(Dated: May 25, 2021)

Quantum self-testing is a device-independent way to certify quantum states and measurements using only the input-output statistics, with minimal assumptions about the quantum devices. Due to the high demand on tolerable noise, however, experimental self-testing was limited to two-photon systems. Here, we demonstrate the first robust self-testing for multi-particle quantum entanglement. We prepare two examples of four-photon graph states, the Greenberger-Horne-Zeilinger (GHZ) states with a fidelity of 0.957(2) and the linear cluster states with a fidelity of 0.945(2). Based on the observed input-output statistics, we certify the genuine four-photon entanglement and further estimate their qualities with respect to realistic noise in a device-independent manner.

Entanglement that exhibits correlations without a classically analog [1, 2] is one of the most mind-boggling phenomena predicted by quantum mechanics. It is of particular importance in understanding the quantum foundations, and plays a prominent role in quantum information processing. As an archetypal example of quantum states with genuine multipartite entanglement, graph states [3] that comprises many popular states such as Greenberger-Horne-Zeilinger (GHZ) states [4] and cluster states [5], act as incredibly useful resources for quantum information applications including computation [5], error correction [6], cryptography [7], and metrology [8]. For this reason, certifying that a given multipartite quantum system is indeed working as intended is a crucial step for practical implementations of these applications.

Self-testing that was originated in device-independent (DI) scenarios and named by Mayers and Yao [9, 10], represents the strongest possible form of verification of quantum systems [11]. Different from certification techniques such as tomography [12, 13] and entanglement witnesses [14, 15] which require the characterization or assumption for the devices, self-testing allows us to verify the underlying functioning of a given quantum apparatus in a black-box fashion without the need to know its inner workings. Specifically, it relies only on the observed classical input-output correlation statistics that maximally violate Bell-like inequalities [16]. A well-known example is that the maximal violation of the Clauser-Horne-Shimony-Holt (CHSH) inequality [17] uniquely implies (self-tests) the presence of a two-qubit maximally entangled state [18]. Such DI certifications have been widely studied for self-testing different quantum states and measurements with distinct Bell inequalities in many scenarios (please see Ref. [11] for a review). Importantly, from a practical perspective, the self-testing methods should be robust against noises, i.e., robust self-testing [19], such that one can still infer the underlying states and estimate the bound on the fidelity of the actual state with respect to the target one even when the maximal violation of Bell inequalities is only approximately met.

Considerable theoretical efforts have been made towards constructing different Bell inequalities for self-testing protocols and improving the robustness bounds for various quantum states [11, 20–27]. To self-test any multipartite graph states with a large number of particles, protocols require an efficient scaling in terms of the computational resources are crucial for experimental implementations [11]. Remarkably, a new family of Bell inequalities are both scalable and robust [26, 27] with a linear number of correlations and improved robustness self-testing fidelity bounds for multipartite graph states, which presents a significant reduction of experimental efforts needed.

Despite of the theoretical recipes, the relevant experimental demonstration is little to know. To date, only a few optical experiments have been implemented principally to self-test quantum states such as a Bell state distributed over 398 meters in a fully DI manner [28], partially entangled pairs of qubits [29–31], bipartite and tripartite qubit states [32, 33], and two-qutrit entangled states [34]. All these demonstrations are only restricted to two photons system. However, to the best of our knowledge, experimental robust self-testing for multipartite graph states beyond two photons, especially the cluster states, remains unexplored.

In this Letter, we perform a proof-of-concept demonstration of robust self-testing for two important examples of multipartite graph states – a four-photon GHZ state and a four-photon linear cluster state, for the first time. We firstly prepare high quality four-photon entanglement...
clients share a four-qubit graph state. As shown in Fig. 1, tum measurement settings are \( \beta \)

\[ \text{for each experimental trial, the clients perform a choice of measurement settings upon receiving classical random inputs } w, x, y \text{ and } z \text{ (0 or 1) to produce classical outputs } a, b, c \text{ and } d \text{ (+1 or -1), respectively. After repeating the experiment sufficiently many times and collecting the observed statistics, the joint conditional probabilities } P(\text{abcd}|\text{wxyz}) \text{ can be estimated for the Bell inequalities in Eq. (1) and Eq. (2), revealing the properties of the prepared states.} \]

