The configuration model is a standard tool for generating random graphs with a specified degree sequence, and is often used as a null model to evaluate how much of an observed network’s structure is explained by its degrees alone. Except for networks with both self-loops and multi-edges, we lack a direct sampling algorithm for the configuration model, e.g., for simple graphs. A Markov chain Monte Carlo (MCMC) algorithm, based on a degree-preserving double-edge swap, provides an asymptotic solution to sample from the configuration model without bias. However, accurately detecting convergence of this Markov chain on its stationary distribution remains an unsolved problem. Here, we provide a concrete solution to detect convergence and sample from the configuration model without bias. We first develop an algorithm for estimating a sufficient gap between sampled MCMC states for them to be effectively independent. Applying this algorithm to a corpus of 509 empirical networks, we derive a set of computationally efficient heuristics, based on scaling laws, for choosing this sampling gap automatically. We then construct a convergence detection method that applies a Kolmogorov–Smirnov test to sequences of network assortativity values derived from the Markov chain’s sampled states. Comparing this test to three generic Markov chain convergence diagnostics, we find that our method is both more accurate and more efficient at detecting convergence.

In the analysis and modeling of networks, random graph models are widely used as both a substrate for numerical experiments and as a null model or reference distribution to evaluate whether some network statistic is typical or unusual. In network science, the configuration model is a special kind of random graph model, which conditions on a specified degree sequence, and allows researchers to assess and explore the structural or dynamical consequences of a network’s degree structure \cite{1–7}. As a result, the configuration model is among the most widely used random graph models across network science, and it provides the basis for many theoretical results, e.g., the broad implications of heavy-tailed degree distributions \cite{8–14}.

The configuration model for networks with self-loops and multi-edges is the most well-known \cite{15}. In fact, however, there are eight different configuration models, depending on whether the random graph to be generated is vertex-labeled or stub-labeled—that is, whether or not it matters which “stub” on a vertex \(i\) an edge from vertex \(j\) lands on—and whether it is allowed to have self-loops and/or multi-edges (Fig. 1). The distinction between these different flavors of the configuration model are not academic: Fosdick et al. \cite{16} showed that the corresponding distributions of network statistics can differ so much that an incorrect choice of graph space can lead to spurious or even opposite conclusions about the significance of some empirical networks’ observed characteristics.

Drawing a graph from a configuration model is straightforward if the graph space is stub-labeled and allows both self-loops and multi-edges. In this case, a simple stub matching algorithm \cite{15, 17}, which chooses a uniform random matching of all the edge stubs of the network, suffices and can be run in \(O(m)\) time, where \(m\) is the number of edges. For the other graph spaces, however, it is common to generate a network using the stub matching algorithm first, and then simply removing the self-loops or collapsing the multi-edges in the generated network. In asymptopia, such self-loops and multi-edges are a vanishing fraction of all edges when the graph is sparse, as is usually desired. However, these modifications change the resulting network in highly non-random ways, because high-degree nodes are more likely to participate in self-loops and multi-edges than are low-degree nodes. Hence, using the stub matching algorithm in this common way ultimately violates the underlying assumptions of the configuration model, and produces non-uniform draws from the target graph space. Or, to

† aaron.clauset@colorado.edu
put it more bluntly: the random graph matching algorithm is only applicable to graph spaces where multi-edges and self-loops are allowed. An alternative solution to drawing from the other seven graph space, e.g., that of simple graphs, is to sample them using a Markov chain Monte Carlo (MCMC) algorithm based on double-edge swaps. Although a number of such algorithms have been defined, the Fosdick et al. MCMC is known to asymptotically converge on the target uniform distribution for each of the eight graph spaces (with rare exceptions in graph spaces that allow loops but not multi-edges [18]). However, practical guidance on the time required for convergence with finite-sized networks remains unknown. This is the question we investigate and answer here.

Past work does provide theoretical upper bounds on the convergence or mixing times for some versions of the double-edge swap MCMC, for very specific types of degree distributions. For example, the mixing time \( \tau(\epsilon) \) for sampling \( d \)-regular undirected graphs with fixed degree sequences is polynomially bounded as \( \tau(\epsilon) \leq d^{14} n^{5}(dn \log(dn) + \log(\epsilon^{-1})) \) [19], where \( n \) is the number of vertices and \( d \) is the degree. A similar polynomial bound exists for directed graphs, as \( \tau(\epsilon) \leq 50d^{15}n^9(dn \log(dn) + \log(\epsilon^{-1})) \) [20]. For half regular bipartite graphs with fixed degree sequence, the mixing time is upper bounded by a polynomial in \( n \) [21]. The mixing time \( \tau(\epsilon) \) for undirected graphs with a minimum degree of at least one and a maximum degree satisfying \( 3 \leq d_{\max} \leq 1/3\sqrt{M} \) is polynomially bounded in \( n \) for any degree sequence as \( \tau(\epsilon) \leq \frac{1}{M} d_{\max}^{14} M^9 (M \log(M) + \log(\epsilon^{-1})) \) [22], where \( M \) is the sum of the degrees. None of these results cover the case of generic degree sequences and hence have limited utility for working with realistic degree structure.

Because convergence for arbitrary MCMCs cannot be calculated theoretically [23], convergence is instead detected in an online fashion by examining the local statistics of the sequence of states the MCMC visits. Such convergence tests have a common structure: (1) a statistic calculated from each state the MCMC visits, (2) a statistical test to assess when this calculated statistic has converged to its steady state or asymptotic distribution. Many such tests have been developed for general MCMCs [24–34], and several are included in popular Python and R packages [35–37]. However, none of these methods is designed for the configuration model and, as we will show, they do not perform well when applied to it. Refs. [38–40] present a detailed comparative analysis of several MCMC convergence detection techniques, and highlight their limitations by analyzing their theoretical biases and practical implementations. Relatedly, Cowles and Carlin [41] study 13 different general convergence diagnostics and find that every method can fail to detect the type of convergence they were designed to identify.

Here, we develop an efficient and accurate convergence method specifically for the double-edge swap MCMC for sampling from the configuration model. This method requires only an input degree sequence and a choice of graph space, and no other free parameters. First, we develop an algorithm for estimating a sampling gap between MCMC states so that the sampled states are effectively independent. We then apply this algorithm to a corpus of 509 real-world and semi-synthetic networks spanning all eight graph spaces, and distill the experimental results into a simple set of decision rules, based on scaling laws, for selecting the sampling gap automatically, along with a set of conditions under which the scaling laws can be applied. We then specify a test for detecting MCMC convergence based on the distribution of sampled network assortativity statistics, and show through a series of experiments that this test is effective at detecting convergence. Further, we compare this method to several generic MCMC convergence detection methods and show that our method is both more accurate and more efficient when applied to real-world networks. Although our method can be applied to any of the eight graph spaces, it is most useful for graph spaces other than stub-labeled loopy multigraphs, where the well-known random stub-matching algorithm provides a computationally efficient direct solution. Finally, to make the methods described here more accessible to the community, we provide our own implementations in a Python package, which can be found here.

I. MATERIALS AND METHODS

The Markov chain Monte Carlo algorithms described by Fosdick et al. guarantee that the resulting stationary distribution is uniform over graphs with the specified degree sequence and graph space, except for very few loopy graphs that do not allow multi-edges [18]. A graph space is chosen by specifying whether self-loops are allowed or not, whether multi-edges are allowed or not, and whether the graph is vertex- or stub-labeled (Fig. 1). In a vertex-labeled graph, each vertex has a distinct label, whereas in a stub-labeled graph, each stub has a distinct label and hence each vertex can be identified by the unique set of stubs attached to it. When a graph is vertex-labeled, the permutations of the stubs attached to a particular vertex are indistinguishable, and hence when multi-edges are present, “crossing” two “parallel” edges does not create another distinct graph. For example, a co-authorship network can be viewed as a vertex-labelled multigraph because it would be nonsensical to match author A’s first collaboration with author B to author B’s second collaboration with author A. On the other hand, when a graph is stub-labeled, crossed edges and parallel edges have different meanings because the different orderings of the stubs attached to each vertex imply distinct patterns of interaction in the underlying system. For example, in a friendship network where each node represents a cohort of students at a school, and stubs represent students in that cohort, every possible matching of stubs represents
FIG. 2. (a) The two degree-preserving double-edge swaps on a pair of edges \( \{x, y\}, \{w, z\} \) results in either \( \{x, z\}, \{w, y\} \) or \( \{x, y\}, \{w, z\} \) as shown. (b) If the vertices \( x, y, w, z \) are not distinct, double edge swap \( \{x, y\}, \{w, x\} \) can introduce a self-loop, (c) Similarly, if a third edge already exists among the vertices \( x, y, w, z \), a double edge swap \( \{x, y\}, \{w, z\} \) can introduce a multi-edge.

a distinct set of friendships. Hence, such a network would be stub-labeled. See Ref. [16] for additional examples of vertex-labeled and stub-labeled networks.

