ABSTRACT. We derive an accurate lower tail estimate on the lowest singular value $\sigma_1(X - z)$ of a real Gaussian (Ginibre) random matrix $X$, shifted by a complex parameter $z$. Such shift effectually changes the upper tail behaviour of the condition number $\kappa(X - z)$ from the slower $P(\kappa(X - z) \geq t) \lesssim 1/t$ decay typical for real Ginibre matrices to the faster $1/t^2$ decay seen for complex Ginibre matrices as long as $z$ is away from the real axis. This sharpens and resolves a recent conjecture in [6] on the regularizing effect of the real Ginibre ensemble with a genuinely complex shift. As a consequence we obtain an improved upper bound on the eigenvalue condition numbers (known also as the eigenvector overlaps) for real Ginibre matrices. The main technical tool is a rigorous supersymmetric analysis from our earlier work [6].

1. Introduction

The condition number $\kappa(X) = \|X\| \|X^{-1}\|$ of large $N \times N$ random matrices $X$ has been a central object in numerical linear algebra at least since the pioneering work of Demmel [17]. He showed that for a large class of complex random matrices $X$ the probability that $\kappa(X)$ is larger than a threshold $t \gg 1$ decays as $1/t^2$, while for real matrices the decay rate is slower, of order $1/t$. While the dependence on $N$ was not optimal in Demmel’s work, for the specific Gaussian case much more precise results are available. Gaussian random matrices have frequently been used as a test case since often explicit formulas are available for their spectral distribution.

The simplest non-Hermitian random matrix model is the real or complex Ginibre ensemble, consisting of matrices with independent identically distributed (i.i.d) Gaussian matrix elements. We fix the customary normalization, $E x_{ab} = 0$, $E |x_{ab}|^2 = N^{-1}$ that guarantees that the density of eigenvalues of $X$ converges to the uniform measure on the complex unit disk (known as the Circular law) and that the spectral radius of $X$ converges to 1 with very high probability (these results also hold for non-Gaussian matrix elements, see e.g. [22, 3, 30, 22, 4, 7, 8]). Edelman in [8] gave an exact formula for the distribution of the lowest singular value of a Ginibre matrix in both symmetry classes and derived a precise large $N$ asymptotic for the condition number, confirming Demmel’s upper tail decay on the distribution of $\kappa(X)$ uniformly in the dimension. Non-asymptotic upper and lower bounds with good explicit constants were obtained in [2] for the real case and later extended to rectangular matrices [19, 12] in both symmetry classes.

In more recent applications Ginibre matrices arise as additive perturbations of a deterministic matrix $A$. The prominent example is the concept of smoothed analysis (originally introduced in [29] in the context of the simplex algorithm), where Sankar, Spielman and Teng [38] considered the Gaussian elimination algorithm without pivoting for solving large dimensional linear systems of equations $Ax = b$. The bit-complexity of Gaussian elimination, i.e. the computational cost of achieving a desired output accuracy, depends primarily on $\kappa(A)$ and its upper tail is mainly determined by the lower tail behaviour of $\sigma_1(A)$, the lowest singular value of $A$ (note that $\sigma_1(A)^2 = \lambda_1(AA^*)$), the lowest eigenvalue of

In order to obtain a bound on the real world accuracy loss of the problem \( Ax = b \), rather than the averaged or worst case accuracy loss, the main result of [28] is an estimate on the smoothed value of \( \kappa(A + \gamma X) \) for small \( \gamma \) and Ginibre-distributed \( X \). In practice \( \gamma \) is then optimized to balance between the gain in bit-complexity versus the loss in precision.

More precisely, the authors proved the following lower tail bound on the (square of the) lowest singular value of the regularized matrix \( A + \gamma X \):

\[
P\left( \sigma_1(A + \gamma X) \leq \frac{\sqrt{x}}{N} \right) \leq C \frac{x}{\sqrt{\gamma^2}}, \quad x > 0,
\]

for a real Ginibre matrix \( X \), and

\[
P\left( \sigma_1(A + \gamma X) \leq \frac{\sqrt{x}}{N} \right) \leq C \frac{x}{\sqrt{\gamma^2}}, \quad x > 0,
\]

for a complex Ginibre matrix \( X \). The constant \( C \) is universal, the estimates are uniform in \( A \) and \( \gamma \). The \( N^{-2} \) scaling naturally comes from the typical \( 1/N \) spacing between the eigenvalues of the corresponding Hermitized matrix

\[
H^A := \begin{pmatrix} 0 & A + \gamma X \\ (A + \gamma X)^* & 0 \end{pmatrix}
\]

in its bulk spectrum. Comparing the bounds (4) and (2) in the small \( x \) regime, note that the regularizing effect of a complex Ginibre matrix is much stronger. Can one achieve the same effect with real Ginibre matrices?

