Clifford algebra from quantum automata and unitary Wilson fermions

Pablo Arnault*

We introduce a spacetime discretization of the Dirac equation that has the form of a quantum automaton and that is invariant upon changing the representation of the Clifford algebra, as the Dirac equation itself. Our derivation follows Dirac’s original one: We required that the square of the discrete Dirac scheme be a discretization of the Klein-Gordon equation. Contrary to standard lattice gauge theory in discrete time, in which unitarity needs to be proven, we show that the quantum automaton delivers naturally unitary Wilson fermions for any choice of Wilson’s parameter.

Discrete-time quantum walks. A discrete-time quantum walk (DQW) is a unitary automaton with an ultralocal evolution operator. The system is called a walker, and its state at time $j \in \mathbb{N}$ is given by a sequence $\Psi_j : (j,p) \mapsto \Psi_{j,p}$ defined over a lattice with sites labeled by $p \in \mathbb{Z}$; the lattice is considered 1D for simplicity. The dynamics of this system is called a walk, written $\Psi_{j+1} = U\Psi_j$, where $U$ is the unitary one-step evolution walk operator. That $U$ is ultralocal means, by definition, that the internal state $\Psi_{j+1,p}$ solely depends on internal states $\Psi_{j,p'}$ that belong to a bounded spatial-lattice neighborhood around $p$. In the context of automata, ultralocality of $U$ is often implicit. In quantum computation it is frequent that $U$ is not ultralocal: this can be either because we purposely apply, in discrete time, a gate which is non-local [1], or because we are in continuous time and evolve a system via a nearest-neighbors Hamiltonian, which yields approximate but not exact ultralocality via Lieb-Robinson bounds [2].

To specify the nature of $\Psi_j$, it is useful to invoke Meyer’s no-go result [3, 4]: No non-trivial ultralocal unitary automaton with a one-step evolution operator that is homogeneous in space (i.e., translationally invariant) can have a scalar walker; the minimum number of internal components for the ultralocal evolution $\Psi_{j+1,p}$ is thus 2. Hence, we consider $\Psi_{j,p} \in \mathcal{H}_2$, a complex Hilbert space of dimension 2. In formal parallel with classical random walks [5], in which a coin is tossed to determine the direction taken by the walker, the internal state $\Psi_{j,p}$ is called coin state, and $\mathcal{H}_2$ is called coin space.

Multiplicative and additive constructions of DQWs. One standard way to construct DQWs, which we refer to as multiplicative, is to build the one-step evolution operator $U$ by concatenating alternately (i) shift operators, that shift $\Psi_j$ (or only one of its two internal components on the lattice) to the left or to the right, and (ii) coin operators, that are rotations of $\Psi_{j,p}$ for all $p$ [6]. There exist canonical decompositions of DQWs in sequences of coin and shift operators [7, 8]. But not all DQWs can be written under symmetric multiplicative forms, i.e., that involve solely shift operators that shift at once one internal component in one direction, and the other component in the other direction.

Another way of building DQWs, which we refer to as additive, is to superpose terms at different sites of the lattice to evolve the system from time $j$ to time $j+1$. Additive constructions make it manifest the superposition of left and right movers at the level of the two-component state sequence. In multiplicative constructions the only interesting shift operators are only those that are internal-state dependent, and so the left and right movers are single-component. That being said, one should not infer from the preceding sentence that in additive constructions the left and right movers are necessarily two-component rather than single-component, but only that such constructions initially favor the two-component aspect of the state sequence.

Single- and two-component left and right movers. It is known that DQWs can deliver the Dirac equation in the continuum limit; here we consider the $(1+1)$D Dirac equation. We call (i) Dirac DQW any DQW having as a continuum limit the Dirac equation, and (ii) Dirac continuum limit such a continuum limit. For such DQWs, the coin state coincides in the continuum with the chirality state of the Dirac particle. For the $(1+1)$D Dirac equation, left and right movers are single-component, but as soon as one discretizes space, one may consider either single-component [9, 10] or two-component left and right movers [11]; in Wilson-type lattice gauge theory (LGT) [12], the movers are two-component, while they are single-component in Kogut-Susskind-type LGT [13].

Additive constructions of DQWs have been extensively used, in the last ten years, by D’Ariano et al., following Meyer [3] and Bialynicki-Birula [14], in relation to discrete symmetries (parity and time reversal) and to Dirac continuum limits [10]. The Dirac continuum limits of (symmetric) multiplicative constructions have been explored in depth, also in the last ten years, by Debbasch et al. and then Arrighi et al., with the notable obtention of curved-spacetime schemes [15–18], and a scheme presenting a coupling of DQWs to non-Abelian Yang-Mills gauge fields [19].

Now, although D’Ariano et al.’s construction is additive, it still features single-component rather than two-component movers. This is because the DQW of D’Ariano et al. is equivalent to a simple type of so-called split-step multiplicative construction. In the present work, the scheme is additive and the movers are two-component, meaning that the multiplicative decomposition [7] of our scheme is more complicated than that of D’Ariano et al.’s additive scheme.

What the present work shows. We unveil a transport structure of generic additive constructions, related to their Dirac continuum limit. We make it possible the emergence of a Clifford algebra out of the coin operators defining the walk operator of these generic additive constructions. This is achieved by choosing appropriate coin operators, but still independent of any choice of basis; they only need to satisfy the above-

---

* pablo.arnault@cea.fr
mentioned Clifford algebra. Associatively, the invariance of ad-
unitary constructions under representation changes, i.e., under
gometric and algebraic meaning, rather than staying a mere
form invariance: Indeed, it is known that the Clifford algebra
is at the grounding of modern geometric algebra [20]. This
Clifford algebra is obtained, following Dirac’s own procedure
in continuous spacetime, by requiring that the Dirac DQW
squares a spacetime-discretized version of the Klein-Gordon
equation. We then show that DQWs also contain, naturally, a
Wilson term that makes fermion doubling be avoided, which is
well-known in LGT. Unitarity is maintained at each step
of the derivation, and this for any choice $r \in \mathbb{R}$ of Wilson’s
parameter.

Transport coin operators of a DQW. Consider the DQW
defined initially, $\Psi_{j+1} = U \Psi_j$. We give $U$ under the generic
additive form $U := W_{-1} T^{-1} + W_1 T + W_0$. In this equation,
(i) $T$ is the translation operator by one lattice site in the direc-
tion of growing $p$, and (ii) the $W_i$’s, $i = -1, 0, 1$, are operators
acting solely on the coin space, that we call jump coin opera-
tors. While one may view the $W_i$’s as $2 \times 2$ complex matrices,
viewing them abstractly is actually the purpose of the present
work, and we will not introduce any basis of $\mathcal{H}_2$. The trans-
lation operator is by construction related to the momentum
operator, $\mathcal{K}$, via $T = e^{i \omega \mathcal{K}}$, where $\omega \in \mathbb{R}$. We will be
identified further on with the spatial lattice spacing. In the Supple-
mental Material, we derive the constraints that the unitarity of $U$
implies on the $W_i$’s [3, 10].