In the MCMC we study here for sampling from the configuration model, each step of the chain is a degree-preserving double edge swap (Fig. 2a), which transitions from one graph \( G_t \) to another graph \( G_{t+1} \). At each step in the chain, we choose two edges \( \{x, y\}, \{w, z\} \) uniformly at random and replace them with either \( \{x, z\}, \{w, y\} \) or \( \{x, w\}, \{y, z\} \) with equal probability. Hence, a double-edge swap slightly rewires a graph, while keeping the degrees of the graph preserved. In order to sample correctly from the target distribution, the space of graphs we choose imposes restrictions on which double-edge swaps are permitted. If the change proposed by a particular swap moves the chain \( G_t, G_{t+1}, G_{t+2}, \ldots \) outside the specified graph space, e.g., by introducing a self-loop (Fig. 2b) or a multi-edge (Fig. 2c) forbidden by the given graph space, or if certain other technical conditions are satisfied (see Ref. [16]), then the proposed change is rejected and the graph is resampled. Because the Markov chain traverses a sequence of graphs where graph \( G_t \) differs from \( G_{t+1} \) by exactly one double edge swap, graphs close to each other in the sequence are highly serially correlated. Additionally, if graphs are resampled very often, the serial correlation is even stronger. This correlation naturally decays between more distantly sampled points in the chain, but the distance required to achieve a certain level of correlation must grow with the size of the network, because each double-edge swap changes only a constant number of edges at a time.

The Fosdick et al. MCMC algorithm is guaranteed to sample graphs with a given degree sequence uniformly from any of the eight desired graphs spaces (with very few exceptions in the loopy graph space [18]), after it has converged to its stationary distribution. Fosdick et al. provide a proof that this convergence is achieved in the asymptotic limit of \( t \to \infty \). However, in practice, there exists some finite time \( t_* \) at which the MCMC has effectively reached this asymptotic state. Our goal is to detect the earliest time at which this is true, but no earlier.

Here, we develop a complete solution to the practical task of sampling from the configuration model. Our solution divides this problem into three parts.

1. We select a network-level summary statistic that quantifies a sufficiently non-trivial aspect of a network’s structure, so that we may transform a sequence of graphs \( G_t, G_{t+1}, G_{t+2}, \ldots \) from the MCMC into a standard scalar time series \( x_t, x_{t+1}, x_{t+2}, \ldots \).

2. We develop an algorithm for choosing a “sampling gap” \( \eta_0 \) for the given network such that the values \( x_t \) and \( x_{t+\eta_0} \) from the MCMC are effectively independent.

3. We define a statistical test to compare two consecutive sets of sampled values \( \{x_t\}_1 \) and \( \{x_t\}_2 \) within a sliding window of the MCMC and decide if they are plausibly drawn from the same underlying (stationary) distribution \( P(x_t) \).

Throughout, we make extensive use of a set of real-world and semi-synthetic networks which span social, biological, technological domains [42]. We use these networks both to evaluate the methods we develop, and to develop a set of computationally lightweight heuristics for automatically parameterizing our solution. These real-world networks include 103 simple graphs, 51 loopy graphs, 32 multigraphs and 110 loopy multigraphs, and range in size from \( n = 16 \) to 30,269 nodes with a variety of edge densities and degree distributions. Real networks with self-loops but no multi-edges and networks with multi-edges but no self-loops are relatively rare compared to those with either both or neither of them. To obtain a sufficient number of such networks for our numerical experiments on these graph spaces, we add or delete self-loops from other networks in our empirical corpus to obtain semi-synthetic networks (see Sections II B and II D).

II. RESULTS

To characterize the progression of the MCMC through a graph space, we select the degree assortativity \( r \) of a network as the cognizant network summary statistic \( x_t = f(G_t) \). The degree assortativity quantifies the tendency of nodes with similar degrees to be connected, and ranges over the interval \([-1, 1]\). Mathematically, \( r \) is calculated as the normalized covariance of the degrees across all the edges of the network, given by

\[
    r = \frac{\sum_{x,y} (A_{xy} - k_xk_y/2m)k_xk_y}{\sum_{x,y} (k_xd(x,y) - k_xk_y/2m)k_xk_y},
\]

(1)
where $A_{xy}$ is the adjacency matrix entry for nodes $x$ and $y$, $k_x$ is the degree of node $x$, $m$ is the number of edges in the network, and $\delta(x, y) = 1$ if $x = y$ and 0 otherwise.

The degree assortativity takes the value $r = 1$ if the graph is composed of only cliques, because in that case, the degree of every node is the same as that of its neighbors. The degree assortativity takes the value $r = -1$ if the graph is composed of only equal-sized stars, i.e., trees with exactly one internal node and $\ell$ leaves ($\ell \geq 2$), because in that case, the highest degree nodes of the network connect only to nodes with the lowest degree. While it is common to expect that $r = 0$ is a random graph, the precise form of the null distribution, and hence its expected value, depends on the chosen graph space [16].

There are, of course, many alternative network-level summary statistics that could be used instead of degree assortativity, e.g., the clustering coefficient $C$, the mean geodesic path length $\langle \ell \rangle$, the mean betweenness centrality, etc. However, most such statistics are expensive to calculate repeatedly over the course of the MCMC, which would limit the scalability of the sampling algorithm. In contrast, the degree assortativity admits a computationally efficient update equation such that it can be calculated quickly after every double-edge swap of the Markov chain, which allows us to sample longer chains and larger networks.

Suppose that a double-edge swap $\{((x, y), (u, z)) \rightarrow ((x, w), (y, z))\}$ is performed (Fig. 2a). Using the definition of degree assortativity, its change from this swap can be written as

$$\Delta r = \frac{(k_x k_w + k_y k_z - k_x k_y - k_u k_z) \times 4m}{(\sum_i k_i^2) - (\sum_i k_i^4)^2},$$

where $k_i$ is the degree of the $i^{th}$ node and $m$ is the number of edges in the network.

Given a particular network, the denominator in eq. (2) is a constant, and hence can be calculated once at a cost of $O(m)$, when the MCMC is first initialised, and stored for reference later. The numerator only requires the degrees $k_x$, $k_y$, $k_u$, $k_z$ of the four vertices involved in the swap, and the number of edges $m$. Hence it takes only $O(1)$ constant time to update $r$, given the assortativity of the current graph $G_t$ and the degrees of the nodes chosen for the double-edge swap. Calculating the initial assortativity $r_0$ is more expensive, but must be done only once. Its value can be calculated as

$$r_0 = \frac{S_1 S_t - S_2^2}{S_1 S_2 - S_2^2},$$

where $S_1 = \sum_i k_i$, $S_2 = \sum_i k_i^2$, $S_4 = \sum_i k_i^4$ and $S_t = \sum_{xy} A_{xy} k_x k_y = 2 \sum_{(x,y) \in E} k_x k_y$. The expression in eq. (1) contains only $O(n + m)$ terms and hence is substantially more efficient than eq. (3), which contains $O(n^2)$ terms [15]. Only in case of dense networks, where $m = \Theta(n^2)$, are the two calculations equally inefficient.

To illustrate the evolution of the degree assortativity $r$ over the course of the Markov chain, we apply the Fosdick et al. MCMC to a modest sized stub-labeled simple graph with $n = 16,062$ nodes and $m = 25,593$ edges (Fig. 3). In the early part of the Markov chain, the quick movement away from the initial value $r_0$ is highly apparent, as the double-edge swaps initially randomize the empirical correlations in each network’s structure. As each chain progresses, the assortativity converges towards a value, and then displays non-trivial fluctuations around it. The key problem that convergence detection seeks to solve is deciding when these excursions are sufficiently random that we may declare the Markov chain to have reached its stationary distribution. In making this decision, we note that it is better to detect convergence too late rather than too early: a late decision merely wastes time in the form of extra steps in the Markov chain, while an early decision results in sampling from the wrong distribution of graphs.

By construction, the states the Markov chain visits are serially correlated, as each double-edge swap changes at most four adjacencies. The magnitude of this serial correlation must therefore increase with the size of the network $m$, because it takes more steps in the Markov chain to randomize a larger number of edges. As the task of detecting convergence is one of deciding when the fluctuations in the structure of the states visited by the Markov chain are indicative of a stationary distribution, large and long-lasting serial correlations pose a significant problem by creating the appearance of non-random structure in the chain. A solution to this problem is to only sample states that are sufficiently well separated in the chain that they are statistically independent. To identify the spacing between states that yields such a sample, we develop an algorithm based on the autocorrelation function and statistical sampling theory, which can be applied to any network for obtaining an appropriate sampling gap $\eta_0$ between states. Given such a choice of $\eta_0$, we expect the sample $X_{\eta_0} = x_t, x_{t+\eta_0}, x_{t+2\eta_0}, ..., x_{t+T\eta_0}$ to behave as a set of $T$ independent draws from the MCMC’s stationary distribution when the MCMC has converged.