On one hand, inspecting the proof in [28], the exponents of \( x \) in the right hand side of (4) and (2) are direct consequences of the one- vs. two-dimensionality of the support of the real vs. complex random variables \( x \) and the effect is completely independent of \( A \). On the other hand, quite remarkably, the local eigenvalue statistics of the real and complex Ginibre ensemble coincide away from the real axis, see [9, Theorem 1]. Very recently in [13, 15] we showed an analogous phenomenon for the singular values of the shifted Ginibre matrix. More precisely, in [13] the density of the low lying singular values of \( X - z \) for a real and complex Ginibre \( X \) was shown to coincide if the shift parameter \( z \) is genuinely complex, \( |\Im z| \gg N^{-1/2} \). In the regime \( |\Im z| \sim 1 \) the same coincidence was proven for all \( k \)-point correlations functions [6, Theorem 2.6]. In particular, on the level of the small singular values, the real Ginibre matrix with a complex shift behaves as a complex Ginibre matrix.

For the purpose of the smoothed analysis this indicates the possibility that real Ginibre matrices are as effectively regularizing as the complex ones, at least away from the real axis. To test this hypothesis, we consider the simplest \( A = -z I \) case, the shifted Ginibre ensemble. In fact, the following conjecture in this spirit was very recently posed in Section 7 of [6] (with our notations and with \( \gamma = 1 \) for simplicity):

\[
P\left( \sigma_1(X - z) \leq \frac{\sqrt{x}}{N} \right) \leq C \frac{x}{|\Im z|}, \quad x > 0.
\]

While (4) highlights the role of \( \Im z \), its scaling is far from optimal: by analogy with the eigenvalues, one expects that a real Ginibre matrix \( X \) near \( z \) behaves essentially as a complex Ginibre matrix as long as \( |\Im z| \gg N^{-1/2} \). Indeed, our main result in Theorem 2.1 shows that

\[
P\left( \sigma_1(X - z) \leq \frac{\sqrt{x}}{N} \right) \leq \left( 1 + |\log x| \right) |x + e^{-\frac{x}{2 N|\Im z|^2}} \min \left\{ \sqrt{x}, \frac{x}{\sqrt{N|\Im z|}} \right\}, \quad x > 0,
\]

proving that the essentially linear bound (in \( x \)) from (2) already dominates the tail behaviour of the lowest singular value for \( |\Im z| \gg N^{-1/2} \), while the much larger \( \sqrt{x} \) tail prevails in the opposite regime. Since \( \kappa(X - z) \sim \sigma_1(X - z)^{-1} \), we directly obtain the transition from 1/t to 1/t^2 for the upper tail \( P(\kappa(X - z) \geq t) \) as \( |\Im z| \) increases well above \( N^{-1/2} \), see Fig. 1. A similar behaviour is expected to hold for general matrix \( A \), see Conjecture 2.4.

The bound (6) has several consequences on the eigenvalue condition number \( \kappa(\lambda) := \|L\|\|R\| \) that determines the stability of the eigenvalue \( \lambda \) against small perturbations, where \( L, R \) denote the corresponding left and right eigenvectors with the customary normalization \( \langle L, R \rangle = 1 \). For complex Ginibre matrices it is known that \( \kappa(\lambda) \) is of order \( \sqrt{N} \), see [11, 10, 20]. For the real Ginibre case a similar result is obtained in [20] but only for real eigenvalues \( \lambda \in \mathbb{R} \). Suboptimal bounds in \( N \) have very recently been established in [6] and [24] that also hold for a general matrix \( A \), in particular for any shift \( z \in \mathbb{C} \).