We define the following coin operators, that we call trans-
port coin operators,

\begin{align}
B := W_1 - W_{-1} \quad &\quad (1a) \\
V := W_1 + W_{-1} \quad &\quad (1b) \\
M := \sum_{i = -1, 0, 1} W_i = V + W_0. \quad &\quad (1c)
\end{align}

In terms of these operators, $U$ reads $U = \frac{1}{2}(V - B)T^{-1} + \frac{1}{2}(V + B)T + M - V$. In the Supplemental Material, we translate
on the transport coin operators the constraints imposed on
the jump coin operators by the unitarity of $U$.

Local Hamiltonian of a DQW. From the one-step dynam-
ics $\Psi_{j+1} = U \Psi_j$, one can conceive a dynamics $i(\Psi_{j+1} - \Psi_{j-1})/2 = \mathcal{H} \Psi_j$ determined by the Hermitean operator
$\mathcal{H} := \frac{1}{2}(U - U^\dagger)$, which is (ultra)local since $U$ is ultralocal,
and that we call local Hamiltonian of the DQW. This dynam-
ics is “two-step”, meaning that while the one-step dynamics
takes as initial condition $\Psi_{j=0}$, the two-step one takes as ini-
tial condition both $\Psi_{j=0}$ and $\Psi_{j=1}$. The two-step dynamics is
equivalent to the one-step one provided that $\Psi_1 = U \Psi_0$. That
the Hamiltonian $\mathcal{H}$ is (ultra)local is in contrast with the case of
the well-known effective Hamiltonian of the DQW. Note that
both Hamiltonians are related by a proportionality constant in
Fourier space [21].

The operator $\mathcal{H}$ can be written in terms of the transport coin
operators as

\begin{equation}
\mathcal{H} = \mathcal{H}_Q := A^1(-iD_1) + \frac{r}{2}Q(-\mathcal{L}) + mA_0, \quad (2)
\end{equation}

where $m \in \mathbb{R}^+$ and $r \in \mathbb{R}$ are two parameters that we force
to appear. In Eq. (2), we have introduced (i) the following operators acting on the position space solely, $D_1 := \frac{1}{2}(T^{-1} - T) \quad \text{and} \quad \mathcal{L} := T^{-1} + T - 2$, and the following coin operators
made out of the transport coin operators, $A^1 := (B + B^\dagger)/2, \quad Q := -\frac{1}{2}(V - V^\dagger)/2$, and $A^0 := \frac{1}{m}(M - M^\dagger)/2$. We have
used the notation $\mathcal{H} = \mathcal{H}_Q$ because we are going to consider
both the case $Q = 0$ and the case $Q \neq 0$.

Dirac-continuum-limit requirement. The two-step dy-
namics can be written

\begin{equation}
(iD_0 \Psi)_j = \mathcal{H} \Psi_j, \quad (3)
\end{equation}

where $D_0 := (d_0 - d_0^\dagger)/2$, with $d_0$ and $d_0^\dagger$ a forwards and a
backwards finite difference in time, respectively. We wish
that the two-step dynamics deliver the $(1 + 1)$D Dirac equa-
tion in the continuum limit. In order to take the continuum
limit, we introduce continuous time and space coordinates $t \quad \text{and} \quad x$, as well as a function of these continuous coordi-
nates, $\Psi(\cdot, \cdot) := (t, x) \rightarrow \Psi(t, x)$, that is as smooth as wished,
and that coincides at coordinates $(t_j := j \epsilon, \quad x := p \alpha)$ with the “value” taken by the coin state at point $(j, p)$, that is,
$\Psi(j, p) := \Psi_{j,p}$. We then consider the ballistic scaling
$\epsilon = a \quad (22)$, and Taylor expand the two-step dynamics in
time and space around the point $(t_j, x_j)$, at second order in $\epsilon$.
For the continuum limit of the two-step dynamics to coincide
with the $(1 + 1)$D Dirac equation, it is sufficient that the two
following Dirac-continuum-limit constraints be satisfied,

\begin{align}
A^1 := \frac{B + B^\dagger}{2} \quad &\sim_{\epsilon \rightarrow 0} \quad a^1 \quad \text{and} \quad mA_0 := \frac{1}{2}M - M^\dagger \quad &\sim_{\epsilon \rightarrow 0} \quad c^0 \alpha^0, \quad (4a)
A^0 := (A^0)^2 = 1 \quad &\sim_{\epsilon \rightarrow 0} \quad (a^0)^2 = (a^1)^2 = 1 \quad \text{and} \quad a^0 a^1 + a^1 a^0 = 0, \quad \text{in order for them to correspond to the well-known} \ \alpha \ \text{“matrices” of the Dirac equation.}
\end{align}

Note that no constraint is imposed on $Q$ and thus neither on $V$
(apart from $V$ not scaling as $1/\epsilon^2$ with $\delta \\geq 1$, i.e., we must
have $\delta < 1$), because as $\epsilon \rightarrow 0$, we have that $L \sim \epsilon^2 D_2^2$
while $D_1 \sim \epsilon D_2$, so that the term $\epsilon Q(-L)$ in Eq. (2) vanishes
in the continuum (again, provided $\delta < 1$); we call this term
Wilson $Q$ term. The Wilson $Q$ term can be chosen non-vanishing
and the scheme still deliver the Dirac equation. This observa-
tion will be useful further on, but for now let us consider that $Q = 0$.

Klein-Gordon-square requirement and Clifford algebra
out of quantum automata. Squaring the equation $iD_0 \Psi_j = \mathcal{H}_Q \Psi_j$
delivers $D_0^2 \Psi_j = -(\mathcal{H}_Q)^2 \Psi_j$, with $(\mathcal{H}_Q)^2 = -(A^1)^2 D_2^2 + m^2 (A^0)^2 + m(A^0 A^1 + A^1 A^0)(-iD_1)$. In the
continuum limit, with the Dirac-continuum-limit constraints,
the non-crossed terms of $(\mathcal{H}_Q)^2$ deliver the desired Klein-
Gordon equation, but the crossed term does not vanish. For
the crossed term to vanish, we impose that the $A$ “matrices”
$A^0$ and $A^1$ satisfy the same algebra as the $\alpha$ “matrices” of
the Dirac equation, that is,

\begin{align}
(A^1)^2 = 1 \quad &\quad (4a) \\
(A^0)^2 = 1 \quad &\quad (4b) \\
A^0 A^1 + A^1 A^0 = 0. \quad &\quad (4c)
\end{align}