The autocorrelation function of a time series measures the pairwise correlation of values $x_t$ and $x_{t+\Delta}$ as a func-
tion of the gap or lag $\Delta$ that separates them (see Appendix A). Our algorithm (Algorithm 1) uses a test for independence based on the autocorrelation function to determine whether a sample $X_\eta$ from the Markov chain can be considered to be composed of draws that are independent and identically distributed (iid).

**Algorithm 1** Choosing the sampling gap $\eta$

**Input:** $G_0$ (initial graph), $T$ (the size of the list $S_T$), $D$ (the number of parallel MCMC runs), and $\alpha_c$ (the significance level).

**Output:** The sampling gap $\eta_0$ for graph $G_0$.

1. Let $m$ be the number of edges in $G_0$. 
2. Run the MCMC for 1000 $m$ swaps (burn-in).
3. Let $x_1$ be the first degree assortativity value after the burn-in.
4. $\eta = 0$.
5. $f_\eta = 1$.
6. $Q = \left(100 - \frac{(100-C)}{2}\right)$
7. while $f_\eta > \alpha_c$ do
8. $\eta = \eta + 1$
9. $f = 0$
10. for $k \leftarrow 1$ to $D$ do
11. Construct $S_T$ such that $s_1 = x_1 \times ((-1)+1)$, $1 \leq i \leq T$.
12. Compute the autocorrelation function $R_h$ for $S_T$, $0 < h < T$.
13. $f_k$ = fraction of autocorrelations beyond $\pm Q \sqrt{n}$ in $R_h$.
14. $f = f + f_k$
15. $f_\eta = f / D$
16. $\eta_0 = \eta$

To construct this algorithm, we exploit the fact that for a sufficiently large choice of gap $\eta$, the sampled values in $X_\eta$ will behave like an iid draw from a stationary distribution. Our goal is to find the smallest value $\eta_0$ for which this behavior occurs. When it does, because the sampled values have finite variance, the autocorrelations of $X_\eta$ for any lag $\Delta > 0$ will follow a Normal distribution $N(0, 1/T)$ for large sample size $T$ [43]. Hence, to assess if $X_\eta$, $\eta > 0$, comprises of iid draws from a stationary distribution (the null hypothesis), we can use a standard autocorrelation hypothesis test that assesses the normality of the autocorrelation values of $X_\eta$. This hypothesis test requires choosing a significance level $\alpha_c$ and deriving the corresponding thresholds outside of which no more than a fraction $\alpha_c$ of the autocorrelation values should fall, if the sampled values in $X_\eta$ are effectively independent. In our experiments, we choose $\alpha_c = 0.05$, and measure the fraction $f_\eta$ of autocorrelations of the sample $X_\eta$ that fall outside the corresponding range of $\pm 1.96/\sqrt{T}$ (see Appendix A). Finally, to select the minimum gap $\eta_0$, we scan upward through the values of $\eta > 0$ until we fail to reject the null hypothesis in the autocorrelation test.

To initialise this algorithm, the MCMC is first run for 1000$m$ swaps. This “burn-in period” ensures that in expectation, every edge has been swapped 2000 times, which we take as a reasonable degree of randomization before samples are taken for any experiment. After this burn-in period, the algorithm creates a sequence of lists of the form $S_T = [s_1, s_2, s_3, \ldots, s_T]$ where $s_i = x_\eta((i-1)+1)$ for $1 \leq i \leq T$, that is, each $S_T$ is a candidate set of sampled values from the Markov chain, for a particular choice of gap $\eta$. As $\eta$ increases, the serial correlations in the Markov chain, and hence also the fraction $f_\eta$ of statistically significant autocorrelations will decay toward zero. Since the Markov chain is stochastic, we calculate $f_\eta$ by averaging over 100 Markov chains. The first value of $\eta$ at which $f_\eta \leq \alpha_c$ is returned as the effective choice of sampling gap $\eta_0$ by which to construct a sample with the target properties, where $\alpha_c$ is the chosen critical threshold.

Unspecified, however, is the number of sampled values $T$ to be used in the test. Intuitively, the smaller the value of $T$, the faster the sampling, but the less accurate our estimate of $\eta_0$ may be. We conduct a set of numerical experiments to identify the number of sampled values $T$ that appears in practice to be sufficient to obtain a stable estimate of $\eta_0$. Specifically, we construct a set of lists $S_T$, for $T = \{20, 30, 50, 100, 150, 200, 250\}$ as described above. For example, when $T = 20$ and $\eta = 1$, $S_T$ is a list of 20 consecutive degree assortativity values from the Markov chain after the burn-in, and when $T = 100$ and $\eta = 2000$, $S_T$ contains 100 values sampled every 2000 steps from the chain after the burn-in, so that the last sample is 200,000 double-edge swaps after the first sample.

Fig. 4 shows the fraction of significant autocorrelation $f_\eta$ as a function of the sampling gap $\eta$, illustrating how $f_\eta$ decays towards zero with increasing $\eta$. With a fixed sample size $T$, the value of $\eta$ for which the fraction of significant autocorrelations becomes less than or equal to 5% is recorded as the sampling gap $\eta_0(T)$ for the network. We observe that the sampling gap $\eta_0(20)$ obtained for sample $S_{20}$ is less than both $\eta_0(30)$ and $\eta_0(50)$, obtained for samples $S_{30}$ and $S_{50}$, respectively. Hence, the sampling gap $\eta_0(20)$ is large enough by our criteria, for a sample containing 20 values, but not large enough when the sample contains 50 values. To resolve such a discrepancy, we take the largest length of sub-samples so that adding more values to it does not induce a significant change in the $\eta_0$ value for this network. Fig. 4 shows that while the sample size is less than 50, increasing it also increases the corresponding value $\eta_0$. However, Fig. 4 inset shows that this pattern disappears once the sample size exceeds 50, meaning the value of $\eta_0$ stabilizes for sufficiently large sub-samples. Hence, to obtain a reliably stable estimate of $\eta_0$, in our sampling gap experiments, we fully automate the selection of $\eta_0$ by running the algorithm for $T = 200$ and $T = 250$ and taking the mean of the two corresponding estimates $\eta_0(200)$ and $\eta_0(250)$ returned by the algorithm.

The autocorrelation test described above also makes an assumption of stationarity of the test sample $X_\eta$ being tested, and may not perform as expected if this behavior is uncommon in practice. Using our corpus of
509 empirical and semi-synthetic networks, we evaluated this assumption [44] on all samples taken for the experiments after the “burn-in”, and found that for 92% of the samples tested across all values of sampling gap \( \eta \), the stationarity assumption is met.

Although for any particular network, one could run the above sampling gap estimation algorithm to choose an appropriate value for \( \eta_0 \), the procedure itself is computationally expensive. To avoid this cost, we now develop a set of heuristics and decision criteria by which to quickly and automatically choose \( \eta_0 \), given only the fixed degree sequence and the choice of the graph space to sample from.

### A. Simple graphs

For simple networks, the Markov chain’s transition probabilities are the same for both stub-labeled and vertex-labeled spaces (see Appendix B 1). Hence, the sampling gaps that our algorithm estimates for particular real-world simple networks will be the same, in either the vertex-labeled and the stub-labeled spaces.

We begin by running the sampling gap algorithm on each of the 103 simple networks in our corpus. Of these, the vast majority (93.2%) exhibit a nearly linear pattern in how the estimated sampling gap \( \eta_0 \) varies with the size of the network \( m \) (Fig. 5a,c). This pattern is very close to the simple form of \( \eta_0 = m/3 + 300 \). Although there are a few networks for whom this heuristic would overestimate the sampling gap, it is generally better to choose a sampling gap \( \eta_0 \) too large—sampling a pair of networks in the Markov chain that are even more uncorrelated—than to choose it too small and risk non-trivial serial correlations. However, for a small number of networks (7), the estimated sampling gap \( \eta_0 \) is far larger than this simple heuristic predicts. This behavior occurs mainly for graph spaces that prohibit multi-edges. In that case, the network’s density plays a crucial role in governing how often the change proposed by a double-edge swap is rejected, and hence a graph is resampled by the MCMC.

The reason the MCMC produces these unusually large \( \eta_0 \) estimates stems from the Markov chain’s boundary enforcement criterion: if the Markov chain proposes a double-edge swap in a simple graph that would create a self-loop or a multi-edge, thereby exiting the specified graph space, the algorithm rejects this change and resamples its current state. Each such resampling extends the time needed for the serial correlation to decay.