\[ \begin{align*}

B_5 : \langle A_1(A_2 - B_2) \rangle + 2\langle B_1(A_2 + B_2)B_3 \rangle + \langle (A_2 - B_2)A_3B_4 \rangle + \langle B_3A_4 \rangle & \leq \beta_{C,2} = 5, \\
B_6 : \langle A_1(A_2 - B_2) \rangle + 2\langle B_1(A_2 + B_2)B_3 \rangle + \langle (A_2 - B_2)A_3B_4 \rangle + \langle (B_1A_2 + B_2)A_4 \rangle & \leq \beta_{C,3} = 4. \\
\end{align*} \]
state $|\psi_G\rangle \langle \psi_G|$, up to local isometries. Meanwhile, one can also estimate the fidelity between underlying state the measured state $\rho$ and the target graph state $\psi_G$ (under local isometry), on account of the Bell inequality value,

$$
F = \max_{\Lambda = \Lambda_1 \otimes \Lambda_2 \cdots \otimes \Lambda_N} \langle \psi_G | \Lambda(\rho) | \psi_G \rangle,
$$

where $\Lambda_i$ is the local channel on $i$-th party. Using the techniques in Ref. [22, 26, 27], the fidelity can be lower bounded via

$$
F \geq s_i \langle \mathcal{B}_i \rangle + \mu_i,
$$

where $\langle \mathcal{B}_i \rangle$ is the observed Bell value in inequality $\mathcal{B}_i$. The coefficients $s_i$ and $\mu_i$ are obtained via optimizing all possible measurement angles (more details see Supplementary Materials [40]). Importantly, $F > \frac{1}{2}$ indicates the underlying prepared state is genuinely entangled [41].

**Experimental realization.**— As illustrated in Fig. 2, with the pulsed laser pumping two ppKTP crystals in polarization-based Sagnac loops [42, 43], two entangled photon pairs in the form of $|\Psi \rangle = (\cos(\theta)|00\rangle + \sin(\theta)|11\rangle)/\sqrt{2}$ are generated, where $|00\rangle$ and $|11\rangle$ represent horizontal $|H\rangle$ and vertical $|V\rangle$ polarization, respectively and $\theta$ is controlled by the spatial polarization [46]. These two entangled pairs in spatial mode 2 and 3 are then superimposed at PBS1 (or PDBS). In order to ensure the photons in mode 2 and 3 arrive at PBS1 (PDBS) simultaneously, we employ single-mode fibers and mount each fiber output end on a translation stage to precisely compensate time delay. When there is only one photon in each path after PBS1 (or PDBS) and conditionally on a four-fold coincidence detection, a four-photon entangled GHZ (or cluster) state is generated [45].

For demonstrating robust self-testing of graph states, we prepare four-qubit graph states with various degrees of noise,

$$
\rho_{\text{exp}} = \frac{1}{1+p} |\psi\rangle \langle \psi| + \frac{p}{1+p} \rho_{\text{noise}},
$$

where the pure state $|\psi\rangle$ is either GHZ states $|G_4\rangle_{1234} = (|0000\rangle + |1111\rangle)/\sqrt{2}$ or linear cluster states $|C_4\rangle_{1234} = (|0000\rangle + |0011\rangle + |1100\rangle - |1111\rangle)/2$, $\rho_{\text{noise}} = |\Psi_{12}\rangle \langle \Psi_{12}| \otimes |\Psi_{34}\rangle \langle \Psi_{34}|$ is the noise state given from four-fold coincidence detection under the condition of no interference between $|\Psi_{12}\rangle$ and $|\Psi_{34}\rangle$, and $p$ is the noisy proportion.

