1. In the discussed paper, the authors assumed that once a plasma channel resulting from a macroscopic dark matter is created at an appropriate location, a lightning leader may be ‘locked in’ to the plasma channel and propagate downwards along it to the ground. However, we would like to point out that as the plasma channel is created in the high electric field of the thundercloud, electric charges will be continuously induced at its forward-moving tip. With a conductivity and diameter comparable to the leader channel, the amount of induced charges would be comparable to that of a normal leader channel propagating downwards in a similar background field [1]. In other words, the plasma channel would automatically convert itself into a charged channel with charges comparable to a normal leader channel. There is no need for an external leader to be ‘locked in’ to the plasma channel. The creation of a plasma channel in the high electric field background of the thundercloud will itself convert naturally into a lightning leader. A plasma channel comparable in conductivity to that of the core of a lightning leader channel has a conductivity of about $10^4$ S/m and this corresponds to a relaxation time of about $8.85 \times 10^{-16}$ seconds. Thus, a plasma channel that decays in a microsecond scale will have ample time to be filled with induced charges.

2. As the electric charges of one polarity are accumulated at the forward end of the plasma channel, current pulses carrying opposite charge will propagate along the plasma channel towards the cloud. These current pulses will slow down the decay of the plasma channel by maintaining its conductivity. The same is true for lightning leaders which are kept hot by the current supplying the charges to the forward moving end of the leader channel.

3. Due to the accumulation of charges at the forward end of the plasma channel, the electric field at the tip of the plasma channel exceeds the streamer inception threshold and bursts of streamers would attempt to move ahead of the plasma channel. The speed of these streamers could be in the range of $10^6$ m/s [2] and if the speed of the macroscopic dark matter particle is lower than the streamers speed, then these streamers will move ahead of the plasma channel depositing charges ahead of it. In the case of a negative plasma channel, these streamers could generate space stems which may launch hot channel sections towards the down coming plasma channel creating branches. This may result in a straight channel containing tortuous branches. Macroscopic dark mater particles with faster speed will generate, as pointed out in the paper, a straight channel without branches.

4. The authors claim that there would not be sufficient time for the upward connecting leaders to be initiated from ground towards the down-coming plasma channel. However, experimental data [3] suggest the existence of upward connecting leaders with leaders travelling towards ground at speeds exceeding $10^6 – 10^7$ m/s. This indicates that the charged plasma channel moving downwards with a speed of 2.5 x
$10^5 \text{ m/s}$ as considered in the paper will provide ample time for the generation of an upward connecting leader.