We now have to find $A$ “matrices” which satisfy (i) this
algebra, (ii) the Dirac-continuum-limit constraints, and (iii)
the unitarity constraints. While the trivial choice \( A^1 = \alpha^1 \), more concretely, \( B = \alpha^3 \), is indeed going to make us reach our purpose, so that we make this choice, the choice of \( A^0 \) is untrivial. Indeed, a standard choice for the mass term \( m A^0 \) in the literature is \( e^{-i \eta m} \alpha^0 \), which makes Constraint (4b) be satisfied, but this term together with \( A^1 = \alpha^1 \) makes Constraint (4c) unsatisfied. The term that is going to make us reach our purpose is a suggestion from both Feynman’s original scheme [23], and Succi’s additive constructions under the form of quantum lattice Boltzmann schemes [24, 25] (while \( e^{-i \eta m} \alpha^0 \) is a suggestion from multiplicative constructions): We choose \( M = \mu(\epsilon m)(1 - i \eta m) \), where \( \mu(\epsilon m) \) is a function that is imposed to us by one of the unitarity constraints (see the Supplemental Material), namely, \( M^1 M = 1 \), so that \( \mu(\epsilon m) = \frac{1}{\sqrt{1 + \epsilon m^2}} \). The algebra (4) is thus now satisfied, since \( A^0 = \mu(\epsilon m) \epsilon \alpha^0 \), and this algebra is equivalent to the following Clifford algebra, \( \{\Gamma^0, \Gamma^v\} = 2\mu^{\nu \mu} \), where \( \{\cdot, \cdot\} \) is an anticommutator, and where we have introduced the Minkowski metric \( \eta = \text{diag}(1, -1, -1) \), as well as the “matrices”, \( \Gamma^0 := A^0 := \frac{1}{m}(M - M^1)/2 \), and \( \Gamma^1 := A^0 A^1 := A^0 \alpha^1 \). One can check that the other and last unitarity constraint involving \( M \) but not \( V \), namely, \( B^1 M = M^1 B \), is satisfied. With these choices for \( B \) and \( M \), our DQW with \( Q = 0 \) is invariant under unitary transformations of the coin state, in such a way that the algebra (4) is preserved, in exact parallel with the continuum situation.

Note that the “matrix” \( A^0 \) depends on the mass, while in the continuum limit none of the \( \alpha \) “matrices” do. Note also that \( (H_{Q=0})^2 = -D^2 + \mu(\epsilon m)^2(\epsilon m)^2 \), with \( \mu(\epsilon m) \neq 1 \) if \( \epsilon m \neq 0 \) (although \( \mu(\epsilon m) \rightarrow 1 \) as \( \epsilon m \rightarrow 0 \)), which is the price to pay to obtain a unitary discretization while having nevertheless discretizing the transport term naively, by a symmetric finite difference \( D_1 \) (a naive “discretization” of the mass term yields 1 instead of \( \mu(\epsilon m) \)). Note finally that the choice made for \( B \), namely, \( B = \alpha^1 \), implies that we are not allowed to choose \( V = 0 \) (but we can still choose \( Q = 0 \) by choosing a Hermitian \( V \)), since this would break one of the unitarity constraints, namely, \( V^1 V = B^1 B \).

Towards avoiding fermion doubling with the Wilson Q term. Consider the two-step Hamiltonian of Eq. (2) for a non-vanishing Wilson Q term: it is convenient in order to further take a continuum limit to rather consider the Hamiltonian density \( h := H/\epsilon \). The reason we have called the Wilson Q term that way is because its spatial-operator part, \(-\mathcal{L}\), is that of the well-known Wilson term of LGT, namely, \((r/2a)\alpha_0(-\mathcal{L})[26]\), i.e., the same as ours but with \( \alpha_0 \) instead of \( Q \). In LGT, this term enables to avoid the so-called fermion doubling problem, which appears when discretizing naively the Dirac equation; these facts are recalled in the Supplemental Material. It is remarkable that such a Wilson term is naturally contained in the decomposition of a generic DQW. The question is now: What \( Q \) can we take in order for the fermion doubling to be avoided, while satisfying the unitarity constraints?

Klein-Gordon-square requirement with the Wilson Q term. We have \( h^2 = -\frac{D^2}{\epsilon} + \mu(\epsilon m)^2 m^2 + \frac{1}{\epsilon^2} Q^2 L^2 + \frac{m^2}{\epsilon^2} [Q A^0 + A^0 Q] \mathcal{L} + \frac{r}{\epsilon^2} [Q A^1 + A^1 Q] (-\mathcal{L})(-iD_1) \). Notice that the three last terms vanish in the continuum limit, so that we recover the KG equation. The validity of the discrete Klein-Gordon scheme, which we define as the possibility of applying the scheme to scalar state sequences (as it is the case in the continuum setting), can be obtained if we require, in addition to the previous Clifford-algebra requirement, that as \( \epsilon \rightarrow 0 \), (i) \( Q^2 \sim 1 \), and (ii) each of the two commutators either vanishes or is proportional to the identity; these requirements suggest to use for the choice of \( V \) the same trick as that used for the choice of \( M \).

Hence, we choose \( V = \nu(r)((1 - i\nu)^3) \), where \( \alpha \) is an “alpha” matrix satisfying the usual algebra of the “alpha” matrices” of the Dirac equation, and where \( V(r) \) is a function that is imposed to us by the unitarity constraint \( V^1 V = B^1 B \) (see the Supplemental Material), which yields \( \nu(r) = \mu(r) := \frac{1}{\sqrt{1 + \nu^2}} \). Thus we have that \( Q = \mu(\epsilon m) \alpha \). The second unitarity constraint in which \( V \) is involved is \( B^1 V = V^1 B \), and for it to be satisfied we need \( \lambda \neq 1 \), which we assume, so that the commutator \( Q A^1 + A^1 Q \) vanishes. Now, the last unitarity constraint in which \( V \) is involved is \( 2V^1 V = V^1 M + M^1 V \). A choice that is compatible with this constraint is \( \lambda = 0 \), and we make this choice, so that we finally have

\[
h = \alpha^1 \left( \frac{-iD_1}{\epsilon} \right) + \left[ \mu(\epsilon m)m + \mu(r) \frac{r}{2\epsilon} (-\mathcal{L}) \right] \alpha^0.
\]  (5)

Avoiding fermion doubling. To find solutions of our two-step scheme, Eq. (3), we consider a superposition-of-plane-waves ansatz (since the solution of the Dirac equation, that we seek to simulate, has this form): \( \Psi(t, x) = \frac{1}{2\pi} \sum_{\omega} \int_{-\infty}^{+\infty} dk \, \Psi_{\omega}(0, k) e^{-i(\omega \epsilon(k)t - kx)} \), where \( t, x \) = \( (t_j, x_p) \). Inserting the plane-wave ansatz into Eq. (3) with \( h = H/\epsilon \) given by Eq. (5), leads, after squaring, to the following dispersion relation \( \sin^2(\omega \epsilon(k)x) = \sin^2(\omega \epsilon(k)t) + \left[ \frac{\mu(\epsilon m)m + \mu(r)}{2\epsilon} (1 - \cos(\omega \epsilon(k)t)) \right]^2 \). The Wilson Q term, which is \( \mu(r) (1 - \cos(\omega \epsilon(k)t)) \), is the same as the standard LGT one [11] except for the factor \( \mu(r) \) which is 1 in LGT.

Now, discrete-time LGT is usually formulated in a Lagrangian way [11, 27], whereas we formulated our discrete-time scheme in a Hamiltonian one. In Lagrangian LGT, a term is naturally added to the action to remove the temporal doublers along with the term added to remove the spatial doublers. Here, this is not the case, and we only treat spatial doublers. Considering a low-frequency limit, \( \omega \epsilon(k) \ll 1 \), of the dispersion relation, finally leads to the solutions \( \omega_{\text{DQW}}(k) = \pm \sqrt{\frac{\sin^2(\omega \epsilon(k)x)}{1 + \left[ \frac{\mu(\epsilon m)m + \mu(r)}{2\epsilon} (1 - \cos(\omega \epsilon(k)t)) \right]^2}} \). The expression obtained in LGT is the same but replacing both \( \mu(\epsilon m) \) and \( \mu(r) \) by 1.