Let \( \rho \) is the iid probability of an edge existing between a uniformly random pair of nodes, i.e., the network density. (We note that for simple graphs \( \rho = \langle k \rangle/n - 1 \) and for loopy graphs \( \rho = \langle k \rangle/n \), where \( \langle k \rangle \) is the mean degree). Suppose two edges \((x,y)\) and \((w,z)\) are chosen uniformly at random for a double-edge swap. Each of the two kinds of swaps (Fig. 2a) is then chosen with equal probability. In both the cases, the probability of rejecting the swap \( \{(x,y), (w,z)\} \rightarrow \{(x,z), (w,y)\} \) or the swap \( \{(x,y), (w,z)\} \rightarrow \{(x,w), (y,z)\} \) due to the creation of a multi-edge after the swap is governed by the likelihood that an edge already exists where the swap proposes to place one:

\[
\text{Pr}(\text{rejection}) = \text{Pr}(\text{multi-edge} | \{(x,y), (w,z)\} \rightarrow \{(x,z), (w,y)\}) + \text{Pr}(\text{multi-edge} | \{(x,y), (w,z)\} \rightarrow \{(x,w), (y,z)\})
\]

\[
= \frac{1}{2} \left(1 - \text{Pr}(\text{either } (x,z) \text{ nor } (w,y) \text{ exists})\right) + \frac{1}{2} \left(1 - \text{Pr}(\text{either } (x,w) \text{ nor } (y,z) \text{ exists})\right)
\]

\[
= \frac{1}{2} \left(1 - (1 - \rho)^2\right) + \frac{1}{2} \left(1 - (1 - \rho)^2\right)
\]

\[
= 2\rho - \rho^2,
\]

where each swap can produce a multi-edge with either of the two swapped edges. We refer to the simplified expression of \( 2\rho - \rho^2 = \omega \) as the density factor of a network, which gives a simple density-based estimate of \( \text{Pr}(\text{rejection}) \). A more precise estimate would exploit the moment structure of the degree distribution, but such a formula is not necessary for our purposes.

Hence, in a space that does not allow multi-edges, higher network density substantially increases the probability that the MCMC will resample states. And, resampling states necessarily increases the estimated sampling gap because resampling preserves the serial correlations in the chain that we seek to avoid. In our corpus of 103 simple networks, the vast majority (86.4%) have a density factor \( \omega \leq 0.25 \), six (5.8%) have one \( 0.25 < \omega \leq 0.5 \), five (4.9%) have one \( 0.5 < \omega \leq 0.75 \) and the remaining four (3.9%) have \( \omega > 0.75 \). These frequencies reflect the fact that real-world networks with very high density
typically occur only rarely [45], unless the network is especially small.

Across our simple network corpus, we find that networks with a density factor $\omega \leq 0.25$ yield sampling gap estimates that scale linearly with the number of edges $m$ (Fig. 5a,e), while networks with a larger density factor are more likely to yield anomalously high sampling gap estimates. We use this observation to divide networks into two categories, based on their calculated density factors $\omega$. If a network’s density factor is $\omega > 0.25$, the sampling gap should be estimated directly via the algorithm described above (Algorithm 1); otherwise, the sampling gap follows a simple pattern and may be chosen automatically via a scaling law that fits the estimated gap (Fig. 5a,e). For any particular network, choosing too small a value of $\eta_0$ would cause the Markov chain to mix more poorly, and so we manually fit a scaling law that fits the estimated gap values (Fig. 5a,e). For any particular network, choosing too small a value of $\eta_0$ would cause the Markov chain to mix more poorly, and so we manually fit a scaling law that fits the estimated gap values (Fig. 5a,e). For any particular network, choosing too small a value of $\eta_0$ would cause the Markov chain to mix more poorly, and so we manually fit a scaling law that fits the estimated gap values (Fig. 5a,e).

For the seven (7.8%) networks for which this function is not an upper bound, the error is modest: 1.9% and 1.1% in the stub and the vertex-labeled spaces, respectively. We note that if the graph is small, e.g., $m < 1000$, and has a relatively high density factor $\omega > 0.25$, then the scaling law still yields a sufficiently high value of $\eta_0$, i.e., one comparable to what the sampling gap estimation algorithm typically produces.

B. Loopy graphs

Real-world “loopy” networks, those with self-loops but no multi-edges, are uncommon. We construct a reasonable empirical corpus of 154 loopy graphs by obtaining 51 such networks from public repositories [42] and generating an additional 103 loopy graphs by adding self-loops to our previous corpus of simple networks. To convert a simple network into a loopy network, we first measured the fraction of nodes with a self-loop in both our corpus of 110 real-world loopy multigraphs and the 51 real-world loopy graphs to obtain an empirical distribution of loopiness. For each simple graph in our corpus, we then chose a fraction iid from this loopiness distribution and added a self-loop to each node with the corresponding probability. We note that this loopiness distribution is strongly bimodal: 44% have at most 5% of nodes with self-loops, while 39.1% have at least 95% of nodes with self-loops.

Although the MCMC algorithm proposed by Fosdick et al. correctly samples graphs with fixed degree sequence post convergence, there are certain conditions [18] that the degree sequence must satisfy for this to hold true in a loopy graph space (i.e graph space that allows loops but no multi-edges). These conditions ensure that the double-edge swap algorithm reaches every valid loopy graph with the given degree sequence. Nearly all empirical loopy degree sequences satisfy these conditions, and in our corpus of loopy graphs, all the 154 networks’ degree sequences do so. However, for the rare empirical degree sequences that do not, a different MCMC sampling algorithm exists, which augments double-edge swaps with triangle-loop swaps for connecting the space of loopy graphs [18]. The solution proposed in this paper only serves those loopy graphs that satisfy the necessary conditions for the Fosdick et al. MCMC. Designing a convergence detection method for the MCMC sampler that uniformly samples loopy graphs with any degree sequence [18] is an interesting direction of future work.

For our loopy network corpus, we repeat our analysis by first running the sampling gap algorithm on each network in the corpus. We note that because multi-edges are not permitted in the loopy space, the density factor $\omega = 2/3 - \rho^2$ has the same relevance here as it does with simple graphs. In our loopy corpus, 90.9% of networks have a density factor $\omega \leq 0.25$, and the same scaling law of $\eta_0 = m/3 + 300$ is an upper bound in both stub- and vertex-labeled spaces (see Appendix B 2) on nearly all of the observed sampling gap values for these networks (Fig. 5b,f). Of the 154 loopy networks, 10 (6.5%) and 18 (11.7%) networks in the stub and vertex-labeled spaces, respectively, have low density factors but the scaling law is not an upper bound for them. In these cases, the error from using the scaling law to choose $\eta_0$ remains modest, being 2.3% and 1.1%, respectively.

C. Loopy multigraphs

For stub-labeled loopy multigraphs, it is common to directly construct networks with a fixed degree sequence by choosing a uniformly random matching on the set of edge “stubs” given by that sequence [15, 17]. Furthermore, this algorithm is computationally cheap, taking $O(m)$ time, compared to an MCMC approach. However, stub matching cannot be used to correctly sample from the vertex-labeled loopy multigraph space. There, we must instead use the Fosdick et al. MCMC, with a convergence criterion. For completeness, we analyze the MCMC’s behavior in both the stub-labeled and vertex-labeled loopy multigraph settings. In the former setting, our results may be useful in cases where correlated draws are desired.

In the loopy multigraph space, the Markov chain’s transition probabilities in the stub-labeled and vertex-labeled spaces are different. In the stub-labeled case, the Markov chain never resamples a state, while in the vertex-labeled space, some transitions are forbidden and hence the Markov chain resamples a state under certain conditions (see Appendix B 3). Due to this resampling, the sampling gap required in the vertex-labeled space should be greater than the gap in the stub-labeled space.

We investigate these differences by running the sampling gap algorithm on our corpus of 110 real-world loopy multigraphs (Fig. 5c,g). We find that, indeed, for a given network size, the estimated sampling gap tends to be higher in the vertex-labeled case than in the stub-labeled case. However, for 42 of 110 (38%) loopy multigraphs
in the vertex-labeled case, the estimated sampling gap is much higher than the simple linear pattern observed in the majority of cases. This peculiar behaviour of the MCMC for these networks can be understood by considering how a network's degree distribution influences the MCMC's dynamics.

Suppose that two edges of the network \((x, y)\) and \((w, z)\) share exactly one common endpoint, implying that only 3 of the 4 vertices are distinct. If a double edge swap proposes the change \(\{(x, y), (w, z)\} \rightarrow \{(x, w), (y, z)\}\), then half the time the degree assortativity will remain unchanged after the swap, i.e., \(\Delta r = 0\). Because these edges are chosen uniformly, the higher the degree of a node, the greater the probability of that node appearing twice in the set \(\{x, y, w, z\}\). The presence of such high-degree nodes in the network increases the likelihood of MCMC steps with \(\Delta r = 0\). The more of these \(\Delta r = 0\) steps that occur, the greater the serial correlation in the Markov chain, and the greater the gap required to obtain independent samples. In the vertex-labeled space, in addition to choosing edges having one common endpoint, the Fosdick et al. MCMC resamples states for other reasons \([16]\), which also creates a \(\Delta r = 0\) step, and therefore further increases the serial correlations in the Markov chain.

