Abstract

Advances in optical trapping design principles have led to tremendous progress in manipulating nanoparticles (NPs) with diverse functionalities in different environments using bulky systems. However, efficient control and manipulation of NPs in harsh environments require a careful design of contactless optical tweezers. Here, we propose a simple design of a fibered optical probe allowing the trapping of dielectric NPs in a contactless regime as well as a transfer of the angular momentum of light to the NP inducing its mechanical rotation. A polarization conversion from linear (guided fundamental mode) to circular one is provoked geometrically by breaking the cylindrical symmetry of a coaxial nano-aperture that is engraved at the apex of a tapered metal coated optical fiber. Numerical simulations show that this simple geometry tip allows powerful light transmission with efficient polarization conversion. This guarantees a very stable trapping in non-contact regime together with potentially highly tunable positive or negative rotation frequencies (up to 45 Hz in water and 5.3 MHz in air for 10 mW injected...
power in the fiber). This type of fiber probe opens the way to a new generation of miniaturized tools for total manipulation (trapping, sorting, spinning) of NPs.

1 Introduction

Since the discovery by Ashkin in 1970 [1], optical tweezers have become a tool of choice for physicists, chemists and biologists in the manipulation of nanoparticles (NPs). The advent of metamaterials in the field of optics has boosted research in this direction with the aim of miniaturizing these systems using them to explore physical chemistry in the field of the infinitely small (chemical bonds between molecules and even atomic bonds). At these scales, the tools must be adapted in size so that they induce the minimum disturbance on the quantities to be measured. It is therefore privileged to set up standalone systems allowing both the trapping of NPs and their translation and rotation. To this end, metamaterials, which have been extensively studied over the past decades, can be of great help. Indeed, they have shown their ability to address a wide range of applications ranging from detection [2], beam shaping and polarization [3–6] to optical trapping through the control of light confinement via changes in the phase and group velocities of the waves passing through them [7]. This confinement is essential to the trapping itself and will allow the translation movement. The rotation, as for it, is generally induced by a transfer towards the NP of the angular momentum of the light. This last one requires the control of the polarization of the light at nanometric scales. Thus, the design of a miniaturized optical tweezers lacks only one element which consists in the miniaturization of the wave-plates. However, optical spinning of NPs was already demonstrated since 1997 [8] and has seen considerable growth both theoretically and experimentally over the past 20 years [9–16]. Most of studies addressed applications in biology [13,15,18]. Recently, Lehmuskero et al. [19] demonstrated NP spinning within a circularly polarized focused beam. They measured rotation frequencies of several KHz. Nevertheless, they only had a 2D trapping (in the transverse plane) meaning the NP is pushed against a glass slide to restrict its motion along the propagation direction of the illumination beam. Some authors [20,23] recently showed optical trapping in vacuum accompanied with high spinning motion frequency beyond 1GHz but their schemes involve bulky systems composed of propagating beams, conventional optical elements such as lenses, polarizers, wave-plates and/or diaphragms which makes the system very cumbersome.

Our fibered Optical Spinning-Trapping Tweezer (OSTT) combines simultaneously a contactless trapping and a linear-to-circular polarization conversion. When operating in vacuum, this could achieve spinning motion of trapped NPs with rel-
atively high frequency. The control of the NP rotation frequency could easily be performed by simply changing the polarization direction of the guided wave inside the monomodal fiber using a conventional polarization controller.

2 Proposed structure and geometry optimization

Our structure is based on an individual coaxial aperture engraved on the apex of a metal (silver for instance) coated tapered single-mode optical fiber. The geometry of the aperture was optimized to exhibit an efficient transmission coefficient and a robust polarization conversion versus the fabrication uncertainties. To this end, we made extensive Finite Difference Time Domain (FDTD) numerical simulations using home-made codes (See Appendix A) to adapt the metal thickness to the desired properties. The polarization conversion is obtained through a geometrical anisotropy induced by breaking the body-of-revolution symmetry of the aperture [24]. The origin of this anisotropy is linked to the excitation of two orthogonally-polarized (TE$_{11}$) guided modes inside the metal thickness having different effective indices. This anisotropy was described in details in refs. [24–26]. It could provoke the spinning of the NP thanks to the linear-to-circular polarization conversion. Nevertheless, a stable trapping is simultaneously necessary to fix the position of the NP in front of the tip. Therefore, electromagnetic confinement within the aperture is essential to induce a gradient force capable of compensating for the radiation pressure induced by the light flow (funnel effect) through the aperture. The geometry of the structure was optimized through calculations that