In the left panel of Fig. 1, we plot the gapless frequencies \( f_M(k) := \sqrt{\omega_{\text{DQW}}(k)^2 - M^2} \), where “M” is the considered model, and takes the “values” \( M = \text{Dirac, naive, LGT, DQW, and } M^2 \) is the central \( (k = 0) \) gap of the model, which is \( m \) for \( M = \text{Dirac, naive, LGT, but } \mu(\epsilon m)m \) for \( M = \text{DQW} \). We see that the naive discretization of the Dirac equation leads to two extra poles in the gapless frequency (yellow plot), which
causes the fermion doubling problem (see the Supplemental Material), while the LGT (green plot) and DQW (red plot) models avoid it by creating gaps at the edges. In-built unitarity for any \( r \in \mathbb{R} \) is an important advantage of our model with respect to LGT.

Take a closer look at the low-momentum \( k \) and small-mass \( m \) limit. We set the lattice spacing to a fixed value \( \epsilon \), and expand \( (\omega_{DQW}^\pm(k))^2 \) given above, in both \( k \) and \( m \), truncating at third order in \( k \) and \( m \) (e.g., \( mk^2 \) is third order); this yields \( (\omega_{DQW}^\pm(k))^2 = (1 + \epsilon \mu(r)m)r^2 + \epsilon \mu(em)m^2 \). The central (\( k = 0 \)) slope, 1, is modified by an added term \( \epsilon \mu(r)m \) as we can see on the middle panel of Fig. 1; this term is smaller in the DQW model than in the LGT one, since \( \mu(r) \leq 1 \), so this is an advantage of the DQW model. Regarding the central gap, the modification in the DQW coming from \( \mu(em) \approx (1 - \frac{1}{2} \epsilon^2 m^2) \) is next order.

The limit \( r \to +\infty \) yields the LGT Wilson term for \( r = 1 \). In the DQW model, the higher \( r \) is, the bigger is the error in the central slope (although it converges to a fixed value, that of LGT), but the wider is the range in \( k \) over which the approximation is good, see the right panel of Fig. 1. Let us conclude by the following remark: If we choose \( \alpha^\lambda = \alpha^2 \), which is compatible with the validity requirement of our discrete Klein-Gordon scheme, we have to give up unitarity, but we can “in exchange” remove the crossed term of the square \( (\mu(em)m + \mu(r)\frac{1}{2}(1 - \cos(kc))^2) \), which results in a central slope which is the same as that of the continuum, i.e., \( \pm 1 \).

**Conclusion.** We showed that a Clifford algebra emerges out of the internal-state operators defining a quantum-automaton discretization of the Dirac equation. This discretization, which is a DQW, is unitary by construction, while discrete-time versions of lattice gauge theory are usually Lagrangian so that unitarity is not in-built. Our DQW is invariant under representation changes of the above-mentioned Clifford algebra, which parallels exactly the continuum situation. Moreover, we show that DQWs naturally contain a Wilson term that makes spatial fermion doubling be avoided, and this without breaking unitarity and for any choice \( r \in \mathbb{R} \) of Wilson’s parameter.

**Acknowledgements.** The author thanks Christopher Cedzich for making him notice that the two-step Hamiltonian is (ultra)local, while the effective Hamiltonian, as a logarithm of the one-step evolution operator, is not (infinite series of growing powers of the one-step evolution operator). This is an interesting feature which is in the prolongation of the ultralocality of the one-step evolution operator that is sought in the development of quantum cellular automata and their one-particle versions, DQWs. The author also thanks Alexei Grinbaum for his stylistic and grammatical energetic advice and corrections.

Supplemental Material

In the first section, we translate, on the transport coin operators $B$, $V$ and $M$, the unitarity constraints imposed on the jump coin operators $W_i$, $i = -1, 0, 1$, by the unitarity of the one-step evolution operator $U$. In the second section, we explain the fermion-doubling problem of lattice gauge theory, and present Wilson’s method to solve it, with so-called Wilson fermions.

I. UNITARITY CONSTRAINTS

We impose the unitarity of $U$, that is, $U^\dagger U = 1$. A couple of computation lines lead to the following conditions on the jump coin operators $W_i$, $i = -1, 0, 1$, that we call unitarity constraints on the jump coin operators:

$$W_{-1}^\dagger W_{-1} + W_1^\dagger W_1 + W_0^\dagger W_0 = 1$$  \hspace{1cm} (6a)

$$W_{-1}^\dagger W_0 + W_0^\dagger W_1 = 0$$ \hspace{1cm} (6b)

$$W_{-1}^\dagger W_1 = 0.$$ \hspace{1cm} (6c)

Let us translate these constrains on the transport coin operators $B$, $V$ and $M$. We start by Constraint (6c), which is the simplest to translate in the sense that it does not involve $M$ while both Constraints (6a) and (6b) do. Constraint (6c) yields

$$0 = (V^\dagger - B^\dagger)(V + B)$$ \hspace{1cm} (7a)

$$= V^\dagger V - B^\dagger B - B^\dagger V + V^\dagger B.$$ \hspace{1cm} (7b)

Computing the sum and the difference, $(7b)^\dagger + (7b)$ and $(7b)^\dagger - (7b)$, yields, respectively,

$$V^\dagger V = B^\dagger B$$ \hspace{1cm} (8a)

$$B^\dagger V = V^\dagger B.$$ \hspace{1cm} (8b)

Conversely, it is trivial to check that these two constraints imply Constraint (6c).

We now proceed with translating Constraint (6b), because we will use one of the two resulting constraints to translate Constraint (6a). Constraint (6b) yields

$$0 = (V^\dagger - B^\dagger)(M - V) + (M^\dagger - V^\dagger)(V + B)$$ \hspace{1cm} (9a)

$$= V^\dagger M - B^\dagger M - V^\dagger V + B^\dagger V + M^\dagger V - V^\dagger V + M^\dagger B - V^\dagger B.$$ \hspace{1cm} (9b)

Computing the sum and the difference $(9b)^\dagger + (9b)$ and $(9b)^\dagger - (9b)$ yields, respectively,

$$2V^\dagger V = V^\dagger M + M^\dagger V$$ \hspace{1cm} (10a)

$$B^\dagger M = M^\dagger B.$$ \hspace{1cm} (10b)
Conversely, it is trivial to check that these two constraints imply Constraint (6b).