Chung-Lu random graphs are a vertex-labeled model of simple graphs that places a constraint on the value of the maximum degree. This constraint serves to limit the likelihood of producing a network with multi-edges, and has a form \(\max_i k_i^2 \leq 2m\) \([46]\). In our setting, this constraint allows for a simple heuristic for deciding how skewed a degree distribution can be before state resamplings are likely to generate too-strong serial correlations in the vertex-labeled space. In our sampling gap experiments, we find that every loopy multigraph in our corpus that exceeds this maximum degree threshold does indeed require an unusually large sampling gap (even larger than \(m\)) in the vertex-labeled space. In contrast, networks in our corpus that fall below \(\frac{1}{3}\) of this threshold (a safe margin) produce estimated sampling gaps that exhibit the same familiar linear relationship with \(m\). In this case, a scaling law of \(\eta_0 = m/3 + 300\) (constructed in the same way as for previous graph spaces) produces a conservative upper bound on \(\eta_0\) (Fig. 5g). And, if a network exceeds this maximum degree safe margin, the sampling gap of the network in the vertex-labeled space should instead be chosen using our sampling gap algorithm (Algorithm 1).

In the stub-labeled case, the corresponding scaling law obtained from all the 110 loopy multigraphs is \(\eta_0 = m/3 + 300\) (Fig. 5c). For the nine (8.1%) loopy multigraphs for which the scaling law is not an upper bound in the stub-labeled space, the resulting error is 1.9%. And, for the nine (13.2%) loopy multigraphs that satisfy our maximum degree constraint and yet have an estimated sampling gap higher than our proposed scaling law for the vertex-labeled space, the error is 14.1%.

D. Multigraphs

Real world networks with multi-edges but no self-loops are also uncommon. We construct an empirical corpus of 142 such networks by obtaining 32 of them from public repositories and generating 110 multigraph networks by removing the self-loops of our loopy multigraphs. We selected this approach for generating semi-synthetic networks because the set of possible graphs with and without various self-loops is exponentially smaller, and thus easier to sample from, than the set of graphs with or without various multi-edges.

The panels Fig. 5c and Fig. 5g show the estimated sampling gaps for 110 and 68 networks in the stub-labeled and vertex-labeled spaces, respectively. In the latter, we exclude the 42 networks whose maximum degree exceeds the threshold given in the text.
As with loopy multigraphs, the network’s maximum degree and whether the space is stub-labeled or vertex-labeled govern the choice of sampling gap $\eta_0$ (see Appendix B 4), just as it does in the loopy multigraph space. Repeating our analysis on this corpus of 142 multigraphs, we find that the estimated sampling gaps of all 142 networks in stub-labeled space and of 78 (54.9%) networks in the vertex-labeled space exhibit a familiar linear pattern in the number of edges $m$ (Fig. 5d,h)$^2$. The scaling laws of $\eta_0 = m/3 + 300$ in the stub-labeled space, and $\eta_0 = m/2.7 + 100$ in the vertex-labeled space for networks whose maximum degree does not exceed the safe margin of $\max_i k_i^2 \leq \frac{1}{2}2m$, provide an upper bound on the estimated sampling gaps for nearly all multigraphs in the corpus. For the 26 (18.3%) loopy multigraphs where this is not true in the stub-labeled space, the resulting error is 3.9%; and, for the seven (8.9%) loopy multigraphs that satisfy our maximum degree constraint and yet the scaling law is not an upper bound in the vertex-labeled space, the error is 11.2%.

E. A complete decision tree for choosing the sampling gap

Although an appropriate sampling gap $\eta_0$ can always be estimated using Algorithm 1, our numerical experiments show that in many cases, a sufficient gap may be chosen more efficiently using a simple scaling law in the number of edges in the network (Fig. 5). However, there are some conditions on applying these scaling laws in practice, depending on the particular graph space and certain structural properties of the network, and in some cases, it may still be necessary to choose $\eta_0$ via Algorithm 1.

The decision tree in Fig. 6 organizes the insights, conditions, and scaling laws obtained from our numerical experiments into a single heuristic for choosing the sampling gap, depending on the network’s particular properties and specified graph space. In cases where a network does not fall into a category in which a scaling law can be used to choose $\eta_0$, the serial correlations in the Markov chain will tend to far exceed those predicted by any of our scaling laws, and we recommend instead directly estimating a network-specific sampling gap via Algorithm 1. Again, we note that the heuristics developed in this paper are derived from the double-edge swap MCMC [16] and do not apply to an extremely rare class of loopy graphs for which the necessary conditions of the graph space connectivity [18] are not satisfied. In those rare cases, one would have to use the MCMC proposed by Nishimura et. al. [18].

We note that the appearance of scaling laws in this setting, and the consistency of their form across different graph spaces is intriguing. This pattern may reflect a currently unknown but common underlying topology both within and across these different graph spaces. Investigating the origins of this common pattern may yield deeper theoretical insights into or guarantees for MCMC
convergence, and is an interesting direction for future work.

From a more practical perspective, this common pattern provides a simple and highly effective heuristic that works well across a wide variety of graph types.

F. Convergence criterion

Given the choice of sampling gap \( \eta_0 \) (Fig. 6), we now specify a convergence test for the Fosdick et al. MCMC. The test we propose compares the states of two consecutive sequences of states from the Markov chain, and assesses whether they are plausibly drawn from a common underlying distribution, and hence are evidence that the Markov chain has converged on its equilibrium.

The test samples states from the Markov chain to populate a window of two lists, each composed of 30 degree assortativity values, denoted as \( L_1 = \{ r_t, r_{t+\eta_0}, r_{t+2\eta_0}, \ldots, r_{t+29\eta_0} \} \) and \( L_2 = \{ r_{t+30\eta_0}, r_{t+31\eta_0}, r_{t+32\eta_0}, \ldots, r_{t+59\eta_0} \} \). We then apply the non-parametric two-sample Kolmogorov–Smirnov (KS) test [47] to the lists \( L_1 \) and \( L_2 \) to determine whether they are plausibly drawn from the same distribution.

This choice of 30 observations in a list is a tradeoff: it is large enough to provide a reasonable degree of statistical power to the KS test, but small enough to be computationally expedient. In some applications, a larger list may be desired, but we caution against a shorter list, which may increase the risk of incorrect early convergence due to low statistical power. Similarly, there are a variety of other tests that could be used to assess the statistical similarity of \( L_1 \) and \( L_2 \). For this task, the KS test has three attractive properties: (i) it is a test of distributional similarity and hence is more sensitive than comparing summary statistics like the mean or variance, (ii) it is computationally light-weight, and (iii) it is non-parametric, making it appropriate for Markov chains with unknown distributional characteristics.

If the KS test rejects the null hypothesis that the two samples are drawn from the same underlying distribution, we discard the contents of the first list, “slide” the window forward by a list-length (30 values), sample new values from the Markov chain in order to populate the rest of the window, and finally test again. We repeat this process of slide, repopulate, and test, until the KS test fails to reject the null hypothesis, which we interpret as an indicator that the MCMC has converged to its stationary distribution. Every \( \eta_0 \) steps beyond this point provides an iid draw from this configuration model.

To illustrate this procedure, Fig. 7 shows the convergence detected by our this test for a simple network in the stub-labeled space with \( n = 2,642 \) nodes and \( m = 3,303 \) edges, and for a loopy multigraph in the vertex-labeled space with \( n = 2,837 \) nodes and \( m = 11,407 \) edges.

G. Validating the diagnostic

We now turn to the question of whether our convergence test can correctly and reliably detect when the MCMC has reached its stationary distribution. If the procedure works as desired, then before convergence, the distribution of assortativity values will be non-stationary, while after convergence is detected, the distribution should appear stationary, meaning that running the Markov chain longer should not alter the sampled assortativity distribution (Fig. 8).

To assess this behavior, we tabulate the assortativity distributions of 500 states sampled after \( m/8 \), after \( m/4 \), and after \( m/2 \) steps, and then again at convergence and after 1000\( m \) steps (well beyond convergence). The latter distribution represents the target distribution of the MCMC, and hence provides a clear comparison against distributions sampled earlier in the Markov chain. As a first test, we apply this assessment to a simple stub-labeled network with \( n = 1,589 \) nodes and \( m = 2,742 \) edges.

