Aldrich. 1,1,3,3,3-hexamethyldisilazane (HMDS, 98 %) was purchased from Acros Organics and kept at –25 °C.

WS₂ Nanosheet Synthesis

0.038 mmol (15 mg) WCl₆, 0.3 mL oleic acid (OA), and 3 mL oleylamine (OlAm) were mixed in a glovebox and ultrasonicated for 1 h in a closed vial under nitrogen. In a second vial 2.37 mmol (76 mg) of elemental sulfur and 4 mL OlAm were mixed inside a glovebox. The sulfur was dissolved stirring at 110 °C for 25 min. During preparation of the tungsten and sulfur precursors, 15 mL of degassed OlAm was transferred into a three-neck flask and connected to a Schlenk-line. The OlAm was degassed by heating to 85 °C for 30 min under vacuum. Subsequently, the flask was set under argon and 150 μL HMDS were added with a syringe before the mixture was heated to 320 °C. While heating, the tungsten and sulfur precursor solutions were combined in a syringe under nitrogen. Subsequently the precursor solution was added to the flask over 30 min with a syringe pump. After adding a few droplets, the clear yellow reaction mixture turned black and
opaque. The reaction mixture was held at 320 °C for 30 min and cooled to room temperature afterwards.

The following precipitation and re-dissolving was performed inside a glovebox to prevent a reaction with oxygen. The synthesis product was precipitated by adding 16 mL hexane and centrifugation. The clear brownish supernatant was decanted and the WS$_2$ nanosheets were redispersed in 5 mL hexane, ultrasonicated for 5 min, and kept under nitrogen for characterization.

**Transmission Electron Microscopy (TEM)**

Samples were prepared on carbon coated copper grids and imaged with a Tecnai G2 F20 TMP from FEI. An acceleration voltage of 200 kV was applied.

**Absorption**

Absorption spectra were obtained with a Cary 5000 UV-vis-NIR spectrometer from Varian. The measurements were performed on colloidal WS$_2$ nanosheet solutions inside an integrating sphere to correct for scattering.

**Micro-Photoluminescence (µ-PL)**

The µ-PL measurements were performed in reflection geometry with a homemade confocal microscope, schematically shown in Figure S2. For the excitation a frequency-doubled Nd:YAG laser (2.33 eV) was used. The linearly polarized (LP) laser beam was reflected by a beam splitter (BS) to a long working distance objective lens (O, NA = 0.45), which focused it to the sample (S) with a typical spot size in the range of 1-2 µm. The sample itself was located under high vacuum (~3x10$^{-6}$ mbar) in a micro-cryostat. Motorized translation stages (TS) ensured an optimal positioning in x-, y- and z-direction and thereby enabled measurements with spatial resolutions on a sub-micrometer scale.
The PL signal was directed into a high-resolution Czerny-Turner spectrometer and detected with a nitrogen-cooled charge coupled device (CCD) array. A longpass filter with a transmission cut-off energy (2.25 eV) above the laser excitation energy was used to avoid negative impacts of the excitation laser on the PL spectra. For in situ monitoring of the sample an optional imaging tool was adapted, consisting of a removable mirror (RM), a white light source (WL) and a camera. All µ-PL measurements were performed at a temperature of 25 °C. Based on the tungsten atom concentration in the product of \( c_{\text{theor}}(W) = 7.6 \text{ mmol/L} \) for a neglected loss, the WS\(_2\) nanosheet solution was diluted with hexane to a concentration of \( c_{\text{high}}(W) = 760 \text{ µmol/L} \), \( c_{\text{med}}(W) = 76 \text{ µmol/L} \), and \( c_{\text{low}}(W) = 7.6 \text{ µmol/L} \) and deposited onto two standard broadband dielectric mirrors. Sample 1 was assembled in the micro-cryostat right after the synthesis. For the validation of the long-term stability, sample 2 was stored for six months under ambient conditions in a container without a desiccant before the investigation. Additionally, an exfoliated WS\(_2\) monolayer sample was used for benchmarking of the results. It was fabricated on a comparable broadband dielectric mirror using an all-dry viscoelastic stamping method.\(^1\) An encapsulation with a thick bottom and thin top hexagonal boron nitride (hBN)-layer was applied to optimize the optical properties.\(^2\) Suitable hBN-flakes and the WS\(_2\) monolayer were identified with a microscope based on their contrast.\(^3\)

Data analysis

All PL spectra were smoothed with a median filter to subtract occasionally occurring spikes in the spectra induced by dead pixel of the CCD array. The background noise was subtracted, and the spectra were subsequently averaged and processed depending on the particular measurement. For broad PL spectra, single spectra were acquired at different central wavelengths of the spectrometer and compiled to the final broad spectrum. PL maps were obtained by integrating the single spectra.
and constructing the map with the related positions. The characteristics of these maps were obtained via the manual identification of each PL feature and the following determination of the averaged PL intensity in consideration of the background noise and the laser excitation power.