![Figure 1 Schematic of the proposed Optical Spinning-Trapping Tweezers (OSTT): (a) Principle of the polarization conversion. (b): Artistic view of the simultaneous trapping and spinning of a NP.](image)

3
cost less in computing time and memory space (please refer to Appendix B). To transfer a single coaxial aperture to the apex of a SNOM (Scanning Near-field Optical Microscope) probe, we consider a metal-coated tapered single-mode optical fiber. The polarization of the guided mode is supposed to be directed at $\alpha = 45^\circ$ with respect to the axes of the ellipse (see inset of Fig. 2a). The temporal variation of the electric field (amplitude and direction) in a transverse plane intersecting the fiber at $z = 4 \mu m$ from its apex is shown in the video "Visualisation1.avi". The fiber core index is $n_c = 1.458$ and the cladding one is $n_g = 1.453$. The core diameter is set to $D_c = 4.2 \mu m$ as for a SMF-28 or X1060 fibers from Thorlabs. The cone angle of the tip has a typical value of $28^\circ$. In the FDTD simulations, the fundamental guided mode of the fiber is injected into the upper part of the probe (see Fig. 2a) at more than $5 \mu m$ from the apex. Nevertheless, as can be expected, the transmission properties of a single aperture can be different from those of a periodic structure of the same aperture, in particular, because the lighting conditions are not the same (here a focused beam instead of a plane wave). For this reason, the geometrical parameters must be adapted to obtain an operation wavelength in the water low-absorption spectral window (around 1080 nm). Consequently, FDTD simulations were performed and led to a slightly different metal thickness value of $h = 125 \text{ nm}$ instead of 95 nm for the periodic structure (See Appendix B). The corresponding transmission coefficients are presented in Fig. 2b (solid red line for the x-component and dashed purple line for the y-component) by normalizing the transmitted energy associated with each component to the total energy injected into the fiber. As it can be seen from Fig. 2b, the intersection of the two spectra should correspond to the required operating wavelength for which the phase difference $\Delta \phi = \text{Arg}(E_x/E_y)$ between the two transverse components ($E_x$ in red solid line and $E_y$ in purple dashed line) is equal to $\pi/2$. The variations of $\Delta \phi$ are plotted in green dotted line on the same figure. One can clearly see the latter condition to be fulfilled exactly for the wavelength value of $\lambda = 1080 \text{ nm}$ corresponding to the abscissa of the intersection point. In addition, the positive value of $\Delta \phi$ means that the $E_x$ is in phase advance with respect to $E_y$. This indicates that the emitted wave is circularly right polarized. The temporal evolution of the transmitted electric field (amplitude and direction) by the OSTT in a transverse plane located at $z = 350 \text{ nm}$ in front of its apex is shown in the video "Visualization2.avi". A light spin transfer from photons to the NP will then induce its rotation in the same direction that corresponds to a positive value of $Q_z$; the z-component of the torque (see the coordinate system of Fig. 2h). Note that, at the operation wavelength, the transmission value is around 1.7% $\approx 2 \times 0.86\%$ (ratio of the transmitted total energy to the injected energy into the fiber), a fairly efficient transmission compared to a simple cylindrical or rectangular aperture. Let us notice that the small oscillations appearing on the spectra of Fig. 2b, have a
Figure 2 (a) Schematic of the modeled OSTT. All geometric parameters and electromagnetic constants are given in the figure. The bottom left inset shows the polarization direction of the guided mode which is oriented at $\alpha = 45^\circ$ from the ellipse axes needed to get circularly polarized transmitted beam. (b) Transmission spectra of the two electric-field components (x in red solid line and y in purple dashed line) associated with the zero-order diffracted light for a silver coating thickness of $h = 125$ nm. The intersection of these two spectra corresponds to the operating point (quarter-wave plate) because the phase difference between the two transverse components of the electric field is well equal to $\pi/2$ as shown by the dotted green curve. (c) Electric field distribution (fifth root of the intensity) in a vertical plane at the operation wavelength. (d) Zoom-in on the area in front of the apex of the probe in Fig. (c) showing the electric field gradient needed for trapping.
Figure 3 Trapping and Spinning of a 150 nm -radius NP. (a) Vertical force $F_z$ exerted on a 150 nm radius latex NP as a function of the injected wavelength and the OSTT-to-NP distance $D$. The white line denotes the NP position for which the optical force vanishes. The blue horizontal line corresponds to the quarter-wave operation wavelength ($\lambda = 1080$ nm). (b) Magnitude of the z-component of the force and the torque for the same NP ($R_b = 150$ nm, $n_b = 1.5$) as a function of $D$ at $\lambda = 1080$ nm. Point A ($D = 305$ nm) corresponds to stable trapping for which the z-component of the torque does not vanish. (c) Electric intensity distributions (fifth square root) in three perpendicular faces of a rectangular parallelepiped corresponding to the operation point A (trapping + spinning). The OSTT-axis coincides with the intersection of the two vertical planes. If we look closely, we could distinguish the presence of the trapped NP just above the green arrow corresponding to the z-axis.
real physical meaning: they result from interferences between the surface plasmon wave propagating along with the metal coating (external walls) and the transmitted guided field by the aperture itself [29]. Figure 2c shows the distribution of the electric field (fifth root of the intensity) at the operation wavelength $\lambda = 1080$ nm in a vertical plane parallel to $xz$ containing the probe axis. Below we present (Fig. 2d) an enlargement of the area in front of the OSTT apex showing the large confinement of the electric field i.e. the high gradient needed to get efficient optical trapping.