To generate four-photon GHZ state, two entangled pairs $|\Psi_{12}\rangle = |\Psi_{34}\rangle = (|00\rangle + |11\rangle)/\sqrt{2}$ are required [45]. Then we estimated the fidelity of our prepared entangled GHZ state by entanglement witness [47], yielding $0.957(2)$ for the ideal situation with $p = 0$ [40]. The GHZ state we produced is local-unitary equivalent to the states with same graph representations, where the local-unitary is $H_2 H_3 H_4$ ($H$ is a Hadamard gate, defined as $H = (X + Z)/\sqrt{2}$). Therefore, the quantum measurement settings for Bell inequalities in Eq. (1) are modified for GHZ state $|G_4\rangle$ (please refer to [40]). The self-testing performance can be verified by the actual fidelity from the expected values $\langle \mathcal{B}_i \rangle$ of the modified Bell inequalities, as shown in Fig. 3. We totally run $1.3 \times 10^5$ trials for the modified Bell inequalities $\mathcal{B}_1$, $\mathcal{B}_2$ and $\mathcal{B}_3$ with different noisy probability $p=0$, 0.1, and 0.2, respectively. The corresponding results are also labeled in Fig. 3. In the case of $p = 0$, experimentally obtained Bell values are $\langle \mathcal{B}_1 \rangle = 4.74(2)$, $\langle \mathcal{B}_2 \rangle = 6.50(4)$, and $\langle \mathcal{B}_3 \rangle = 8.27(5)$ as well as their related fidelities which are 0.91(2), 0.89(3) and 0.89(3), respectively [40]. In our experiment, Bell inequality $\mathcal{B}_1$ shows the best fidelity estimation. Note that when $F > 1/2$, we could also witness the genuine entanglement of prepared states. When $p = 0$ and 0.1, we can...
still witness the genuine entanglement via the three Bell inequalities in Eq. (1). While in the case of \( p = 0.2 \), only Bell inequality \( B_1 \) allows us to witness the existence of genuine entanglement.

To generate four-photon linear cluster state, two non-maximally entangled states \( |\Psi_{12} \rangle = |\Psi_{34} \rangle = (|00 \rangle + \sqrt{3}|11 \rangle)/2 \) are required \[44\]. Instead of using PBS1 that transmits \( |H \rangle \) and reflects \( |V \rangle \) polarization for the generation of GHZ states, PDBS is employed for cluster states, where its transmission and reflection efficiencies for \( |V \rangle \) and \( |H \rangle \) photons are set to be \( T_V = 1/3 \) and \( R_V = 2/3 \), and \( T_H = 1 \) and \( R_H = 0 \), respectively. Also, the transmission rate of \( |V \rangle \) photons can be finely adjusted by tuning the photon incident angle on the PDBS. To ensure that photons in paths 2 and 3 arrive at the PDBS simultaneously, we perform a Hong–Ou–Mandel interferometer of two \( |V \rangle \) polarized photons \[48\]. By measuring expectation values of 16 stabilizers \[41\], we estimate the fidelity of the linear cluster state \( |C_4 \rangle \) as 0.945(2) when \( p = 0 \). In the demonstration of Bell inequalities \( B_4, B_5 \) and \( B_6 \), we perform the quantum measurement settings via local-unitary \( H_1 H_4 \). We then totally perform \( 3.1 \times 10^4 \) trials for the modified Bell inequalities. In the case of \( p = 0 \), we experimentally obtain Bell values \( \langle B_1 \rangle = 4.66(4), \langle B_2 \rangle = 6.43(7) \) and \( \langle B_6 \rangle = 5.43(6) \) as well as the corresponding fidelities that are 0.84(4), 0.84(6), and 0.86(4), respectively \[40\]. In Fig. 3, Bell inequality \( B_6 \) shows the best performance for fidelity estimation. When \( p = 0 \) and 0.1, we can certify the genuine entanglement with the Bell inequalities in Eq. (2). When \( p = 0.2 \), we could only observe the existence of entanglement. From Fig. 3, we see that the minimum fidelity curve varies with the Bell inequalities, it would be interesting to further improve the robust self-testing performance by proving a tighter minimum fidelity curve or proposing a more suitable Bell inequality tailored for the specific prepared states.

We have for the first time demonstrated a robust self-testing for multi-qubit graph states with two important examples – a four-photon GHZ state and a four-photon linear cluster state, based on a systematical framework where the constructed Bell inequalities are directly from stabilizers \[26, 27\]. By preparing the high-quality four-photon entanglement source, we certify the genuine entanglement and estimate the fidelity at least 0.91(2) and 0.86(3) for GHZ state and cluster state respectively as well as their mixtures with various noise. We shall note that, our experiment is a proof of principle studies of the proposed scalable and robust self-testing for any multipartite graph states with the fair sampling assumption. How to close the loopholes from multipartite Bell inequality in self-testing, such as detection, locality, and freewill loopholes, are interesting open questions for future works. Our demonstration and the Bell inequalities constructed from stabilizers may also be extended to detect more detailed entanglement structure \[39\], and self-test high dimensional entangled states and hypergraph states \[49\]. Our work will pave an important step towards future DI applications such as randomness generation \[50–53\], secret sharing \[7, 54\] under untrusted channels, entanglement-based distributed quantum networks benchmarking \[55–57\], and delegated quantum computation \[36, 58\].