The paper [28] states the result only for the real case, but the complex case easily follows by the same proof.
The proof of our main estimate (5) uses the supersymmetric (SUSY) approach that is common in the physics literature on random matrices, but is less known in the numerics community. Most of the necessary technical work has already been done in our previous paper [16]; hence the current paper is short and focuses on the results. Our purpose is to demonstrate the power of the SUSY method to obtain very accurate estimates. For example, the exponential suppression factor \( \exp\left(\frac{-1}{2N}|\Im z|^2\right) \) in (5) expressing the true effect of the non-zero imaginary part of the shift parameter seems very hard to obtain with any other method, while it easily comes out from the SUSY formalism.

Acknowledgement. We would like to thank Folkmar Bornemann for valuable comments on a preliminary version of the present paper.

Notations and conventions. For positive quantities \( f, g \) we write \( f \lesssim g \) and \( f \sim g \) if \( f \leq Cg \) or \( cg \leq f \leq Cg \), respectively, for some constants \( c, C > 0 \) which are independent of \( N \) and \( z \). We write \( D \subset \mathbb{C} \) for the open unit disk. We abbreviate the minimum and maximum of real numbers by \( a \wedge b := \min\{a, b\} \) and \( a \vee b := \max\{a, b\} \).

2. Main results

We consider the ensemble \( Y^z := (X - z)(X - z)^* \) with \( X \in \mathbb{R}^{N \times N} \) being a real Ginibre matrix, i.e. its entries \( x_{ab} \) are such that \( \sqrt{N}x_{ab} \) are i.i.d. standard real Gaussian random variables, and \( z \in \mathbb{C} \) is a fixed complex parameter such that \( |z| \leq 1 \). Our main results are an optimal lower tail estimate for the smallest singular value of \( X - z \) and its consequences for eigenvector overlaps and eigenvalue condition number of real Ginibre matrices.

2.1. Singular value and condition number tail estimates for \( X - z \). The following theorem gives an estimate on the lowest singular value of \( X - z \) uniformly in all the relevant parameters and on the optimal scale. Its direct corollary is an analogous estimate on \( \kappa(X - z) \).

Theorem 2.1. Let \( \eta := \Im z, \delta := 1 - |z|^2 \) and
\[
c(N, \delta) := \frac{1}{N^{3/2}} \wedge \frac{1}{N^2|\delta|}.
\]
Then, uniformly in \( x \in [0, \infty), \eta \in [-1, 1], \delta \in [-10N^{-1/2}, 1] \), it holds
\[
\mathbb{P} \left( \lambda_1(Y^x) \leq xc(N, \delta) \right) \leq C_x(1 + |\log x|)x + C_xe^{-\frac{1}{2}N^\eta} \left( \sqrt{x} \wedge \frac{x}{\sqrt{N|\eta|}} \right)
\]
where \( C_x \) is a universal constant.

Note that \( c(N, \delta) \) is the correct scale of the typical size of \( \lambda_1(Y^x) \). Indeed the level spacing of the eigenvalues of \( Y^x \) close to zero for \( |z| < 1 \) is given by \( N^{-2}\delta^{-1} \) and for \( |z| = 1 \) by \( N^{-3/2} \), see [1, Section 5]. The \( N^{-3/2} \) scaling in the edge regime \(|z| = 1\) comes from the fact that the density of eigenvalues of the Hermitized matrix
\[
H^x := \begin{pmatrix} 0 & X - z \\ (X - z)^* & 0 \end{pmatrix}
\]
develops a cubic cusp singularity that has a natural eigenvalue spacing \( N^{-3/4} \).

**Remark 2.2.** Introducing the coupling parameter \( \gamma \) and thus replacing \( \lambda_1(Y^x) \) by \( \lambda_1[(\gamma X - z)(\gamma X - z)^*] \) we then conclude a bound analogous to (7) after replacing \( x \) by \( x\gamma^{-2} \).

**Remark 2.3.** Theorem 2.1 is proven only for matrices \( X \) with Gaussian entries. However, the bound (7) can be extended to matrices \( X \) with generic independent identically distributed (i.i.d.) entries at the price of an additional error term. More precisely, for such matrices there exists \( \omega > 0 \) such that
\[
\mathbb{P} \left( \lambda_1(Y^x) \leq xc(N, \delta) \right) \leq \text{rhs. of } (7) + C_{x}N^{-\omega},
\]
for any \( x \geq N^{-\omega} \). Given (7), the bound in (9) is obtained by a standard Green function comparison (GFT) argument (see e.g. [14, Proposition 3]).