Fig. 8 shows these five sampled distributions, along with the assortativity coefficient for the original empirical network, which is the initial condition of the Markov chain. In the pre-convergence phase, as the MCMC walk lengthens from \( m/8 \), to \( m/4 \), to \( m/2 \) steps, the assortativity distribution for the sampled networks moves progressively further away from the empirical value of the initial network. This non-stationarity is indicative of a steady decorrelation of the Markov chain relative to its initial state, as progressively more double-edge swaps are
applied to randomize the network’s structure. Once convergence is detected, this non-stationary behavior is no longer present, and instead the difference between the assortativity distribution at convergence, and well beyond it, is negligible. The stationarity of the two latter distributions indicates that the test of convergence correctly detected the Markov chain’s convergence on the target, uniform distribution. Finally, repeating this same experiment on networks drawn from our corpuses for other graph spaces produces similar results.

### H. Comparing convergence tests

Detecting convergence in a Markov chain Monte Carlo algorithm is a common and non-trivial problem, especially for scalar time series. Although the underlying states in the double-edge swap Markov chain are networks, our approach for detecting convergence converts this graph sequence into a sequence of scalar values. Hence, it is reasonable to wonder how existing scalar-valued techniques perform in this setting.

To explore this question, we compare the methods described above with three commonly used scalar time series convergence tests: (i) the Geweke diagnostic [37], (ii) the Gelman-Rubin diagnostic [35] and (iii) the Raftery-Lewis diagnostic [36]. (Each of these methods is available via libraries in Python [48] and R [49]).

A crucial consideration when selecting a convergence test is whether the Markov chain in question satisfies the test’s underlying requirements and assumptions [41]. Each of these three alternative tests make assumptions that may not hold for the configuration model. For instance, the Geweke diagnostic assumes that the Geweke statistic derived from the sampled states will be distributed as a standard normal variable in the asymptotic limit (see Appendix C 1). The Gelman-Rubin diagnostic assumes that the MCMC’s stationary distribution is normally distributed, and requires multiple Markov chains to be initialized at highly dispersed initial states in the sample space (see Appendix C 2). And finally, the Raftery-Lewis diagnostic depends on the quantile of interest, and in some cases, the estimated convergence rate may fall far below the rate required of the full chain [50] (see Appendix C 3).

The Geweke and the Raftery-Lewis method assess one list at a time for detecting convergence, while our method and the Gelman-Rubin method compares two consecutive lists from the Markov chain to conduct its test for convergence (see Appendix C). However, none of the other three diagnostics specify their sampling list sizes, and that choice of parameter is left to the user. In contrast, our method described above has a fixed list size of $29\eta_0 + 1$ steps, which yields exactly 30 sampled values, each $\eta_0$ double-edge swaps apart.

We evaluate the performance of the four convergence tests along two dimensions: accuracy and efficiency. First, we say that a test is more accurate if the assortativity distribution at the time that the test detects convergence is closer to the corresponding distribution at 1000m steps into the Markov chain (a point sufficiently deep in the chain that we assume it represents the converged distribution). Second, we say that a test is more efficient if it uses fewer steps to detect convergence. An ideal convergence test will perform well on both accuracy and efficiency measures. An efficient but inaccurate test would use relatively little data, but would tend to declare convergence too early, producing a distribution of assortativity values that differs substantially from the target distribution. In contrast, an inefficient but accurate test would run a very long Markov chain and declare convergence long after the stationary distribution had been reached.

As a common basis for evaluating the four tests, we select 50 loopy multigraphs uniformly at random from our empirical corpus. Because the three alternative tests do not specify a sampling list size, we evaluate them under two choices, which allows us to also assess whether a test’s performance is sensitive to that choice. In the first, we fix their sampling list size at an arbitrary $m/2$ steps, while our method uses its fixed value of $29\eta_0 + 1$. In the second, we fix all sampling list sizes to be that of our method. In both experiments, we apply the four tests to each of the networks in our test corpus. To measure a test’s accuracy, we perform a standard two-sample KS-test (with a significance level of $\alpha = 0.05$) between the assortativity distribution at the time of convergence detected by a test and the distribution obtained after 1000m swaps, and record the corresponding KS distance as our measure of accuracy. To measure a test’s efficiency, we record the number of steps run in the Markov chain before the test detects convergence.

Fig. 9a,b show the measured KS distance (accuracy) vs. the mean number of double-edge swaps $\bar{s}$ used to detect convergence (efficiency). In the first experiment (Fig. 9a), our approach exhibits a very high accuracy, in the form of a low rate of early convergence (2% false
and (b) convergence tests every 29 \( \eta \) portions, the 5% rate expected from our choice of \( \alpha \) agnostic’s rates are statistically indistinguishable from rate), and both our method’s rates and the Geweke di-
alarms). The Geweke diagnostic also performs well (6% rate), and both our method’s rates and the Geweke di-
agnostic’s rates are statistically indistinguishable from the 5% rate expected from our choice of \( \alpha \) (test of propor-
tions, \( p = 0.41 \) and \( p = 0.82 \), respectively). In contrast, the Gelman-Rubin diagnostic exhibits a mod-
est and significant error rate (18%, \( p = 0.04 \)), while the Raftery-Lewis diagnostic performs very poorly (94%, \( p < 10^{-5} \)). We find that our method’s accuracy is statistically indistinguishable from that of the Geweke di-
agnostic (\( p = 0.30 \)), but significantly better than the Gelman-Rubin diagnostic (\( p < 0.01 \)) and the Raftery-
Lewis diagnostic (\( p < 10^{-5} \)).

In the second experiment, where all tests use the same sampling list size (Fig. 9b), our approach again exhibits a very high accuracy (0% false alarms). The Geweke and Gelman-Rubin diagnostics also exhibit high accuracies (2% and 8% false alarms, respectively), and all three methods’ rates are indistinguishable from the expected 5% false alarm rate based on the chosen \( \alpha \) (test of proportions, \( p = 0.10 \), \( p = 0.41 \), and \( p = 0.54 \), respect-
ively). The Raftery-Lewis diagnostic again performs poorly (98%, \( p < 10^{-5} \)). We find that in this setting our method’s accuracy is statistically indistinguishable from that of the Geweke diagnostic (\( p = 0.31 \)), but significantly better than the Gelman-Rubin diagnostic (\( p = 0.04 \)) and the Raftery-Lewis diagnostic (\( p < 10^{-5} \)). Comparing error rates across experiments, we find that each alternative convergence test has a similar error rate in both experiments. This consistency suggests that the particular choice of sampling list size makes little differ-
ence in the resulting accuracy of these three methods. In terms of accuracy, the Geweke diagnostic performs similarly to our method, and both methods are highly accurate. However, the Geweke diagnostic can be sub-
stantially less efficient (Fig. 9b), letting the Markov chain run for many more steps than is necessary, often produc-
ing late alarms, compared with our method.

Across both experiments, our assortativity-based test exhibits high accuracy and efficiency, while other tech-
niques tend to perform either slightly or dramatically worse on one or both dimensions. Of the three, the Geweke diagnostic performs most similarly, exhibiting equivalent accuracy, but can also be substantially less ef-
icient (Fig. 9b). An interesting direction of future work would be to understand why, and whether a more efficient test than ours can be constructed. Finally, we find that repeating these experiments on the other graph spaces yields similar results.

III. DISCUSSION

The configuration model is among the most widely used models of random graphs in the analysis and model-
ing of networks. For instance, it is both a standard way to generate synthetic networks with a specified degree structure, e.g., with a heavy tail or from an empirical network, and a null model by which to evaluate whether some observed network statistic is typical or unusual, given the degree structure. The most common method for sampling configuration model networks—the popular stub-matching algorithm—correctly generates only stub-
(labeled loopy multigraphs, and heuristics for convert-
ing these networks into other types, e.g., simple graphs, can introduce structural artifacts that contaminate their use [16]. A Markov chain Monte Carlo algorithm proposed by Fosdick et al. [16] based on a degree-preserving double-
edge swap can correctly sample from the configuration model after its convergence, in any of the either graph spaces, with very rare exceptions in the loopy graph space [18]. However, the proof of correctness for the Fos-
dick et al. MCMC does not provide criteria for identifying when the Markov chain has converged on the target distribution.

The method we developed here provides a complete so-
lution to the convergence detection problem of the Fos-
dick et al. MCMC, for all eight graph spaces, defined by whether the target graph is stub-labeled or vertex-
labeled, and whether it allows self-loops or not, and multi-edges or not. This solution provides an efficient and accurate means to detect its convergence on the target, uniform distribution over the specified graphs.

