(Dated: June 2, 2021)

We studied bulk viscosity in the modified $f(Q,T)$ gravity theory formalism, where $Q$ represents the non-metricity and $T$ denotes the trace of energy-momentum tensor within a flat Friedmann-Lemaitre-Robertson-Walker metric (FLRW). We consider the effective equation of state, which includes a bulk viscosity term explicitly. We find the exact solutions relating to bulk viscosity by assuming a specific form of $f(Q,T) = \alpha Q + \beta T$, where $\alpha$ and $\beta$ are constants. Furthermore, we constrained our model with revised Hubble datasets consisting of 57 data points and newly published Pantheon samples with 1048 points to obtain the best fitting values of the model parameters. Our model is found to be in good agreement with observations. Furthermore, we analysed the cosmological behavior of the density parameter, the equation of state (EoS) parameter ($\omega$), and the deceleration parameter ($q$). The universe appears to be evolving from a decelerated to an accelerated phase. The EoS parameter is further found to be in the quintessence phase, indicating that the universe is accelerating. We can deduce that the accumulation of bulk viscosity as effective dark energy is responsible for the current accelerated expansion of the universe.

I. INTRODUCTION

Observations of type Ia supernovae in recent years have suggested that the universe is expanding faster than usual [1, 2]. To understand the acceleration, physicists proposed a new fluid called dark energy, which has enough negative pressure. It is seemingly, seventy percent of the total content of the matter and energy in the universe. The straightforward way to explain dark energy is to introduce a cosmological constant, which leads to the claimed accelerated expansion and establishes the $\Lambda$CDM model, which has proven to be accurate [3]. Even though observations favor the cosmological constant model, it has several serious flaws. The significant difference between its expected and observed value and the cosmic coincidence problem is that we live specifically in the universe whose matter density and dark energy density are of the same order. This motivates to study alternative models for accelerated expansion [4–6].

Since the advent of relativistic thermodynamics, viscous cosmological scenarios have been extensively studied. Eckart obtained the standard expression for relativistic viscosity in 1940 [7]. Furthermore, Treciokas and Ellis [8], and Weinberg [9] investigated the cosmological implications of the Eckart viscosity. The concept of bulk viscosity was later explored in the form of inflation [10, 11] and as a source for the rapid expansion of the universe [12]. Bulk viscosity, on the other hand, is measured in a homogeneous and isotropic background.

The bulk viscosity in a cosmic fluid can occur when the fluid expands faster than the system has time to recover its local thermodynamic equilibrium. An effective pressure emerges, restoring the system to its thermal stability [13]. This effective pressure can be regarded as an indicator of bulk viscosity. Perhaps, due to the presence of bulk viscosity, it is reasonable to assume that the expansion phase is simply a set of states out of thermal equilibrium in a limited fraction of time in an accelerated expanding universe [14]. There have been theories about viscous fluids playing a part in dark matter [15] and dark energy in the literature [16, 17].

Modified gravity has recently emerged as an influential branch of modern cosmology, seeking to provide a coherent explanation of the early epoch of the universe while also accounting for the accelerated expansion at later stages. Modified gravity theories are geometrical extensions of Einstein General Relativity (GR), in which Einstein-Hilbert action is altered to accomplish cosmic acceleration. Many modified gravity theories are sug-
gested to describe the late and early acceleration of the universe. The $f(R)$ gravity proposed in [18], is the most basic and widely used modification to GR. Several authors have investigated several aspects of $f(R)$ gravity and how it can cause cosmic inflation and acceleration [19, 20]. The existence of the non-minimal coupling between matter and geometry is another extension of Einstein-Hilbert’s action. As a result, this leads to the so-called $f(R, T)$ modified theory of gravity. Harko et al. [22] proposed $f(R, T)$ gravity, in which the gravitational Lagrangian is described by an arbitrary function of Ricci scalar $R$ and the trace of energy-momentum tensor $T$. There are astrophysical and cosmological implications investigated in $f(R, T)$ gravity [21]. Harko [23] presented the thermodynamic interpretation of generalized gravity models with geometry-matter coupling. Jamil et al. [24] also reconstructed several cosmological models in $f(R, T)$ theory. Moraes and Sahoo [25] proposed the modeling of static wormholes within the $f(R, T)$ extended theory of gravity. Similarly, there exists several other modified theories with different cosmological implications such as $f(G)$ theory [29–31], $f(R, G)$ theory [32, 33], $f(T, B)$ theory [34], etc. As it is known, the GR theory is formulated in Riemann geometry. So, another interesting approach for creating extended theories of gravity is to investigate more general geometric structures that could characterize the gravitational field at the solar system level. As a result, a more unified theory equivalent to GR has been developed known as a teleparallel equivalent to GR or $f(T)$ theory [26–28], where $T$ is the torsion defining the gravitational effects. The third generalization of GR is the symmetric teleparallel representation which is further extended to the non-metric gravity known as $f(Q)$ gravity [35, 36], where $Q$ is the non-metricity expressing the geometric variable defining the characteristics of the gravitational interaction. Studies on the cosmology of the $f(Q)$ theory with observational constraints show the accelerated expansion of the universe without the requirement for exotic dark energy or additional fields [37, 38]. Mandal et al. [39] investigated energy conditions using a comparison of $f(Q)$ theory and $\Lambda$CDM. Khyllep et al. [40] examined cosmological solutions and the growth index of matter perturbations in $f(Q)$ gravity. Yixin et al. [41, 42] have proposed a new extension of $f(Q)$ known as the $f(Q, T)$ theory, where the non-metricity $Q$ is non-minimally coupled with the trace $T$ of the energy-momentum tensor. They focused on the three types of basic models and came up with solutions that described both the accelerating and decelerating evolutionary phases of the universe. Arora et al. [43] also tested $f(Q, T)$ gravity models with observational constraints to address the present cosmic acceleration. In Weyl-type $f(Q, T)$ gravity, Yang et al. [44] derived the geodesic deviation and Raychaudhuri equations. Therefore, one can study the viability of this newly proposed $f(Q, T)$ gravity under different cosmological implications.