3 Optical forces and torques

To quantitatively evaluate the optical force $\vec{F}$ and the torque $\vec{Q}$ induced by the electromagnetic field transmitted by the probe on a given NP, we use the classical definition given by:

$$\vec{F} = \iint_{s} \vec{T} \cdot \vec{d}s \quad \quad \vec{Q} = - \iint_{s} \vec{T} \wedge \vec{r} \cdot \vec{d}s$$

(1)

Where, $\vec{T}$ is the well-known Maxwell stress tensor with elements defined by:

$$\vec{T}_{ij} = \varepsilon_0 (E_i \cdot E_j - \frac{1}{2} \delta_{ij} \vec{E}^2) + \mu_0 (H_i \cdot H_j - \frac{1}{2} \delta_{ij} \vec{H}^2)$$

(2)

Equations (1) are valid in harmonic regime ($e^{-i\omega t}$). The integration domains in both integrals consist of any surface surrounding the NP. Practically, we consider a cube that encompasses the NP (Ostrogradski divergence theorem) and whose faces remain in the same medium (here water). Figure 3a shows the evolution of the vertical component $F_z$ of the optical force applied on a NP made in latex ($n = 1.5$) with a radius $R_b = 150$ nm as a function of the wavelength and the NP-to-OSTT distance $D$. The NP is supposed to move along the OSTT-axis so that, due to the symmetry of the configuration, only the vertical components of the force and of the torque are predominant. The white line on Fig. 3a corresponds to the positions where $F_z$ vanishes meaning a possible trapping of the NP. Nonetheless, to be stable, the trapping must corresponds to a minimum of the potential meaning a $F_z$ variation from negative to positive values when the distance $D$ increases (see the $xyz$ frame on Fig. 2a). As can be seen in Fig. 3a, this stable trapping condition is well met at the $A$ point corresponding to $D = 305$ nm and the operating wavelength of the quarter-wave plate ($\lambda = 1080$ nm). Figure 3b shows the vertical components of both the optical force $F_z$ in solid blue line, and of the torque $Q_z$ in dashed red line as a function of $D$ for $\lambda = 1080$ nm. As predicted, the force cancels out for $D = 305$ nm but not the torque whose value
Figure 4 Optical force, optical torque, and potential variations. (a) Vertical force variations exerted on a latex NP as a function of $D$ for different values of the NP radius $R_b$. In all cases, the refractive optical index of the latter is fixed to $n_b = 1.5$. (b) Magnitude of the z-component of the torque as a function of $D$ for the same $R_b$ values as in (a). Vertical dashed lines denote stable trapping that occurs for all considered values of $R_b$ except $R_b = 100$ nm. (c) Potential derived from the optical force as a function of $D$ for the same $R_b$ values as in (a) and (b). Notice that a value of $10kT$ is generally assumed for a stable trapping to compensate the Brownian motion. (d) Trapping distance and torque as a function of $R_b$. In cases where trapping occurs, the torque is never equal to zero.
is equal $Q_z = 35.3 \text{ fN/mW}$. This positive value is consistent with the rotation direction of the electric field associated with the circularly polarized wave emitted by the OSTT. Figure 3c corresponds to this trapping-spinning state (point A of Fig. 3b) and shows the electric intensity distributions in three perpendicular planes at the operation wavelength for a linearly polarized incident guided mode along $\alpha = 45^\circ$ (the angle $\alpha$ is shown in Fig. 2a). As expected, the mode inside the aperture is excited in both $xz$ and $yz$ planes even though its dimensions are not the same in both planes.