Our approach transforms the sequence of graphs sam-
ped by the Markov chain into a scalar-valued sequence of degree assortativity values for the graphs (Fig. 3), and then uses a hypothesis test to detect when this time series

![FIG. 9. KS distance (accuracy) as a function of the mean number of double-edge swaps (efficiency) applied on 50 stub-
labeled loopy multigraphs, for the four diagnostics. (a) Con-
vergence tests every \( m/2 \) swaps for the three alternative tests, and (b) convergence tests every \( 29\eta + 1 \) swaps for all tests.](image-url)
appears to have converged (Fig. 7). There are, of course, many alternative network summary statistics that one could use instead of degree assortativity, such as the clustering coefficient or average path length. For this task, the global assortativity measure $r$ is more computationally efficient to calculate on a potentially long sequence of networks than many alternatives, and it provides a good measure of the overall “shape” of a state in the Markov chain.

The strong serial correlations in the Markov chain, however, creates problems both for drawing a graph from the configuration model, after convergence, and for using hypothesis tests to detect convergence, which typically assume that samples are iid. To mitigate this issue, we develop a novel algorithm for estimating a sampling gap $\eta_0$ (Algorithm 1) by which to obtain effectively uncorrelated draws from the MCMC. This algorithm is based on a standard autocorrelation test to determine how far apart two sampled states must be in order to be statistically independent. Here again, other choices are certainly possible for how one might quantify the degree of autocorrelation between two sampled states. We leave an exploration of these possibilities, which may yield more efficient gap estimation algorithms, for future work. Applying this gap estimation algorithm to a large corpus of 500 real world and semi-synthetic networks, we identified a set of simple decision rules based on the empirical scaling behavior of estimated gaps $\eta_0$ with the number of edges $m$. These rules allow a researcher to automatically select an appropriate sampling gap for a given network usually without having to run the gap estimation algorithm (Algorithm 1).

Our analysis of the estimated sampling gaps revealed several interesting patterns, along with useful insights as to when the double-edge swap MCMC tends to misbehave. For instance, in multigraphs, when the maximum degree is particularly large, the MCMC tends to resample states at higher rates in the vertex-labeled space, producing more serial correlations and hence delayed convergence. A similar issue occurs, but for a different reason, when the overall network density is especially high in networks where multi-edges are not allowed. Additionally, across all eight graph spaces, we find that the estimated sampling gaps $\eta_0$ of nearly all networks scale very nearly linearly with the number of edges in the network $m$ (Fig. 5). We have no explanation for this appearance of scaling laws here, or their common form across different graphs spaces. However, these findings suggest that the overall topologies of the different graph spaces may be fundamentally similar in some unknown, but likely important, way. Further investigation of these underlying similarities may lead to more reliable convergence criteria.

In cases where the conditions of the heuristics (Fig. 6) are not satisfied, the sampling gap algorithm (Algorithm 1) can be used to estimate a bespoke sampling gap $\eta_0$ for the particular network, albeit at a non-trivial computational cost.

Given a set of effectively independent samples from the Markov chain, many different statistical convergence tests could be applied. The non-parametric two-sample Kolmogorov–Smirnov test we employ here has the advantage of being a test of distributional differences, which provides greater sensitivity than tests that merely compare summary statistics like the mean value. Moreover, when applied to a set of values sampled according to the estimated gap, this test can accurately detect convergence (Fig. 8). Compared to three common tests of convergence for MCMCs, our approach is both more accurate and more efficient—converging neither too early nor too late—than three commonly used MCMC convergence tests (Fig. 9).

The convergence detection method we introduce thus resolves the open question of how to accurately sample from the configuration model. Our study may also provide insights on developing convergence detection methods for other Markov chain sampling algorithms for networks [18], and we note that our approach can likely be adapted to other variations of the configuration model, e.g., on graphs of fixed core-value sequence [51].

The methods developed here are only applicable to the classic configuration model on dyadic networks, i.e., networks where edges are defined as pairs of nodes. As such, different methods may be needed for correctly sampling from either the hypergraph configuration model [52], in which edges are polyadic, or the configuration models for simplicial complexes [53], or for networks where edge weights cannot be interpreted as multi-edges, although it can be adapted to work on directed networks. Finally, the degree-preserving double-edge swap approach employed by the Fosdick et al. MCMC cannot be applied to the loopy networks that do not satisfy the necessary conditions for the loopy graph space to be connected [18]. However, such loopy networks occur extremely rarely.

In closing, we note that the lack of accurate and efficient convergence tests for drawing graphs from the configuration model has encouraged researchers to often use the fast random stub-matching algorithm first and then convert that loopy-multigraph into whatever graph type is desired, e.g., a simple network. Fosdick et al. showed that this approach is risky when one desires a precise comparison between an empirical network and the distribution defined by the configuration model, as the conversion process can introduce problematic statistical artifacts. The methods described here provide a complete solution to sampling from the degree-preserving configuration model using the Fosdick et al. MCMC algorithm, and we hope they will enable researchers to more accurately and more broadly compare the rich variety of empirical patterns found in networks with those of random graphs with a specified degree structure.

AC conceived the research, UD and AC designed the analyses, and wrote the manuscript. U.D. conducted the analyses. Competing interests: None.
Appendix A: The Autocorrelation function

The autocorrelation function of a sequence measures the degree to which its values are serially correlated, so that the greater the serial correlation, the larger the value of the autocorrelation function [54]. Mathematically, the autocorrelation $R_h$ quantifies the average correlation between a pair of values $x_t$ and $x_{t+h}$ in the sequence, separated by a lag of $h$, and ranges from $-1 \leq R_h \leq 1$. It is defined as

$$R_h = \frac{C_h}{C_0},$$

where

$$C_h = \frac{1}{T} \sum_{t=1}^{T-h} (x_t - \bar{x})(x_{t+h} - \bar{x}),$$

and $C_0 = \frac{1}{T} \sum_{t=1}^{T} (x_t - \bar{x})^2$.

Hence, the autocorrelation $R_h$ is the covariance of the sample and itself at a lag of $h$, normalized by the variance of the sample. Here $T$ is the maximum separation over which we consider the autocorrelation of the pairs of states.

It can be shown (see Brockwell and Davis [43] p.222) that if a sample of $n$ points comprises of only independent and identically distributed (iid) noise with finite variance, the sample autocorrelations $R_h$ of this sample, for $h > 0$, are approximately iid $N(0,1/n)$ for large $n$. Hence, $C\%$ of the sample autocorrelations will lie between the bounds $\pm Q/\sqrt{n}$, where $Q$ is the $(100 - (100-C)/2)$% quantile of the standard normal distribution.

Appendix B: Dependence of sampling gap on the MCMC transition probabilities

For reference, we have presented the stub-labeled and the vertex-labeled double-edge swap MCMC algorithm in Algorithm 2 and 3 adapted from Fosdick et al [16]. In this appendix, we provide a discussion of how the MCMC’s transition probabilities in different graph spaces govern the respective sampling gaps we obtain using Algorithm 1.

Algorithm 2 stub-labeled MCMC

**Input:** initial graph $G_0$, graph space (simple, multigraph, or loopy multigraph)

**Output:** sequence of graphs $G_t$

1: for $i \leq \text{number of graphs to sample}$ do
2: choose two edges at random
3: randomly choose one of the two possible swaps
4: if edge swap would leave graph space then
5: resample current graph: $G_i \leftarrow G_{i-1}$
6: else
7: swap the chosen edges, producing $G_i$

Algorithm 3 vertex-labeled MCMC

**Input:** initial graph $G_0$, graph space (simple graph, multigraph, or loopy multigraph)

**Output:** sequence of graphs $G_t$

1: for $i \leq \text{number of graphs to sample}$ do
2: choose two distinct edges $(u,v)$ and $(x,y)$ uniformly at random
3: if $\text{Unif}(0,1) < 0.5$ then
4: $u,v \leftarrow v,u$
5: if edge swap would leave the graph space then
6: resample current graph: $G_i \leftarrow G_{i-1}$
7: if $\exists 4$ distinct vertices in $u,v,x,y$ then
8: $A \leftarrow w_{uv}w_{xy}$
9: $B \leftarrow (w_{ux} + 1)(w_{vy} + 1)$
10: else if $\exists 3$ distinct vertices in $u,v,x,y$ then
11: if $u = v$ or $x = y$ then
12: $A \leftarrow 2w_{uv}w_{xy}$
13: $B \leftarrow (w_{ux} + 1)(w_{vy} + 1)$
14: else
15: $A \leftarrow w_{uv}w_{xy}$
16: $B \leftarrow 2(w_{ux} + 1)(w_{vy} + 1)$
17: else if $\exists 2$ distinct vertices in $u,v,x,y$ then
18: if only one of $(u,v)$ or $(x,y)$ is a self-loop then
19: $G_i \leftarrow G_{i-1}$
20: continue
21: else if both $(u,v)$ and $(x,y)$ are self-loops then
22: $A \leftarrow 2w_{uv}w_{xx}$
23: $B \leftarrow (w_{ux} + 2)(w_{uy} + 1)$
24: else
25: $A \leftarrow \frac{1}{2}w_{uv}(w_{uv} - 1)$
26: $B \leftarrow 2(w_{uu} + 1)(w_{vv} + 1)$
27: else
28: $G_i \leftarrow G_{i-1}$
29: continue
30: $P \leftarrow \min(1, \frac{B}{A})$
31: if $\text{Unif}(0,1) < P$ then
32: swap $(u,v),(x,y) \leftrightarrow (u,x),(v,y)$ to produce $G_i$
33: else
34: $G_i \leftarrow G_{i-1}$
1. Simple graphs