We finally proceed with translating Constraint (6a), which can be written

\[ 4 = (V^\dagger - B^\dagger)(V - B) + (V^\dagger + B^\dagger)(V + B) + 4W_0^\dagger W_0 \]  

\[ = V^\dagger V + B^\dagger B - B^\dagger V - V^\dagger B + V^\dagger V + B^\dagger B + V^\dagger B + V^\dagger B + 4W_0^\dagger W_0 . \]  

Inserting both Constraint (8a) and Constraint (8b) in the preceding one, Constraint (11b), delivers

\[ 1 = V^\dagger V + W_0^\dagger W_0 \]  

\[ = V^\dagger V + (M^\dagger - V^\dagger)(M - V) \]  

\[ = 2V^\dagger V + M^\dagger M - M^\dagger V - V^\dagger M . \]  

Finally, inserting Constraint (10a) into the preceding one, Constraint (12c), results in

\[ M^\dagger M = 1 . \]  

II. FERMION DOUBLING AND WILSON FERMIONS IN CONTINUOUS AND DISCRETE TIME

A. The Schrödinger equation for translationally invariant systems

1. The generic Schrödinger equation and its spectral solution

The generic Schrödinger equation is a partial differential equation (PDE) of the form

\[ i\partial_0 \Psi |t = h \Psi (t) , \]  

where \( h \) is a Hermitean linear operator acting on the function \( \Psi (t) : x \mapsto \Psi (t, x) \), where here we choose \( x \in \mathbb{R} \). Since this equation is linear, we solve it spectrally, i.e., by finding the eigen-elements \( (\omega_\sigma, \Phi_\sigma)_{\sigma \in \Sigma} \) of \( h \), where \( \Sigma \) is a certain indexing space; By definition, these eigen-elements satisfy

\[ h \Phi_\sigma = \omega_\sigma \Phi_\sigma , \]  

where the eigen-values \( \omega_\sigma \) are real since \( h \) is Hermitean.

The method is the following. Assume we have determined the eigen-elements of \( h \). Since \( \Psi (t) \) belongs to a Hilbert space, we can decompose it on the eigen-basis \( (\Phi_\sigma)_{\sigma \in \Sigma} \) at an arbitrary time \( t \):

\[ \Psi (t) = \sum_{\sigma \in \Sigma} C_\sigma (t) \Phi_\sigma , \]  

where the \( C_\sigma(t) \)s are the coefficients of \( \Psi(t) \) on the eigen-basis. Now, using Eq. (15), the generic Schrödinger equation on \( \Psi \), Eq. (14), which is a PDE, can be translated into a family of ordinary differential equations (ODEs) – indexed by \( \sigma \) – for the coefficients \( C_\sigma \), that is,

\[ i\partial_0 C_\sigma |t = \omega_\sigma C_\sigma (t) , \]  

whose solution is well-known:

\[ C_\sigma (t) = C_\sigma (0) e^{-i\omega_\sigma t} . \]  

Hence, the solution seeked is

\[ \Psi (t) = \sum_{\sigma \in \Sigma} C_\sigma (0) e^{-i\omega_\sigma t} \Phi_\sigma . \]  

Because they intervene in the periodic functions \( t \mapsto e^{-i\omega_\sigma t} \), the \( \omega_\sigma \) are called frequencies; More precisely, they are the eigen-frequencies of \( h \). To be more definite, one should actually use the denomination “angular frequency” rather than “frequency”.
2. Fourier analysis

We will use the more definite notation $\Psi(t, \cdot)$ for $\Psi(t)$ when needed. Let us take the Fourier transform of $\Psi(t, \cdot)$ at a given time $t$:

$$\tilde{\Psi}(t, k) := \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} dx \Psi(t, x) e^{-ikx}. \quad (20)$$

Inverting this equation, we obtain the decomposition of $\Psi(t)$ into its Fourier components:

$$\Psi(t, x) = \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} dk \tilde{\Psi}(t, k) e^{ikx}. \quad (21)$$

To be precise, the function $x \mapsto \tilde{\Psi}(t, k) e^{ikx}$ is the Fourier component of $\Psi(t, \cdot)$ associated to the value $k$ of the Fourier variable, and $\tilde{\Psi}(t, k)$ is the Fourier coefficient, or Fourier amplitude of $\Psi(t, \cdot)$ associated to the value $k$. Because $x$ is a spatial position, the Fourier variable $k$ is a spatial frequency; Again, as in the case of $\omega_\sigma$ above, to be more definite one should use the denomination “angular pulsation” rather than “frequency”.

3. Case of translationally invariant systems

If $h$ does not depend on the point $x$, i.e., if $h$ is translationally invariant, then one can check by considering Eq. (14) for Expression (21) that each Fourier coefficient satisfies the equation

$$i\partial_t \tilde{\Psi}(\cdot, k) = \tilde{h}(k) \tilde{\Psi}(t, k), \quad (22)$$

where $\tilde{h}(k)$ is the expression obtained when replacing, in $h$, the operator $-i\partial_t$ by the real number $k$.

Hence, if $h$ does not depend on the point $x$, each Fourier coefficient evolves independently of the others, while this is not the case if $h$ does depend on $x$. Moreover, the “Schrödinger equation in Fourier space”, Eq. (22), is simpler to solve than the original Schrödinger equation, (14), because the operator $-i\partial_t$ has been replaced by a real number $k$, so that Eq. (22) is not a PDE as the original Schrödinger equation, but a family of ODEs indexed by $k$. Let us now make the link with Sec. II A: One can actually mathematically show (via, e.g., “mere” constructive proofs) for a large class of operators $h$, that there exist an indexing space $\Sigma$ such that $k$ is one of the indices, i.e., $k \in \sigma$ $^1$. In the language of quantum mechanics, and index $i \in \sigma$ is referred to as a good quantum number: It is an eigenvalue of an operator whose diagonalization serves as a partial diagonalization of $h$, i.e., $h$ is codiagonalizable with that operator.

We often speak of Fourier modes for the Fourier components; The term “mode” refers, in its most general acception, to one of the terms of a particularly relevant decomposition of an object, take, e.g., the Fourier decomposition of a function. In the case of an $x$-independent $h$, the Fourier modes are actually proper modes, because by considering the Fourier version $h(k)$ of $h$ we have (at least partially) “diagonalized” $h$ (which is summed up by writing $k \in \sigma$).

B. The solution of the Schrödinger equation for translationally invariant systems: A superposition of plane waves

1. No internal structure for $\Psi(t, x)$

a. Final solution. If $\Psi(t, x)$ has no internal structure, i.e., if $\Psi(t, x) \in \mathbb{C}$, then we simply have that $k = \sigma$, and the eigenvalues are $\omega_\sigma = \omega(k) := \tilde{h}(k) \in \mathbb{R}$; The sum over $\sigma$ in Eq. (19) is an integral over $k$, and the eigen-basis is the following family of functions of $x$, $(\Phi(\cdot, k))_{k \in \mathbb{R}}$, with

$$\Phi(x, k) := \frac{e^{ikx}}{\sqrt{2\pi}}, \quad (23)$$

so that the solution given in Eq. (19) here reads

$$\Psi(t, x) = \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} dk \Phi(0, k) e^{-i(\omega(k)t - kx)}. \quad (24)$$

$^1$ We take the liberty to consider $\sigma$ as convenient; Here, it is a set of indices, i.e., an unordered family; In practice, we will often order its elements, i.e., we will consider a list rather than a set.
By taking \( t = 0 \) in this equation we realize by identification (they are unique) that the \( C(0, k) \) are the Fourier coefficients of \( x \mapsto \Psi(0, x) \), i.e.,

\[
C(0, k) \equiv \tilde{\Psi}(0, k) .
\] (25)

The value \( \omega(k) \) is the eigen-frequency associated to the spatial frequency \( k \). Now, an important remark is that \( \Psi(t, \cdot) \) is actually a superposition of plane waves, with weights the Fourier coefficients of the initial condition. Because of this (plane-)wave structure, the spatial frequency \( k \) is called wavevector\(^2\). The fact that the frequency of the wave \( \omega(k) \) depends on the wavevector \( k \) is called dispersion, and the expression \( \omega(k) \) is called the dispersion relation. Notice that the fact that we have a dispersion phenomenon while we are in vacuum is specific to quantum mechanics, more precisely, to the quantum mechanics of massive bodies.