For a general deterministic matrix \( A \) we can make the following conjecture. Note that (7) proves Conjecture 2.4 for the special case \( A = -zI \) up to a logarithmic correction.

**Conjecture 2.4.** Let \( X \) be an \( N \times N \) real Ginibre matrix. There exist constants \( c_x, C_x > 0 \) such that for any deterministic matrix \( A \) and for any \( \gamma > 0 \) it holds
\[
\mathbb{P} \left( \sigma_1(\gamma X + A) \leq \frac{\sqrt{2}}{N} \right) \leq C_x \frac{x}{\gamma^2} + C_xe^{-c_x \text{Tr}(\Im A)^2} \left( \frac{\sqrt{2}}{\gamma} \wedge \frac{x}{\sqrt{\text{Tr}(\Im A)^2}} \right)
\]
where \( \Im A := A - A^* \).

We conclude this section by remarking that, by \( \kappa(X - z) = [\lambda_{\text{max}}(Y^x)/\lambda_1(Y^x)]^{1/2} \), from a lower tail estimate (7) on \( \lambda_1(Y^x) \) we immediately obtain an upper tail bound on \( \kappa(X - z) \) for \(|z| < 99/100 \) (the complementary bound in the edge regime \( |z| \approx 1 \) follows similarly)
\[
\mathbb{P} \left( \kappa(X - z) \geq t \right) \leq |\log t| \left( \frac{N}{t} \right)^2 + e^{-\frac{1}{2}N^\eta} \left( \frac{N}{t} \wedge \frac{N^{3/2}}{|\eta|^2} \right) + e^{-N}.
\]

Here we used that the largest eigenvalue \( \lambda_{\text{max}}(Y^x) \) can be controlled by the large deviation bound \( \mathbb{P}(||X|| \geq K) \leq e^{-nK^2N} \) for some small \( n \) and any large \( K \). The bound (u) shows Demmel's transition between the \( 1/t \) and \( 1/\sqrt{t} \) tail behaviour up to an exponentially small additive error.

## 2.2 Overlaps and condition numbers for \( X \)

Our main result on the tail of the smallest singular value from (7) directly translates into optimal (up to logarithmic corrections) bounds on the eigenvector overlaps and eigenvalue condition number. We denote the left- and right eigenvectors of \( X \) corresponding to an eigenvalue \( \lambda_i \) by \( L_i, R_i \) so that \( X = \sum \lambda_i L_i R_i^* \) with the normalization \( \langle L_i, R_i \rangle = 1 \) customary in the theory of non-normal matrices. The diagonal eigenvector overlap \( O_{ii} \) or eigenvalue condition number \( \kappa(\lambda_i) \) are defined as
\[
O_{ii} := \|L_i\|^2 \|R_i\|^2 =: \kappa(\lambda_i)^2.
\]
The overlap \( O_{ii} \) is directly related to the stability of the eigenvalue \( \lambda_i = \lambda_i(X) \) under perturbations in the sense that
\[
\lim_{\epsilon \to 0} \sup_{\|E\| \leq 1} \frac{\|\lambda_i(X + \epsilon E) - \lambda_i\|}{\epsilon} = \sqrt{O_{ii}}.
\]
Theorem 2.5. Let $X$ be a real Ginibre matrix with left- and right eigenvectors $L_i, R_i$ corresponding to the eigenvalue $\lambda_i$. Then for any open set $\Omega \subset \mathbb{D}$ and any $K > 0$ we have

$$
P\left( \sum_{i, \lambda_i \in \Omega, \lambda_i \geq t(\log N)N^2} \|L_i\|_2^2 \|R_i\|_2^2 \geq 1 - |z|^2 \right) \leq CK t^{-1} + \frac{C_K N}{N^2} \quad \text{(14)}$$

for any $t > 0$, with some universal constant $C$ and $K$-dependent constants $C_K$. Here $\Omega + B(0, N^{-1/2})$ denotes the Minkowski sum of $\Omega$ with the ball of radius $N^{-1/2}$.

Remark 2.6.