**Photodegradation:**

The delicate colloidal WS$_2$ structures exhibit photodegradation under laser excitation. This photodegradation process is investigated via the measurement of the induced decrease of the PL intensity. Suitable positions were initially selected via PL maps and exposed with a defined laser excitation. PL spectra were acquired at chosen time steps and subsequently smoothed with a median filter. The background noise as well as the laser excitation power (Figure S7) were monitored during the measurement to notice and subtract changes. For a quantitative analysis of the photodegradation induced decrease of the PL the averaged PL was normalized with respect to the during the maps measured original PL intensity. Significant parameters like the integration time and the laser excitation were taken into account. The decrease of the PL intensity $I$ was conclusively fitted with an exponential function:

$$I = I_0 + A e^{-\tau}$$

The critical parameters of the decay time $\tau$ and the constant PL intensity $I_0$ are summarized in Table S1 for the different measurements and show no pronounced difference for the directly investigated and aged sample.

However, the photodegradation induced decrease of the PL is affected by the laser excitation power (Figure S9A) and the position (Figure S9B). The intensity dependence was measured at similar positions in the medium dilution area and shows a faster and stronger decrease of the PL intensity for the higher excitation power (Figure S9A). The position dependence was measured
with comparable laser excitation powers at the highlighted positions of the associated PL map (Figure S10) and reveals a varying PL decrease for the different positions.

**Interference effect:**

A negative interference effect was observed in the PL spectra of the colloidal WS$_2$ nanosheets. To investigate this effect multiple broad PL spectra were acquired at different positions of the directly investigated sample 1 and the aged sample 2. The interference effects seem to have an influence on PL spectra of the aged sample (Figure S11A) as well as of the directly investigated sample (Figure S11C). In the directly investigated sample spectra with a negligible influence (Figure S11B) are present likewise. The interference effect varies between different concentration areas but is constant within a region (Figure S11C) and seems to be related to thin film interference of same thicknesses within a region. Therefore, it is assumed to be introduced by the thin structure of the WS$_2$ nanosheets as observed before in other thin film materials.$^{4,5}$ In addition, the formation of a capping layer of “dried” oleic acid and oleylamine ligands, visible especially in the microscope images of the high concentration (Figure S12), might influence the effect comparable to similar effects in hBN encapsulated TMDs.$^6$ Further work is needed to validate these assumptions and to find a way to suppress the interference effects based on simulations of the interference function.
Supplemental Figures:

Figure S1. Absorption spectrum of the as-prepared colloidal WS₂ nanosheets measured in an integrating sphere to correct for scattering. Excitonic transitions appear in the form of shoulders or maxima. The exact values of the transitions were determined by using the 2\textsuperscript{nd} derivative of the absorption to find the point of maximum curvature. Before derivation, the absorption data were filtered by local regression (LOESS filter).
**Figure S2.** Simplified schematic of the $\mu$-PL setup with an exemplary PL spectrum and microscope image of the exfoliated and hBN encapsulated WS$_2$ monolayer. The red circle highlights the monolayer position.
**Figure S3.** Magnified microscope image of sample 1 close to the monolayer feature. The position of the monolayer was calculated based on the laser spot position and is highlighted with the red circle. In addition, the red square indicates the area of the associated PL map (Figure 2B).

**Figure S4.** Consecutive acquired single PL spectra showing the degradation of the monolayer PL signal at position 4 of the related PL map (Figure 2B).
**Figure S5.** Enlarged microscope image of an extended agglomerate of colloidal WS$_2$ nanosheets in the medium concentration area of sample 1. These extended agglomerates occur especially in the medium and high concentration areas due to the stochastic preparation process. The red frame indicates the region of the related PL map shown in Figure 3F.

Figure S7. Subtraction of randomly occurring small fluctuations of the laser power (exemplary depicted in [A]) in the photodegradation induced decreases of the PL based on the known intensity dependence of the multilayer PL [B]. The original (black) and recalculated (red) curve were both normalized to the first measured PL intensity.

Figure S8. Selected single spectra of the photodegradation induced decrease of the PL shown in Figure 3G. A laser excitation power of 155 µW was used.
**Figure S9.** [A] Intensity dependence of the photodegradation process including an exponential fit of the integrated PL intensity. [B] Photodegradation process at different positions in the high concentration area using excitation powers of 170 µW. The related PL map and single PL spectra of the positions are shown in Figure S10.

**Figure S10.** PL map [A] and single PL spectra [B] related to Figure S9B. The measurement spots of the photodegradation induced PL decrease are indicated with the red numbers. For the acquisition of the PL map a step-size of 2 µm and a laser excitation power of around 180 µW were used.
Figure S11. Characteristics of the interference effect: [A] PL spectra at different positions of the high concentration area of the aged sample, acquired with laser excitation powers of around 230 µW. [B] PL spectrum with a negligible interference effect acquired in the medium dilution area of sample 1 with a laser excitation power of 175 µW. [C] PL spectra at different positions of the high concentration area of sample 1, acquired with laser excitation powers of around 180 µW.
Figure S12. Typical microscope images for the three concentrations of the directly investigated and six months aged sample. The different concentrations were obtained by diluting the worked up product solution after fabrication and were used to investigate the influence of the concentration on the optical properties. It should be noted that the final allocation of the colloidal WS$_2$ nanosheets exhibits a stochastic nature which results in small variations that might occur within areas of the same concentration.
**Figure S13.** Comparison of the multilayer PL of the three different concentration areas. For each concentration a typical PL map of the aged sample with a region of 400 µm² and a lateral step-size of 2 µm is displayed. The colloidal WS₂ nanosheets seem to agglomerate to larger features with increasing concentration.