SUPPLEMENT INFORMATION

1. THEORETICAL DETAILS

(1). Construction of Bell inequalities for graph states

According to the construction procedure in Ref. [27], we first choose a subset of the stabilizer set as $S\mathcal{T}$. We define pairable stabilizers in $S\mathcal{T}$ as $\mathcal{P} = \{(l,k)|S^l, S^k \in S\mathcal{T} \text{ are pairable, } l < k\}$.

Here two stabilizers are called pairable, if there exists at least one position $i$ such that local operators are anti-commutative. We also include the set of all the other non-pairable stabilizers in $S\mathcal{T}$ as $R$. Moreover, we choose some specific positions, denoted as $\mathcal{AC}$, to replace the operators $X_i$ and $Z_i$ in the stabilizers with the observables $A_i + B_i$ and $A_i - B_i$.

In a four-party GHZ state, the generators are

$$G_1 = X_1 Z_2 Z_3 Z_4, \quad G_2 = Z_1 X_2, \quad G_3 = Z_1 X_3, \quad G_4 = Z_1 X_4.$$

Here we use stabilizers as $S_1 = G_1 = X_1 Z_2, S_2 = G_2 = Z_1 X_2, S_3 = G_3 = Z_1 X_3, S_4 = G_4 = Z_1 X_4, S_5 = G_2 G_3 = X_2 X_3, S_6 = G_2 G_4 = X_2 X_4$.

We construct the following inequalities with various $\mathcal{AC}, \mathcal{P}, R$ as the following table. For 4-party Cluster state, we have the generators and use the stabilizers as

$$S^1 = G_1 = X_1 Z_2 Z_3 Z_4, S^2 = G_2 = Z_1 X_2, S^3 = G_3 = Z_1 X_3, S^4 = G_4 = Z_1 X_4,$$

$$S^5 = G_2 G_3 = X_2 X_3, S^6 = G_2 G_4 = X_2 X_4.$$

Our constructions are shown in the following table. The proof of the classical bounds and quantum bounds are shown in Ref. [27]. We refer to Ref. [27] for more details of construction.

(2). Robust self-test of graph state

In this section, we give the detailed explanation about numerical robustness results of self-testing. All the constructed Bell inequalities shown above are suitable for the self-testing of graph states. We could lower bound the
fidelity between the measured state $\rho$ and the target graph state $\psi_G$ (under local isometry), with the knowledge of the Bell inequality value. Here one can adopt local extraction channel and the maximal fidelity shows

$$F = \max_{\Lambda = \Lambda_1 \otimes \Lambda_2 \cdots \Lambda_N} \langle \psi_G | \Lambda(\rho) | \psi_G \rangle,$$

(10)

where $\Lambda_i$ is the local channel on $i$-th party. Alternatively, the fidelity can be written as follows,

$$F = \text{Tr}[\rho \Lambda_i^\dagger \otimes \Lambda_2^\dagger \cdots \Lambda_N^\dagger (|\psi_G\rangle \langle \psi_G|)]$$

(11)

where $\Lambda_i^\dagger$ is the dual channel of $\Lambda_i$. Here denote the state after this dual channel as $K = \Lambda_1^\dagger \otimes \Lambda_2^\dagger \cdots \Lambda_N^\dagger (|\psi_G\rangle \langle \psi_G|)$. To lower bound $F$ and $K$, we need to choose appropriate parameters $s$ and $\mu$ such that the following inequality on operators always holds,

$$K \geq sB + \mu I$$

(12)

where $B$ is Bell inequality to self-test the state. Then the fidelity is bounded as $F \geq s\langle B \rangle + \mu$, with $\langle B \rangle = \text{Tr}(\rho B)$ the Bell inequality value. Note that here $B$ consists of the dichotomic measurements. According to the Jordan lemma, one can reduce the state to the $N$-qubit space, and all the possible measurements can be parameterized by the angles $	heta_i \in [0, \pi/2]$ as,

$$A_i = \cos \theta_i X_i + \sin \theta_i Z_i, \quad B_i = \cos \theta_i X_i - \sin \theta_i Z_i, \quad i \in \mathcal{AC},$$

$$A_i = \cos \theta_i H_i + \sin \theta_i V_i, \quad B_i = \cos \theta_i H_i - \sin \theta_i V_i, \quad i \notin \mathcal{AC},$$