(i) For complex Ginibre matrices Chalker and Mehlig [27, 11] computed the expected overlap (rigorously only for $z = 0$) and showed for its conditional expectation that

$$
\mathbb{E} \left[ \Omega_i \mid \lambda_i = z \right] = \mathbb{E} \left[ \|L_i\|_2^2 \|R_i\|_2^2 \mid \lambda_i = z \right] \sim N (1 - |z|^2). \quad \text{(5)}
$$

See Fig. 2 for a comparison between the real Ginibre overlaps far away from the real axis and the complex Ginibre overlaps as a function of $|z|$.

(ii) In the case of complex Ginibre matrices the distribution of individual overlaps $\|L_i\|_2^2 \|R_i\|_2^2$ has been identified in [10, 20], showing that

$$
N^{-1} (1 - |\lambda_i|^2)^{-1} \|L_i\|_2^2 \|R_i\|_2^2
$$

converges in distribution to an inverse $\gamma_2$ random variable.

(iii) Similarly, in the case of real Ginibre matrices the joint distribution of overlaps and their corresponding real eigenvalues has been identified in [20] via supersymmetric techniques. See Fig. 3 for the tail decay of the CCDF of the overlaps corresponding to real and complex eigenvalues in the real Ginibre ensemble. Our numerics reproduce the $t^{-1}$ decay for the CCDF of overlaps corresponding to real eigenvalues as shown in [20, Eq. (2.2)].

(iv) Recently, suboptimal versions of (14) could be established for the more general case of non-Hermitian random matrices $X$ with i.i.d. entries with deterministic additive deformation $X + A$ in [6] and [24], resulting in bounds of order $N^3$ and $N^3$, respectively.
The complementary cumulative distribution functions $P(O_{ii}/N \geq t)$ for the eigenvector overlaps of real and complex Ginibre matrices obtained from 10,000 matrices of size $100 \times 100$. The complex overlaps as well as the real overlaps away from the real axis share the same decay exponent of $1.9 \approx 2$, consistent with the fact [20] that in the complex case the overlaps are $1/\gamma_2$-distributed. The fatter tail of the real overlap close to the real axis is responsible for the fact [20] that $E[O_{ii}^R | \lambda_i \in \mathbb{R}] = \infty$.

Eigenvector overlaps can be used to estimate the eigenvector condition number

$$
\kappa_v(X) := \inf_{V: XV^{-1} = D} \|V\| \|V^{-1}\| \leq \sqrt{N} \sum_{i=1}^N \|L_i\|^2 \|R_i\|^2,
$$

where $D$ is the diagonal matrix of eigenvalues. Thus we immediately obtain the following corollary.

**Corollary 2.7.** For real Ginibre matrices $X$ we have

$$
P(\kappa_v(X) \geq tN^{3/2} \sqrt{\log N}) \leq CKt^{-2} + C_{K,N}, \quad t > 0,
$$

for any $K > 0$ with some universal constant $C$ and $K$-dependent constants $C_K$.

We note that it is generally expected that for dense random matrices $\kappa_v(X)$ scales linearly in $N$, c.f. [3], Page 386. Therefore our Corollary 2.7 is still an overestimate by a factor $N^{1/2} \sqrt{\log N}$, even though the estimate in (15) seems optimal. This is essentially due to the fact the the ultimate inequality in (16) loses a factor of $\sqrt{N}$ by estimating operator norms by Frobenius norms.

### 3. Proof of Theorem 2.1

Supersymmetric methods, especially the superbosonization formula (see e.g. [25]), provide an explicit formula for $E \text{Tr}[Y^z + E]^{-1}$. This was derived in [16, Eqs. (44)-(37)]. Then by [16, Eq. (86)] we have that

$$
E \text{Tr}[Y^z + E]^{-1} = \frac{N}{4\pi i} \int_{\Gamma} d\xi \int_0^{+\infty} da \int_0^1 d\tau \frac{\xi^2 a}{\tau^{1/2}} e^{N[f(\xi) - g(\tau, \sigma, n)]} G_N(a, \tau, \xi, z),
$$