Figures 4a and b present the $z$-component of the force $F_z$ and the torque $Q_z$ respectively for different values of the NP radius $R_b$. Quantitatively, the force amount is comparable to that found in Ref. [30] with coaxial aperture and it is at least twice as great as that obtained theoretically and experimentally with the bowtie nano-aperture antenna of Ref. [31]. The origin of this high efficiency is linked to the excitation of a frozen (small group velocity) guided mode inside the coaxial aperture resulting in significant energy funneling (large radiation pressure) together with high electric field confinement (gradient force). The torque seems to present an almost exponential decreasing with $D$ as shown in Fig. 4d.

To quantify the trapping strength, we plot on Fig. 4c the variations of the associated scalar potential (defined by $\vec{F} = -\nabla(U)$) from which the optical force derives. One can clearly see that when trapping occurs ($R_b \in [125;160] \text{ nm}$), a power source less than 1.5 mW leads to highly stable trapping for which the potential well is deeper than $-10kT$ (horizontal orange dashed-dotted line). The evolution of the stable trapping distance as a function of the NP radius $R_b$ is given in Fig. 4d (blue curve) in addition to the corresponding $z$-component of the torque for each NP radius. As expected, when the radius increases, the stable trapping position increases, and the torque decreases. Nevertheless, the behaviour of these two variations is different: it is a fairly linear function of $D$ while it is almost exponential for the torque. As mentioned earlier, a conventional polarization controller can be used to tune the rotation frequency or even invert its sign (and even cancel it if desired). To demonstrate this effect, we have performed FDTD simulations by modifying the polarization direction of the guided mode defined by the angle $\alpha$ (see inset of Fig. 2a) as it can be done using such a controller. In these simulations, the NP has an optical index of $n_b = 1.5$ and we set its radius to $R_b = 150 \text{ nm}$ while the distance to the OST is $D = 305 \text{ nm}$ corresponding to the stable distance trapping previously calculated (see Fig. 4b). Figure 5a shows a schematic view of the studied configuration. The variations of the $z$-components of the force and torque are presented in Fig. 5b. As expected, the force is quite constant and its value is very small (smaller than 0.01 pN/mW), so that the trapping distance is almost independent of the direction of polarization. The torque, on the other hand, undergoes a change in amplitude and a sign inversion when the incident
polarization aligns with the axes of the ellipse (transmitted beam is then linearly polarized). As shown in figure 5b, the behavior is not symmetrical as in the ideal case of a quarter-wave plate where the torque varies as \( \sin 2\alpha \). This is due to the non-perfect geometry of the probe (aperture not perfectly aligned with the fiber axis & a symmetry of revolution which is broken by the mesh used in the FDTD [32]) which leads to a cancellation of the angular momentum for an angle \( \alpha = 82^\circ \) instead of 90°.

Figure 5 **Trapping and spinning properties** as a function of the polarization direction of the guided mode inside the fiber given by the angle \( \alpha \). (a) Schematic of the studied configuration corresponding to a stable trapping of a NP radius \( R_b = 150 \) nm at a distance \( D = 305 \) nm. (b) Variations of the z-components of the force (in black solid line) and the torque (red dashed line) as a function of the guide mode polarization direction \( \alpha \). The solid red line corresponds to the torque variations within a perfect quart-wave plate.

Figure 4: shows that an injected power of 5 mW allows guaranteeing the stable trapping criterion of \( U > 10KT \) for NP radius \( R_b \) between 125 nm and 160 nm. The optical torques (median value of 25 fN·\( \mu \)m for only 1 mW injected power) are then as big as the one measured in Ref. [23] \( (Q_z = 28 \pm 13 \) fN·\( \mu \)m) using a bulky configuration with a wide propagating light beam where only the radiation force is supposed to oppose the weight of the NPs to be trapped. This suggests an excellent spinning efficiency even if the NP is in water. In fact, the relation given the steady-state rotation motion (torques equilibrium) in the case of a pure dielectric sphere (without absorption) is given by [21][33]

\[
\tau_{\text{sphere}}^{\text{drag}} = -Q_z = -\frac{4\pi^2 \mu R_b^4 \nu_r}{1.497\Lambda}
\]
Where $\tau_{\text{drag}}^{\text{sphere}}$ is the viscous torque for a $R_b$-radius hard-sphere rotating at frequency $\nu_r$ in a liquid of dynamic viscosity $\mu$ with a molecular mean free path of $\Lambda$. If we consider a $R_b = 125$ nm-radius NP immersed in water ($\mu = \mu_{\text{water}} = 8.9 \times 10^{-4}$ Pa.s, $\Lambda = \Lambda_{\text{water}} = 2.5$) trapped within an injected power of 1 mW, the spinning frequency of the rotational steady-state is evaluated to be $\nu_{r_{\text{water}}} = 28.2$ Hz. This relatively small value of the rotation frequency can be greatly enhanced when NP is trapped in air (up to $\nu_{r_{\text{air}}} = 3.34$ MHz for $\mu_{\text{air}} = 1.8 \times 10^{-5}$ and $\Lambda_{\text{air}} = 0.6 \mu$m) and obviously higher values in vacuum.