In quantum mechanics, the use of the word “wavevector” is actually extended to non translationally invariant systems, because this wavevector is, due to the wave-particle duality, in one-to-one correspondence with the momentum of the free particle associated to the wave in question, solution of a free (i.e., with \( x \)-independent \( \hbar \)) Schrödinger equation. More precisely, \( k \) is the De Broglie wavevector of a particle of momentum \( p = k \) (with \( \hbar = 1 \)). There is also an analog relation for the eigen-frequencies, referred to as Einstein’s relation: The frequency \( \omega_\sigma \) is the frequency associated to an energy \( E_\sigma = \omega_\sigma \) (with \( \hbar = 1 \)) for the particle in question.

b. Final solution rederived by focusing on the linear algebraic structure. It is the opportunity to rederive the above solution, Eq. (24), by focusing on the linear algebraic structure of the computations. This will make gentler the above replacement of \( \sigma \) by \( k \). We first rewrite Eq. (19) with a braket notation, which emphasizes the linear algebraic structure,

\[
|\Psi(t)\rangle = \sum_{\sigma \in \Sigma} \langle \Phi_\sigma | \Psi(0)\rangle e^{-i\omega_{\sigma} t} |\Phi_\sigma \rangle .
\] (26)

By taking \( t = 0 \) in this equation, we see that we have simply applied the closure relation \( \sum_{\sigma \in \Sigma} \langle \Phi_\sigma | \Psi(0)\rangle = |\Psi(0)\rangle \), and then evolved the eigen-states up to time \( t \). We then consider the present case \( \sigma = k \), so that \( \Phi_\sigma = \Phi(\cdot, k) \), which means that the eigen-basis is the basis made up of the \( |k\rangle := |\Phi(\cdot, k)\rangle \) with \( k \in \mathbb{R} \),

\[
|\Psi(t)\rangle = \int_{\mathbb{R}} dk \langle k |\Psi(0)\rangle e^{-i\omega_{k} t} |k\rangle .
\] (27)

We then apply the bra \( \langle x| \) to have the value at point \( x \),

\[
\langle x|\Psi(t)\rangle = \int_{\mathbb{R}} dk \tilde{\Psi}(0, k)e^{-i\omega_{k} t} \langle x|\Phi(\cdot, k)\rangle ,
\] (28)

that is, using Eq. (23), exactly Eq. (24),

\[
\Psi(t, x) = \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} dk \tilde{\Psi}(0, k)e^{-i(\omega(k)t-kx)} .
\] (29)

2. Internal structure for \( \Psi(t, x) \)

Now, if \( \Psi(t, x) \) has an internal structure, then \( k \not\subset \sigma \)\(^3\), and \( \hat{h}(k) \) can be seen as a matrix indexed by \( k \), that one has to diagonalize to finally find the eigen-values of \( h \). The eigen-values of \( \hat{h}(k) \) can be denoted \( \omega_\sigma = \omega_i(k) \), where \( i = 1, \ldots, d \), with \( d \) the dimension of the matrix \( \hat{h}(k) \) (some eigen-values may be equal, e.g., \( \omega_1(k) = \omega_{i_k}(k) \)). The final solution is then

\[
\Psi(t, x) = \sum_{i=1}^{d} \frac{1}{\sqrt{2\pi N}} \int_{\mathbb{R}} dk \tilde{\Psi}_i(0, k)e^{-i(\omega_i(k)t-kx)} ,
\] (30)

where \( N \) is a normalization factor, needed if we want the eigenvectors \( \tilde{\Psi}_i(0, \cdot) \) of \( \hat{h}(k) \) to be normalized. We see that the solution is still a superposition of plane waves, and there are \( d \) dispersion relations \( \omega_i(k), i = 1, \ldots, d \).

\(^2\) The question that one may ask oneself is whether there exist a “physical” phenomenology.

\(^3\) We have identified \( k \) with the singlet \( \{k\} \).

C. Dirac fermions (continuous spacetime)

The Dirac Hamiltonian in 1 + 1 dimensions is

$$\hat{h}_{\text{Dirac}} := \alpha^1 \hat{k} + m\alpha^0,$$

(31)

where $\hat{k}$ is the momentum operator, i.e., the abstract version of the operator $-i\partial_1$, and the alpha matrices satisfy $(\alpha^0)^2 = (\alpha^1)^2 = 1$ and $\alpha^0\alpha^1 + \alpha^1\alpha^0 = 0$. We see that $\hat{h}_{\text{Dirac}}$ is Hermitian, and so it is a valid Hamiltonian for the generic Schrödinger equation considered in Sec. II A and II B above. Moreover it is translationally invariant.

We consider the “Hamiltonian in momentum space”,

$$\tilde{h}_{\text{Dirac}}(k) := \alpha^1 k + m\alpha^0$$

(32)

The eigen-value equation with unknowns the eigen-elements $(\omega_i(k), V_i(k))_{i=1,\ldots,d; k \in \mathbb{R}}$ of $\tilde{h}_{\text{Dirac}}(k)$ is, in matrix notation,

$$\tilde{h}_{\text{Dirac}}(k)V_i(k) = \omega_i(k)V_i(k).$$

(33)

Now, to find the eigen-values of $\tilde{h}_{\text{Dirac}}(k)$, there is actually a “trick”, related to the fact that the square of the Dirac equation is, by (historical) construction of the Dirac equation, the Klein-Gordon equation, and hence applicable to scalar state functions: The square $(\tilde{h}_{\text{Dirac}}(k))^2$ is proportional to the identity matrix. By squaring Eq. (33), we arrive to

$$\omega(k)^2 = k^2 + m^2,$$

(34)

so that the eigen-values are

$$\omega_{\pm}(k) := \pm \sqrt{k^2 + m^2}.$$

(35)

D. The doubling problem when discretizing space but keeping time continuous: Spatial doublers

To discretize space, we can simply perform the naive replacement of the partial derivative $\partial_1$ by a finite difference on a 1D lattice that we introduce, with sites labeled by $p \in \mathbb{Z}$ and lattice spacing $a$. The finite difference has to be symmetric if we want the resulting Hamiltonian to be Hermitian. Since the translation operator in the direction of growing ps is, in abstract space, $\hat{T} = e^{-iKA}$, the substitution of $\partial_1 = iK$, where $K := -i\partial_x$, by the announced symmetric finite difference,

$$D_1 := \frac{1}{2}(T^{-1} - T),$$

(36)

corresponds to the following substitution in the “Dirac Hamiltonian in momentum space” $\hat{h}_{\text{Dirac}}$, as well as in the dispersion relation, Eq. (35):

$$k \rightarrow (-1)^{p} \frac{e^{ika} - e^{-ika}}{2a} = \frac{\sin(ka)}{a}. $$

(37)

To explain the doubling problem, it is customary to consider the following function of $k$,

$$f_{\text{naive}}(k) := \sqrt{\left(\omega_{\pm}(k)\right)^2 - m^2} \equiv \left|\frac{\sin(ka)}{a}\right|, $$

(38)

to be compared with

$$f_{\text{Dirac}}(k) := \sqrt{\left(\omega_{\pm}(k)\right)^2 - m^2} \equiv |k|.$$

(39)

Notice first that the spatial discretization implies that now $k \in [-\pi/a, \pi/a)$. Second, notice that we of course recover the continuum situation for $ka \ll 1$, because $\sin(ka) = ka + O((ka)^3)$. We call the function $f^M(k)$ the gapless frequency of Model M.