with $\Gamma$ any counter-clockwise contour around zero. Here

$$
f(\xi, w) := E\xi + \log(1 + \xi) - \log \xi - \frac{|z|^2}{1 + \xi},
$$

The proof of the simple inequality can be found e.g. in [1, Lemma 3.4].
g(a, \tau, \eta, w) := E a + \frac{1}{2} \log[1 + 2a + a^2 \tau] - \log a - \frac{1}{2} \log \tau - \frac{1}{2} \log \tau \left(1 + a\right) - 2\eta^2a^2(1 - \tau),

where we denoted \eta := \Im z. Furthermore, the function \( G_N = G_N(a, \tau, \xi, \eta) \) is given by

\[
G_N := \left(\frac{N^2}{a^2(1 + \xi)^2} - \frac{N^2}{a^2(1 + 1)^2} \right) + \delta N^2 \frac{a^2(1 + 1)^2}{a^2(1 + 1)^2} - \frac{N^2}{a^2(1 + 1)^2} \frac{P_{2,0.0}}{a^2(1 + 1)^2} \frac{P_{2,0.0}}{a^2(1 + 1)^2} + \delta N^2 \frac{a^2(1 + 1)^2}{a^2(1 + 1)^2} \frac{P_{2,0.1}}{a^2(1 + 1)^2} \frac{P_{2,0.1}}{a^2(1 + 1)^2} + \delta N^2 \frac{a^2(1 + 1)^2}{a^2(1 + 1)^2} \frac{P_{2,0.2}}{a^2(1 + 1)^2} \frac{P_{2,0.2}}{a^2(1 + 1)^2}
\]

\[
\times \left(\frac{a^2(1 + 1)^2}{a^2(1 + 1)^2} \right)^{-1},
\]

where \( P_{i,j,k}(u, v, w) \) are explicit polynomials in \( a, \tau, \xi \) which we defer to Appendix A and \( \delta := 1 - |z|^2 \). The indices \( i, j, k \) in the definition of \( P_{i,j,k} \) denote the \( N, \eta \) and \( \delta \) power, respectively. We conclude this section with the proof of Theorem 2.1.

Proof of Theorem 2.1. In order to bound (18) we split the analysis into several regimes. Using [16, Lemma 5.2] to estimate the regime \( |\xi| \geq N^\omega \), for some small fixed \( \omega > 0 \), [16, Lemma 6.2] and [16, Lemma 6.3] to estimate the regime \( \tau \geq N^{\omega} a^{-1} \) and \( a \geq N^{\omega} \), respectively, and [16, Lemma 6.4] to show that the regime when one among \( \xi, a, \tau \) is small is negligible, similarly to [16], we conclude that

\[
\left[ E \text{Tr}[\mathbb{Y}^2 + \hat{E}] \right]^{-1} \leq \frac{E^{N^{3/4}}(N^2 + \sqrt{\mathbb{E}|N|})}{\sqrt{\mathbb{E}}} \right] \left[ 1 + \log(N^{2/3}) \right].
\]

Note that in [16, Lemma 6.4] we proved a bound \( N^{5/2+\omega}(N^{1/2} \vee N|\delta|) E^{-1/2} \vee N^{1/2} \vee N^\omega \), however inspecting its proof it is easy to see that using [16, Lemma 6.3] we easily get an improved bound \( N^{5/2+\omega}(N^{1/2} \vee N|\delta|) E^{-1/2} \vee N^{1/2} \vee N^\omega \), but we did not exploit this additional gain in [16, Lemma 6.4] since it was not needed for the proof of [16, Theorem 2.3]. Finally, by (22) and a simple Markov inequality, we conclude (7).

\[ \square \]

4. Proof of Theorem 2.5

We begin with an a priori bound on the minimal eigenvalue gap

\[
\Delta := \min_{i \neq j} |\lambda_i - \lambda_j|
\]

which follows directly from estimating the smallest two singular values of \( X - z \), see e.g. [31, Theorem 3.1] or [26, Theorem 1.9].

Lemma 4.1. There exist constants \( c, C > 0 \) such that for Ginibre matrices \( X \) and for any large \( K \) we have

\[
\Omega_\Delta := \{ \Delta > N^{-3K} \}, \quad P(\Omega_\Delta) \leq \frac{C}{N^{2K-\delta}} + C e^{-cN}.
\]

Together with the singular value bound from Theorem 2.1 we obtain the following a priori bound on overlaps.