In the stub-labeled space, if a double-edge swap would cause the Markov chain to leave the graph space, e.g., by creating a self-loop or a multi-edge, the swap is rejected and the current graph $G_{t-1}$ is resampled by the MCMC (Algorithm 2). Otherwise, the swap is accepted, producing the new graph $G_t$. In the vertex-labeled space, if a double-edge swap would cause the Markov chain to leave the graph space, the current graph $G_{t-1}$ is also resampled (Algorithm 3). Otherwise, the algorithm checks the number of distinct vertices and self-loops in the chosen double edges. In simple graphs, the number of distinct vertices among $u, v, x$ and $y$ would either be 3 or 4, and the multiplicity $u_{ab}$ of any edge $(a, b)$ would be 1, because multi-edges are forbidden in the simple graph space. Hence, in Algorithm 3, the variable $B/A$ will be greater than or equal to 1, and the variable $P$ in the algorithm will always be 1. As a result, if a double-edge swap does not leave the graph space in the vertex-labeled graph space, it will always be accepted, producing the new graph $G_t$. Hence, for simple graphs, the transition probabilities are the same for both the stub-labeled and the vertex-labeled space, and thus so are the induced null distributions too.

2. Loopy graphs

In the stub-labeled space, if a double-edge swap introduces a multi-edge in the graph (which is forbidden), the current graph $G_{t-1}$ is resampled. Otherwise, the swap is accepted, producing the new graph $G_t$. In the vertex-labeled space, if a double-edge swap would cause the Markov chain to leave the graph space, $G_{t-1}$ is resampled, otherwise, Algorithm 3 performs the following check. If none of the edges chosen for the swap are self-loops, then $P = 1$ and the swap is accepted. But, if either of the chosen edges is a self-loop, then in Algorithm 3, we set $A = 2$ and $B \in 1, 2, 4$. When $B = 1$, then $P = 1/2$, and the swap will be rejected half the time. For all other values of $B$, we have $P = 1$, and hence the swap is accepted. In our corpus of 161 multigraphs and loopy multigraphs, 86 (53%) of these networks have less than 5% of edges as self-loops, and 129 (80%) of them have less than 20% of edges as self-loops. Because of the relative scarcity of self-loops, the chance of a double-edge swap resulting in $P = 1$, when the swap does not leave the graph space, is high for most networks. For this reason, the Markov chains for loopy graphs in the stub-labeled and vertex-labeled spaces have very different transition probabilities, which leads to substantially different sampling gaps between the two spaces.

3. Loopy multigraphs

In the stub-labeled space, every double-edge swap is allowed, and hence never rejected. Hence, the graph $G_{t-1}$ is never resampled. However, in the vertex-labeled space, whether the proposed double-edge swap is accepted or rejected depends wholly on the multiplicity of the edges and the number of distinct vertices chosen for the double-edge swap. In Algorithm 3, there can be several ways in which the value of the variable $P$ is far below 1 and hence the graph $G_{t-1}$ will be resampled. For this reason, the MCMCs for stub-labeled and vertex-labeled loopy multigraphs behave very differently, with a substantial number of resamplings done in the vertex-labeled space, and none in the stub-labeled space.

4. Multigraphs

In both the stub-labeled and the vertex-labeled spaces, a graph is resampled only if a double-edge swap would introduce a self-loop in the network. However, in the vertex-labeled space, resampling can occur for an additional reason (Algorithm 3), depending on the multiplicity of the edges chosen for the double edge swap. In this case, the Markov chain in the stub-labeled and the vertex-labeled spaces have very different transition probabilities, which leads to substantially different sampling gaps between the two spaces.

Appendix C: Commonly known MCMC convergence tests

PyMC [48] is a Python package for Bayesian statistical modeling and advanced MCMC algorithms, and it provides implementations of three commonly used convergence tests for generic MCMCs the Geweke diagnostic [37], the Gelman-Rubin diagnostic [35], and the Raftery-Lewis diagnostic [36].

1. The Geweke diagnostic

The Geweke convergence diagnostic [37] compares the mean and the variance of samples from the beginning and the end of a single chain of a MCMC walk. Geweke [37] suggests that the beginning section be the first 10% of the chain and the ending section be the last 50%. The test uses the Geweke statistic, defined as the difference between the means of the two samples divided by the standard error. These statistics are estimated using the spectral densities of the two samples evaluated at zero, which takes into account the autocorrelations in the samples. The method uses the departure of the statistic from the standard normal assumption as an indicator of convergence failure. However, the test statistic is calculated under the assumption that when the MCMC reaches its stationary distribution, the two chain samples will be distributed according to a standard normal, in the asymptotic limit. The test also assumes that the spectral density of the time series has no discontinuities at frequency
zero [41]. Of course, whether these assumptions are satisfied depends on the process that produces the time series. The Geweke diagnostic is known to be very sensitive to the chosen spectral window [41]. Hence, the behavior of the Geweke test will likely depend on the degree to which the properties of the stationary distribution of the particular MCMC are known.

2. The Gelman-Rubin diagnostic

The Gelman-Rubin diagnostic [35] compares the within-sequence variability and between-sequence variability of multiple (at least two) sequences obtained from MCMC walks with starting points sampled from an overdispersed distribution. This test is based on the idea that when an MCMC has not yet converged, the variance within each chain is much less than that between the chains, because prior to convergence, the MCMC samples states non-uniformly. If \( \theta \) denotes the sequence of an MCMC chain, then first, an estimate of the marginal posterior of \( \text{Var}(\theta) \), is calculated as a function of the within-sequence variance \( (W) \) and between-sequence variance \( (B) \) of the multiple sequences. If the MCMC walks have not yet converged, \( B \) would overestimate \( \text{Var}(\theta) \) because the walks’ starting values were chosen to be overdispersed, whereas \( W \) would underestimate \( \text{Var}(\theta) \) because the MCMC walks have not yet saturated the states in the stationary distribution. The Gelman-Rubin statistic is then given by the square root of the ratio of \( \text{Var}(\theta) \) and \( W \). In the stationary distribution of the MCMC, both \( \text{Var}(\theta) \) and \( W \) should approach the true variance of the MCMC chain, and hence values of the Gelman-Rubin statistic close to 1 indicate convergence. In general, practitioners often use a cutoff of 1.1 as an indicator of convergence. This convergence test assumes that the stationary distribution of the MCMC is normal. Cowles and Carlin [41] suggest that both the assumption of a normal approximation of the target distribution, and the requirement of multiple MCMC chains with highly dispersed initial conditions, may not be reasonable in most practical situations.

3. The Raftery-Lewis diagnostic

The Raftery-Lewis diagnostic [36] is based on two-state Markov chain theory and standard sample size formulae for binomial variance. In particular, it calculates the burn-in period of the Markov chain and the total number of subsequent iterations required to accurately estimate \( u \), a \( q \)-quantile of the MCMC’s posterior distribution. The value of \( q \), the margin of error \( r \), and the probability \( s \) of obtaining the estimate in the interval \( (q-r, q+r) \), are all user-defined parameters, although the default value of \( s \) is 95%. The method also calculates a thinning interval \( k \), which is the number of iterations that should be skipped to produce a chain of independent samples from the Markov chain (analogous to \( \eta_0 \) in our method).

From the Markov chain \( \{\theta_t\} \), the Raftery-Lewis method first constructs a 0-1 binary chain \( \{Z_t\} \), and then chooses the thinning interval \( k \) to be the smallest natural number for which a first-order Markov chain model of the thinned out chain is statistically preferred over the second-order Markov chain model. For convergence detection purposes, we are interested only in the burn-in period’s value, which provides an estimate of the number of steps needed before the MCMC reaches its stationary distribution [40]. A detailed analysis of the Raftery-Lewis method by Brooks and Roberts [50] shows that the method depends strongly on the quantile of interest \( q \) and it does not provide information about the chain as a whole [50]. Furthermore, in certain cases, the convergence rate estimated by this method is far below the convergence rate of the full chain [50]. As a general rule, they find that the routine value of \( q = 0.025 \) commonly used in the literature should not be used, as it tends to underestimate the true convergence time. Instead, they suggest that for practical purposes, the diagnostic could be applied to several different \( q \) values and then choose the quantile that estimates the largest burning length.