4 Conclusion

In summary, the proposed OSTT offers a unique fibered/miniatuized design of an optical tweezers able to act as a quarter-wave nano-antenna inducing a contactless trapping together with a spinning of a NP. The geometric parameters of the OSTT can be adapted to operate over a wide spectral range as well as according to the physico-chemical nature of the NP and/or of the host medium. The metal coating can also be treated to inhibit any chemical reaction (oxidation, sulfurization, ...). Nevertheless, one should be aware of the fact that the presence of metal could induce harmful effects (heating then destruction of the probe) in the case of high injected power. This is for this reason that the coaxial aperture remains an excellent compromise due to its high transmission efficiency allowing to use it as an OSTT with low optical power in many applications (biology, sorting, translational and rotational nanopositioning) that require relatively low light powers.

APPENDIX A: Simulation method

We use home-made FDTD codes that were adapted to the studied geometry. The FDTD is based on the solving of Maxwell equations through a temporal iterative scheme. The space is discretized into small cells of dimension as small as $\lambda/30$ and the electromagnetic field is calculated for each cell through a finite-difference schema. Due to the temporal character of the FDTD, dispersive materials need to be modeled through an analytical model giving their permittivity as a function of the wavelength. The model is then integrated into the FDTD algorithm using the auxiliary differential equation method or the recursive convolution method. In the case of the grating of Fig. periodic boundary conditions in the $x$ and $y$ directions while absorbing (Perfectly Matched Layer technique) ones are used in the $z$-direction to cancel parasitical reflections on the limits of the simulation window. For the OSTT, a Full 3D-FDTD code is used where the absorbing boundary conditions are applied in the three directions of the space due
to the finite character of the configuration. In this case, the simulations are much heavier and require a calculation time of about 3 days per NP position. In both codes, we used a non-uniform mesh allowing us to describe the geometry of the structure (cell size) as well as possible. The size of the cell varies from 5 nm near the probe apex and the NP to 20 nm elsewhere. The force and torque calculations are done using Matlab software using a code that allows implementation of Eqs. 1 (see article). The integration is made over a cube which encompasses the NP and all its faces must be in the same medium (here water or air) in order to fulfill the condition of conservation of the force (or torque) to be able to use Ostrogradski’s theorem which allowed us to transform the volume integral into a surface integral. In all simulations, the side of the cube was set to the diameter of the NP increased by 6 FDTD cells (3 cells on each side).

APPENDIX B: Optimization of the geometry

We start by considering a 2D square lattice grating of elliptical coaxial apertures (see Fig. 6a) as in ref. [24] deposited on a glass substrate and we adapt the metal thickness by taking water as superstrate. In fact, for trapping applications, NPs are generally immersed in a liquid to counteract their weight by the buoyancy forces. Home-made FDTD codes were used to simulate the light transmission through this grating. A schema of the modeled structure is presented in Fig. 6a; the geometrical parameters and notations are shown on the sketch of the top-view of Fig. 6b, and their values are given in the caption. The glass substrate optical refractive index is fixed to \( n_s = 1.458 \) and the dispersion of the silver film is described through a Drude-Critical Points (DCP) model [35] which has been adapted to the studied spectral range (\( \lambda \in [600 \text{ nm}, 1400 \text{ nm}] \)).

Figure 6c shows a diagram giving the transmission spectrum as a function of the metal thickness \( t \). Similarly to Ref. [25], we superimposed dotted green lines corresponding to a phase difference of \( \Delta \phi = \pi/2 \) between the two transmitted transverse components of the electric field; essential condition to have a quarter wave plate. Moreover, the cyan lines correspond to another condition for which the transmission coefficients of the \( x \)- and \( y \)- components are identical. This fulfills the requirement on the transmitted amplitudes to obtain a circular polarization instead of an elliptical polarization. All intersections of the green line with the cyan lines give solutions that fulfill a quarter-wave plate behavior. The last step is then to choose the intersection point corresponding to the higher value of the transmission coefficient. From Fig. 6c, the more adapted thickness is obtained for \( t = 95 \text{ nm} \) and the operation wavelength value is then around \( \lambda = 1093.5 \text{ nm} \) for which transmission spectra and phase difference are shown on Fig. 6d. Note that the geometry has been adapted to obtain an operating wavelength value
corresponding to low light absorption by water [31,36].