Lemma 4.2. There exists a constant \( C > 0 \) such that for Ginibre matrices \( X \) the event \( \Omega_\circ := \{ \max_i O_{ii} < N^{12K} \} \) satisfies

\[
P(\Omega_\circ \cap \Omega_\Delta) \leq \frac{C}{N^K}.
\]

Proof. We claim that

\[
\Omega_\circ \cap \Omega_\Delta \subset \bigcup_{z} \{ \sigma_1(X - z) \leq 2N^{-10K} \},
\]

where the union is taking over \( z \)'s on an \( N^{-4K} \)-grid inside the unit disk. Indeed, for \( i := \arg \max_j O_{jj} \) there exists \( z \in B(\lambda_i, N^{-4K}) \) on the grid and we now show that \( \sigma_1(X - z) \leq 2N^{-10K} \) for this \( z \). We use \( \sigma_1(X - z) = \| (X - z)^{-1} \|^{-1} \) and the spectral decomposition

\[
\frac{1}{X - z} = \sum_i \frac{R_i L_i^*}{\lambda_i - z}.
\]
Comparing the volumes of both sides we obtain (26). Thus it follows from Theorem 2.1 and an union bound that
\[ P(\Omega^c \cap \Delta) \leq C N^{8K-10K+2} \leq \frac{C}{N^K}. \]
confirming (26). The basic idea is to relate the eigenvalue overlaps to the area of the pseudo-spectrum of \( X \), see e.g. \cite[Section 5.2]{10}, \cite[Section 3.6]{5}, \cite[Lemma 1]{3} or \cite[Lemma 2.3]{24} for a quantitative version.

**Proof of Theorem 2.5.** We introduce the event \( \Delta \cap \cap) := \Omega^c \cap \Omega \) and claim that on \( \Delta \cap \cap) \) we have
\[
\sum_{\lambda_i \in \Omega \cup B(0, N^{-6K})} O_{\lambda_i} \leq \frac{4}{\epsilon^2} \left\{ z \in \Omega + B(0, N^{-6K}) : \sigma_1(X - z) \leq \epsilon \right\}.
\]
Indeed, first note that \( B(\lambda_i, O_{\lambda_i}^{1/2}/\epsilon/2) \cap B(\lambda_j, O_{\lambda_j}^{1/2}/\epsilon/2) = \emptyset \) for \( i \neq j \) due to
\[ |\lambda_i - \lambda_j| \geq \Delta > N^{-3K} > \epsilon (O_{\lambda_i}^{1/2}/2 + O_{\lambda_j}^{1/2}/2). \]
Then, for \( z \in B(\lambda_i, O_{\lambda_i}^{1/2}/\epsilon/2) \) we have
\[
\frac{1}{\sigma_1(X - z)} = \|(X - z)^{-1}\| \geq \frac{O_{\lambda_i}^{1/2}}{|\lambda_i - z|} - \sum_{j \neq i} \frac{O_{\lambda_i}^{1/2}}{|\lambda_j - z|} \geq \frac{2}{\epsilon - N^{-6K}} \frac{O_{\lambda_i}^{1/2}}{\Delta - \epsilon O_{\lambda_i}^{1/2}/2} \geq \frac{1}{\epsilon}
\]
and from this relation it follows that
\[
\bigcup_{\lambda_i \in \Omega} B(\lambda_i, O_{\lambda_i}^{1/2}/\epsilon/2) \subset \left\{ z \in \Omega + B(0, N^{-6K}) : \sigma_1(X - z) \leq \epsilon \right\}.
\]
Comparing the volumes of both sides we obtain (29).