---

4 Pay attention to the fact that, although we use the notation $\hat{k}$, on the lattice $k$ and the position operator $\hat{x}$ do not satisfy the canonical commutation relations.
for the momentum as in the continuum situation, \( f \) the form

\[
\phi_0 = \sqrt{\omega_0^2 - m^2}
\]

Figure 2. This figure illustrates the fermion doubling problem in discrete space but continuous time. The lattice dispersion relation under the form \( f_{\text{naive}}(k) \) (in gold color) has 3 poles, \(-\pi/a, 0, \pi/a\), instead of a single one, 0, for the continuum dispersion relation (in blue color), so that for each target value \( \phi_0 \) of the gapless frequency, we have two extra momentum solutions on the lattice with respect to the continuum situation.

In Fig. 2, we plot both \( f^{\text{Drae}}(k) \) and \( f^{\text{naive}}(k) \) over the Brillouin zone \([-\pi/a, \pi/a]\). The doubling problem is the following. For a given target value \( \phi_0 := \sqrt{\omega_0^2 + m^2} \) of the gapless frequency, there are, in the naive discretization, not 2 possibilities for the momentum as in the continuum situation, \( k_0 \) and \(-k_0\) such that \( f^{\text{Drae}}(k_0) = \omega_0 \), i.e., \( k_0 = \omega_0 \), but 4 solutions, 2 corresponding to the low-momentum modes that we seek to simulate with the discretization, which have \( k_0' \approx k_0 \) and \(-k_0'\) such that \( f^{\text{naive}}(k_0') = \phi_0 \), and 2 additional, high-momentum modes, namely, \( \pi/a - k_0' \) and \(-\pi/a + k_0'\), so that frequencies and momenta are not in one-to-one correspondence anymore. In a non-interacting model, i.e., if \( \hbar \) does not depend on \( x \), this is actually not a problem because the Fourier modes are independent from each other, and so the one-to-one correspondence between frequency and momentum can be tracked, e.g., fundamentally, as time evolves; More precisely and concretely: In a non-interacting model, the momentum distribution is unchanged by the dynamics, i.e., in other words, the states of fixed momentum are stationary states. In an interacting model, the Fourier modes will not evolve independently from each other, and the interaction term will cause the production of high-momentum modes from low-momentum ones – because of the 2 extra poles of \( f^{\text{naive}}(k) \) with respect to \( f^{\text{Drae}}(k) \) – which can be proved rigorously in, e.g., perturbative studies of interacting models having as zeroth order \( f^{\text{naive}}(k) \) [277].

As a conclusion: In discrete space (but keeping time continuous), we will have extra, spurious modes when looking for superpositions of plane waves as Eq. (30) for the solutions. These spurious modes are called spatial doublers, where the specification spatial is due to the fact that what is spurious in these modes is the spatial part (high momenta, not compatible with a continuum description, even if the temporal part is – i.e., low frequencies).

E. The doubling problem in discrete spacetime: Temporal doublers in addition to the spatial doublers

We start from the discrete-space but continuous-time situation described just above in Sec. II F, that is

\[
i \partial_0 \Psi(\cdot, x)|_t = \hbar^{\text{naive}} \Psi(t, \cdot)|_{x}.
\]  

As we did for space in Sec. II F, we discretize time naively, with a symmetric finite difference, in order to treat time on the same footing as space (for which we have indeed used a symmetric finite difference), which yields (replacing \( \hbar^{\text{naive}} \) by its expression):

\[
\frac{i}{2\epsilon}(\Psi(t + \epsilon) - \Psi(t - \epsilon)) = \left[ \frac{1}{2\epsilon} (e^{iK_a} - e^{-iK_a}) \alpha^1 + m \alpha^0 \right] \Psi(t, \cdot)|_{x}.
\]  

Notice right away that this scheme takes two initial conditions, exactly as the two-step scheme we present in our paper; The only difference with the two-step scheme we present is that in the latter there is a factor \( \mu(\epsilon) \) in front of \( m\alpha^0 \), but this is enough to
make that scheme unitary, while the present, naive one, is not. We consider an ansatz which is a superposition of plane waves with internal components, that is, we look for solutions of the form of Eq. (30). If we insert Eq. (30) into Eq. (41), we obtain after a few computation lines the following equation in momentum space:

\[ \frac{\sin(\omega_i(k)e)}{\epsilon} \Psi_i(0, k) = \left[ \frac{\sin(\omega_i(k)a)}{a} \alpha + m \alpha^0 \right] \Psi_i(0, k), \] (42)

an equation which, squared, and choosing the ballistic scaling \( \epsilon = a \), finally yields the following dispersion relation,

\[ \sin^2(\omega_i(k)e) = \sin^2(ke) + \epsilon^2 m^2. \] (43)

First of all, notice that for low frequencies \( \omega_i(k)e \ll 1 \) in Eq. (43), we recover the discrete-space but continuous-time situation, with gapless frequency given by Eq. (38) in the preceding section, Sec. II F. Now, there are solutions \( \omega_i(k) \) to Eq. (43) if and only if \( |\sin^2(ke) + \epsilon^2 m^2| \leq 1 \), which leads to

\[ \epsilon^2 m^2 \leq \cos^2(ke). \] (44)

Replacing in the dispersion relation, Eq. (43), \( \sin^2(A) \) by \( (1 - \cos(2A))/2 \), we obtain the following solutions,

\[ \omega_{\text{temporal}}(k) := \pm \frac{2}{\epsilon} \arccos \left( 1 - 2 \sin^2(ke) - 2 \epsilon^2 m^2 \right). \] (45)

For small enough \( k \) and \( m \), i.e., \( ke \ll 1 \) and \( \epsilon m \ll 1 \), we have that \( |\omega_{\text{temporal}}(k)e| < \pi/2 \), and actually that \( |\omega_{\text{temporal}}(k)e| < \pi/2 \), and these two solutions approach the low frequencies \( \omega_{\text{Dirac}}(k) \) of the continuum model.