(13)

where $\mathcal{AC}$ is the rotated set, and $H_i(V_i) = (X_i \pm Z_i)/\sqrt{2}$. Here we consider a specific extraction channel in Ref. [22],

$$\Lambda_i(\rho) = \frac{1 + g(x)}{2} \rho + \frac{1 - g(x)}{2} \Gamma_i(\rho) \Gamma_i(x),$$

(14)

where $g(x) = (1 + \sqrt{2})(\sin x + \cos x + 1)$, and $\Gamma_i(x)$ is the operator on $i$-th qubit: for $i \in T$, $\Gamma_i(x) = X_i(Z_i)$ as $x < (\geq)\pi/4$; for $i \notin T$, $\Gamma_i(x) = H_i(V_i)$ as $x < (\geq)\pi/4$. Here the Bell inequality $B$ and the operator $K$ are both parameterized with the parameters $\theta_i$, and the inequality in Eq. (12) is equivalent to the following inequality,

$$K(\theta_1, \theta_2, \cdots, \theta_N) \geq s\langle B \rangle(\theta_1, \theta_2, \cdots, \theta_N) + \mu I.$$  

(15)

There are a lot of suitable $s$ and $\mu$. We should find optimal $s$ and $\mu$ which gives the best lower bound for all possible $\theta_1, \theta_2, \cdots, \theta_N$. Here we first fix $s$ and find the minimal eigenvalue of $K(\theta_1, \theta_2, \cdots, \theta_N) \geq s\langle B \rangle(\theta_1, \theta_2, \cdots, \theta_N)$ for all $(\theta_1, \theta_2, \cdots, \theta_N)$. Then we want to find the minimum $s$ satisfying the relation $s\beta_Q + \mu = 1$ hold. A smaller $s$ indicates a better bound. Consequently, we list all the obtained $s$ and $\mu$ in Table III as follows.

TABLE III. Numerical fidelity bounds for the 4-qubit GHZ state and Cluster state.

2. EXPERIMENTAL DETAILS

(1). Fidelity estimation

We observe an average two-photon coincidence count rate $\sim 23000$ Hz with a correlation visibility of $99\%$ in $|+\rangle/|\rangle$ basis under 450mw laser power, yielding the polarization entanglement of the photon-pair source. For characterization of the $N$-photon states, we measure their state fidelities, that is, the overlap of the experimentally produced state with the ideal one: $F(\psi) = \langle \psi^N | \rho_{\text{exp}} | \psi^N \rangle = \text{Tr}(\rho_{\text{ideal}} \rho_{\text{exp}})$, where $|\psi^N \rangle$ denotes the ideal $N$-photon state and $\rho_{\text{ideal}}(\rho_{\text{exp}})$ represents the density matrix of the ideal state (experimentally prepared state). For the GHZ state,
the fidelity can be calculated by the expectation values of the average of \( F(GHZ^N) = \frac{\langle P^N \rangle + \langle C^N \rangle}{2} \), with \( \langle P^N \rangle = (|H\rangle \langle H|)^{\otimes N} + (|V\rangle \langle V|)^{\otimes N} \), which denotes the population of \(|H\rangle^{\otimes N}\) and \(|V\rangle^{\otimes N}\) are consisted of GHZ states. Furthermore, the coherence of the N-qubit GHZ state, which is defined by the off-diagonal element of its density matrix and reflects the coherent superposition between the \(|H\rangle^{\otimes N}\) and \(|V\rangle^{\otimes N}\) component of the GHZ state, can be calculated by

\[
C^N = \frac{1}{N} \sum_{k=0}^{N-1} (-1)^k \langle M_{k\pi/N}^{\otimes N} \rangle
\]

with \(M_{k\pi/N} = \sigma_x \cos(k\pi/N) + \sigma_y \sin(k\pi/N)\), where \(\sigma_x\) and \(\sigma_y\) are Pauli operators and \(k = 0, 1, ..., N - 1\). We measure the N single photons individually along the basis of \((|H\rangle \pm e^{ik\theta/4}|V\rangle)/\sqrt{2}\) and detect all the 2N combinations of N-photon output. From these measurements, we obtain the experimentally estimated expectation values of the observable \(M_{\theta}^{\otimes N} = (\cos \theta \sigma_x + \sin \theta \sigma_y)\). Finally, the population and coherence measured in our experiment is 0.994(2), 0.920(7) are shown in Fig. 4. If two 10nm filters in spatial mode 2 and 3 are replaced with 5nm filters, the fidelity become 0.963(3), we can get greater violation 4.759(31), 6.544(54), 8.323(77).