Now from (29) and (7) we get
\[
E \left[ \sum_{\lambda_i \in \Omega} O_{\lambda_i} \right] \lesssim \int_{\Omega + B(0, N^{-6K})} \frac{P[\sigma_1(X - z) \leq \epsilon \cup \Omega^c \cap \cap)}{\epsilon^2} d^2z
\]
\[
\lesssim \int_{\Omega + B(0, N^{-1/2})} \left[ (N^{2}|1 - |z|^2| \lor N^{3/2}) K \log N + e^{-\frac{1}{2} N (|z|)^2} \left( N^{3/2} |1 - |z|^2| \lor N^{3/4} \lor N^{3/2} (|1 - |z|^2|) \lor N \right) \right] d^2z
\]
\[
\lesssim K \log N \left( N^{2} \int_{\Omega + B(0, N^{-1/2})} |1 - |z|^2| d^2z \lor N^{3/2} |\Omega + B(0, N^{-1/2})| \right).
\]
In the last inequality, in order to estimate the terms multiplied by \( e^{-N (|z|)^2/2} \), we performed the \( d^2z \) and \( d|z| \) integrations separately and split the analysis into three regimes: (i) \( |1 - |z|^2| \leq N^{-1/2} \),
(ii) \( |1 - |z|^2| > N^{-1/2} \) and \( |z| \geq N^{-1/2 + \xi} \), for some small \( \xi > 0 \), (iii) \( |1 - |z|^2| > N^{-1/2} \) and \( |z| \leq N^{-1/2 + \xi} \). The regime (i) is trivial since the factor \( |1 - |z|^2| \) can be neglected; for (ii) we used that \( e^{-N (|z|)^2/2} \leq e^{-N/4} \) and so the contribution of this regime is exponentially small; finally in (iii) we used that \( |1 - |z|^2| \leq |1 - |z|^2| \) and that
\[
\int_{\Omega(\xi)} (1 - y^2) dy \lesssim \sqrt{N} \int_{\Omega} (1 - |z|^2) d^2z,
\]
where $\bar{\Omega} := (\Omega + B(0, N^{-1/2})) \cap \{ |z| \leq N^{-1/2+\frac{\epsilon}{2}} \} \cap \{ 1-|z|^2 > N^{-1/2} \}$ and $\Pi(\bar{\Omega}) \in \mathbf{R}$ is the projection of $\bar{\Omega}$ onto the real axis. Finally, by the estimate (50) used on the event $\Omega_{\Delta,0}$ together with a simple Markov inequality combined with the probability bound on the complement $\mathbf{P}(\Omega_{\Delta,0}) \leq N^{-h}$ from Lemmas 4.1–4.4, we conclude (44).

Appendix A. Explicit formulas for the real symmetric integral representation

Here we collect the explicit formulas for the polynomials of $a, \xi , \tau$ in the definition of $G_N$ in (68).

\begin{align*}
p_{2,0,0} &:= a^2 \tau^2 + 2a^3 \xi \tau + 4a^3 \xi^2 + 4a^2 \xi^2 + 2a^2 \tau + 4a^4 \xi^3 + 8a^3 \xi^3 + 10a \xi + 4a + \xi^4 + 4\xi^2 + 6\xi^2 + 4\xi + 1, \\
p_{1,0,0} &:= -a^2 \xi^2 + a^2 \tau^2 - 2a^3 \xi^2 \tau - 2a^3 \xi^3 \tau - 3a^2 \xi^2 \tau - 2a^2 \xi^2 \tau + 4a^2 \xi^2 + 4a^2 \xi + 2a^2 \xi^2 + 6a \xi + 4a + \xi^3 + 3\xi^2 + 3\xi + 1, \\
p_{2,2,0} &:= 4(a + 1) \left( a^2 \tau + a \xi \tau + 2a \tau + \xi^2 + 2\xi + 1 \right), \\
p_{2,2,0} &:= 4(a + 1) \left( a^2 \tau + a^2 \xi \tau + 4a^2 \xi \tau + 2a \xi \tau + 4a^2 \xi^2 + 2a \xi \tau + 4a \xi + 3\xi^2 + 3\xi + 1 \right), \\
p_{2,0,1} &:= 2 \left( a^2 \tau^2 + 2a^2 \xi \tau + 4a^2 \xi^2 \tau + 2a \xi \tau + 4a \xi + 3\xi^2 + 2\xi^2 + 5\xi + 2 \right) \\
p_{2,0,1} &:= 2 \left( a^2 \tau^2 + 2a^2 \xi \tau + 4a^2 \xi^2 \tau + 2a \xi \tau + 4a \xi + 3\xi^2 + 2\xi^2 + 5\xi + 2 \right), \\
p_{2,2,1} &:= 4(a + 1)(a + \xi + 2), \\
p_{2,2,2} &:= a^2 \tau + 2a \xi + 4a + \xi^2 + 4\xi + 4.
\end{align*}