Now, in addition to these two solutions, Eq. (45), we also have the solutions,

\[ \Omega_{\text{temporal}}(k) := \pm \left[ \frac{\pi}{\epsilon} - \omega_{\text{temporal}}(k) \right], \] (46)

which are high-frequency solutions when \( |\omega_{\text{temporal}}(k)e| < \pi/2 \). These two extra solutions are spurious because not compatible with a continuum description, but they will intervene in the dynamics in interacting models, and the modes associated to these solutions are called temporal doublers. As we have seen, these temporal doublers arise even for low momenta (the only ones compatible with a continuum description), and this is best seen as follows. Consider low momenta in Eq. (43); This yields, replacing \( k \) by the notation \( \kappa(w) \) and \( \omega_i(k) \) by the variable \( w \),

\[ g_{\text{naive}}(w) := \sqrt{\kappa(w)^2 + m^2} = \left| \frac{\sin^2(we)}{\epsilon} \right|, \] (47)

an expression which, apart from the fact that there is a \( + m^2 \) instead of a \( - m^2 \), corresponds exactly to the expression of the gapless frequency, Eq. (38), but having exchanged in it the roles of \( \omega(k) \) and \( k \), i.e., replaced the latter by \( \kappa(w) \) and \( w \), respectively, so that one can derive the same explanations for the temporal doublers than for the spatial doublers. Notice that, in this low-momentum context, the condition (44) for a solution \( \omega_i(k) \) to exist is

\[ \epsilon^2 m^2 \leq 1 - \frac{1}{2}(ke)^2. \] (48)

F. Removing the doublers with Wilson fermions

1. We limit ourselves to spatial doublers

In the preceding section, Sec. II F, we have illustrated the problem of temporal doublers starting from a continuous-time description. A framework which is more appropriate to further remove temporal doublers is that of Lagrangian LGT, which starts from a Lagrangian continuum description rather than a Hamiltonian one. This leads to a modification of the action rather than the Hamiltonian to solve the problem of fermion doubling, with a Wilson term, and this procedure removes the spatial doublers, as well as the the temporal ones for Wilson’s choice \( r = 1 \) [11]. Here, however, we will stick to a Hamiltonian formulation and treat only spatial doublers. This is because in our paper the scheme is formulated in a Hamiltonian way. To treat temporal doublers in the two-step scheme of our paper one would have to modify the original, DQW scheme.

\[ g_{\text{naive}}(w) := \sqrt{\kappa(w)^2 + m^2} = \left| \frac{\sin^2(we)}{\epsilon} \right|, \]

an expression which, apart from the fact that there is a \( + m^2 \) instead of a \( - m^2 \), corresponds exactly to the expression of the gapless frequency, Eq. (38), but having exchanged in it the roles of \( \omega(k) \) and \( k \), i.e., replaced the latter by \( \kappa(w) \) and \( w \), respectively, so that one can derive the same explanations for the temporal doublers than for the spatial doublers. Notice that, in this low-momentum context, the condition (44) for a solution \( \omega_i(k) \) to exist is

\[ \epsilon^2 m^2 \leq 1 - \frac{1}{2}(ke)^2. \] (48)
Figure 3. Gapless frequency $f^{M}(k)$ of Model “M” (left panel) and absolute difference $f^{M}(k) - f^{\text{Dirac}}(k)$ (right panel), for “M” = “Dirac” (blue), “naive” (gold), “LGT” (green), and “LGT non-crossed” (red), where $f^{\text{Dirac}}(k) = |k|$, $f^{\text{naive}}(k) = \frac{|\sin(ka)|}{a}$, $f^{\text{LGT}}(k) = \sqrt{\sin^2(ka) a^2 + \left[m + \frac{r}{a} (1 - \cos(ka))\right]^2 - m^2}$, and $f^{\text{LGT non-crossed}}(k) = \sqrt{\sin^2(ka) a^2 + \frac{r^2}{a^2} (1 - \cos(ka))^2}$, for $a = 1$, $m = 0.1$, and $r = 1$ (Wilson’s choice).

Figure 4. In blue, $(f^{\text{Dirac}}(k))^2$, in gold, $(f^{\text{naive}}(k))^2$, in green, the non-crossed term $g^{\text{non-crossed}}(k)$, and in red, the crossed term $g^{\text{crossed}}(k)$. We see that the biggest contribution to the fixing of the fermion doubling comes from the non-crossed term (with respect to the crossed term).

2. Treatment of spatial doublers in the naive continuous-time scheme, via Wilson fermions

In order to treat the problem of spatial doublers in continuous-time, described in Sec. II F, we consider the following Hamiltonian [26],

$$h^{\text{LGT}} := h^{\text{naive}} + h^{\text{Schr.}},$$

where

$$h^{\text{naive}} := \alpha^1 \left( -i \frac{\partial_1}{a} \right) + m\alpha^0,$$

is the naive-discretization Hamiltonian considered in Sec. II F, and

$$h^{\text{Schr.}} := \alpha^0 \frac{\tau}{a} (-\mathcal{L}),$$

is the Wilson term, whose spatial operator, $\mathcal{L}/a$, is a discrete Laplacian$^6$,

$$\mathcal{L} = \mathcal{T}^{-1} + \mathcal{T} - 2.$$

$^6$ This discrete Laplacian has been obtained by replacing $a\partial_1^2$ by $\mathcal{L} \equiv d_1^2 d_1$, where $d_1$ and $d_1^*$ are respectively a forwards and a backwards finite difference (let us notice that they commute).
Let us notice that the Laplacian is the spatial operator that intervenes in the non-relativistic Schrödinger equation, hence the superscript “Schrö.”.

The dispersion relation is now, plotted under the form of a gapless frequency,

\[
\begin{align*}
\tilde{f}_{\text{LGT}}(k) := & \sqrt{(\omega_{\text{LGT}})^2 - m^2} = \sqrt{\frac{\sin^2(ka)}{a} + \left[ m + \frac{r}{a} (1 - \cos(ka)) \right]^2} - m^2 .
\end{align*}
\]

(53)

In the left panel of Fig. 3, we see that the doubling problem is fixed with this expression, since there are no more poles at $-\pi/a$ and $\pi/a$. To develop explanations, it is practical to consider the square of the previous expression,

\[
(f_{\text{LGT}}(k))^2 = g_{\text{naive}}(k) + g_{\text{non-crossed}}(k) + g_{\text{crossed}}(k) .
\]

(54)

where

\[
\begin{align*}
g_{\text{naive}}(k) := & \frac{\sin^2(ka)}{a} = (f_{\text{naive}}(k))^2 , \\
g_{\text{non-crossed}}(k) := & \frac{r^2}{a^2} (1 - \cos(ka))^2 , \\
g_{\text{crossed}}(k) := & 2mr(1 - \cos(ka)) .
\end{align*}
\]

(55a-55c)

It will also be useful to develop this expression, Eq. (54), at fourth order in $k$ and $m$ (e.g., $k^3 m$ is a fourth-order term),

\[
(f_{\text{LGT}}(k))^2 = \left( 1 + amr + \frac{1}{4} a^2 r^2 k^2 \right) k^2 + m^2 .
\]

(56)

In Fig. 4, we see that the biggest contribution in fixing the doubling problem comes from the non-crossed term; This is actually also visible in the left panel of Fig. 3. Moreover, we see in Eq. (56) that the crossed term unfortunately adds a first-order correction (in $m$, or in the lattice spacing) to the initial slope, that is, the latter becomes $1 + amr$ instead of $1$, which is visible in the right panel of Fig. 3. Hence, it is a pity that this crossed term appears naturally when modifying the Hamiltonian. Now, one can actually make this crossed term disappear, by choosing in the Wilson term $\tilde{h}_{\text{Schrö.}}$, Eq. (51), the operator $\alpha^2$ instead of $\alpha^0$. While in continuous time this has no impact on the unitarity of the scheme, it will a priori have an impact in discrete time [11], so this replacement cannot be made carelessly.