![FIG. 4. Experimental results of a four-photon GHZ state. (a) Fourfold coincidence counts in the H/V basis with data collection in 800s; the value of \( (|H\rangle \langle H|)^{\otimes 4} + (|V\rangle \langle V|)^{\otimes 4} \) is 0.994(2). (b) The expectation values of \(M_{\theta}^{\otimes 4} = \cos(k\pi/4) \sin(k\pi/4)(k = 0, 1, 2, 3)\) are obtained by the measurements in the basis of \((|H\rangle \pm e^{ik\pi/4}|V\rangle)/\sqrt{2}\). Each basis accumulates about 5000 events in 1200s. The error bar is derived from raw detection events by Poissonian counting statistics analysis with one standard deviation. The measured expectation values are 0.918(9), -0.924(7), 0.916(7), and -0.920(7).

To evaluate the four-photon linear cluster state, we estimate its fidelity as \(F_{C4} = \langle C_4|\rho_{exp}|C_4\rangle\), by averaging expectation values of sixteen stabilizers. As a four-photon linear cluster state, its stabilizer generators are

\[
g_1 = Z_1Z_2I_3I_4, g_2 = X_1X_2Z_3I_4, g_3 = I_1Z_2X_3X_4, g_4 = I_1I_2Z_3Z_4,
\]

where \(X, Y, Z,\) and \(I\) denote Pauli operators \(\sigma_x, \sigma_y, \sigma_z\) and the Identity operator, respectively. Therefore, the fidelity for the target state equals to the average expectation value of all the stabilizer operators. The measurement result are shown in Table IV. The state fidelity is calculated to be \(F_{C4} = 0.945(2)\), and the result of fourfold coincidence achieved from H/V basis is shown in Fig. 5.

(2). Bell inequalities implementations

In our implementation, the prepared states is equivalent to the graph states up to the local unitary. Thus we have to change the measurement settings accordingly. For GHZ states, the local-unitary is \(H_2H_3H_4\) (\(H\) is a Hadamard gate,
TABLE IV. Sixteen expectation values of stabilizers of a four-photon cluster state and their experimental results. The data collection time of each is 1400s and the error bars are deduced from the raw data and Poisson counting statistics.

$F_{C_4} = 0.945(2)$

FIG. 5. Experiment results of the four-photon cluster state, fourfold coincidence counts acquired in an H/V basis.

defined as $H = (X + Z)/\sqrt{2}$. Thus the measurements are implemented as $A_1 = \frac{X + Z}{\sqrt{2}}, B_1 = \frac{X - Z}{\sqrt{2}},$ and $A_i = Z, B_i = X$ when $i \neq 1$. For cluster states, the local-unitary is $H_1H_4$. For the Bell inequality $B_4$, we set $A_1 = \frac{X + Z}{\sqrt{2}}, B_1 = \frac{Z - X}{\sqrt{2}}, A_i = X, B_i = Z \ (i = 2, 3), A_4 = Z, B_4 = X,$ and $A_i = Z, B_i = X \ (i = 1, 4), A_2 = \frac{X + Z}{\sqrt{2}}, B_2 = \frac{X - Z}{\sqrt{2}}, A_3 = X, B_3 = Z$ for $B_5$ and $B_6$. We show the experimental results for different measurement settings and and the corresponding Bell values with various degree of noise in Tables.V-VII as well as the comparison with the entanglement witness in Fig.6.

TABLE VII. Noise values of every measurement setting in the experiment when $p=0.2$
FIG. 6. Red columns show the device dependent fidelity estimation obtained from entanglement witness. Blue columns show the device independent fidelity estimation via our Bell inequalities. \( p = 0, 0.1, 0.2 \) means the ratio of the noise-pure state preparing in the experiment.