However, several studies suggest that viscous pressure may be a driving force behind the current acceleration of the universe [45–47]. Davood [48] studied the effect of bulk viscosity matter in $f(T)$ gravity. Singh and Kumar [49] investigated the role of bulk viscosity in $f(R, T)$ gravity. Arora et al. [50] used an effective equation of state to investigate cosmological evolution with bulk viscosity in $f(R, T)$ theory. This work aims to use the bulk viscous pressure inside the cosmic fluid without incorporating any dark energy element in the $f(Q, T)$ modified theory of gravity to drive the current acceleration. We consider the bulk viscosity of the form $\zeta = \zeta_0 + \zeta_1 H$, where $H$ is the Hubble parameter, $\zeta_0$ and $\zeta_1$ are constants. The term $\zeta_0$ refers to the most basic parametrization of bulk viscosity, which is a constant and $\zeta_1$ refers to the possibility of a bulk viscosity proportional to the expansion rate of the universe. Also, the functional form of $f(Q, T) = \alpha Q + \beta T$ is assumed to get the exact solutions of field equations. We try to constrain the model parameters using the released 57 Hubble data points and 1048 Pantheon samples. To find the optimal values for the model parameters, we use MCMC techniques.

The following article is organized into sections. The field equation formalism in $f(Q, T)$ gravity is presented in section II. In section III, we explain the FLRW universe dominated by bulk viscous matter and obtain the Hubble parameter expression. We used the revised 57 Hubble datasets and Pantheon samples to constrain the model parameters in section IV. We observed the behavior of cosmological parameters such as the density parameter, the EoS parameter, and the deceleration parameter in section V. Finally, in section VI, we discuss our conclusions.

II. BASICS OF $f(Q, T)$ GRAVITY

The action which is used to define $f(Q, T)$ gravity read as [41, 42],

$$S = \int \left( \frac{1}{16\pi} f(Q, T) + L_m \right) \sqrt{-g} d^4x,$$

where $f(Q, T)$ is an arbitrary function that couples the non-metricity $Q$ and the trace of the energy-momentum
We can also define a superpotential or the non-metricity tensor $Q_{\gamma\mu
u} = \nabla_\gamma g_{\mu\nu}$, with trace of the non-metricity tensor given as

$$Q_\beta = g^{\mu\nu} Q_{\beta\mu\nu} = \tilde{Q}_\beta = g^{\mu\nu} Q_{\mu\beta\nu}. \tag{5}$$

We can also define a superpotential or the non-metricity conjugate as

$$p_{\mu\nu}^\beta = -\frac{1}{2} L_{\mu\nu}^\beta + \frac{1}{4} (Q^\beta - \tilde{Q})_{\mu\nu} + \frac{1}{4} \delta_{(\mu} Q_{\nu)}. \tag{6}$$

giving the non-metricity scalar as \[35\]

$$Q = -Q_{\beta\mu\nu} p^{\beta\mu\nu}. \tag{7}$$

In addition the energy-momentum tensor is known to be defined as

$$T_{\mu\nu} = -\frac{2}{\sqrt{-g}} \delta (\sqrt{-g} L_m) \delta g^{\mu\nu}, \tag{8}$$

and

$$\Theta_{\mu\nu} = g^{\alpha\beta} \delta T_{\alpha\beta} \delta g^{\mu\nu}. \tag{9}$$

Also, the variation of energy-momentum tensor with respect to the metric tensor is such that

$$\frac{\delta g^{\mu\nu} T_{\mu\nu}}{\delta g^{\beta\alpha}} = T_{\mu\nu} + \Theta_{\mu\nu}. \tag{10}$$

Thus, after varying the action (1) with respect to the metric and equating it to zero, we get the following field equations:

$$-\frac{2}{\sqrt{-g}} \nabla_\beta (f_Q \sqrt{-g} p_{\mu\nu}^\beta - \frac{1}{2} f g_{\mu\nu} + f_T (T_{\mu\nu} + \Theta_{\mu\nu}) - f_Q (P_{\mu\beta\alpha} Q_{\nu} - 2Q_{\mu\rho\beta} p_{\rho\nu} = 8\pi T_{\mu\nu}), \tag{11}$$

where $f_Q = \frac{df}{dQ}$ and $f_T = \frac{df}{dT}$.

### III. Friedmann Cosmology with Bulk Viscosity

We assume the bulk viscosity coefficient as \[51\]

$$\zeta = \zeta_0 + \zeta_1 H, \tag{12}$$

where $\zeta_0$ and $\zeta_1$ are two constants, regarded as positive and $H = \frac{\dot{a}}{a}$. Here, dot(·) represents the derivative with respect to time. The reason for addressing this bulk viscosity is since we know the transport viscosity phenomenon are related to the velocity $\dot{a}$, which is further associated with the scalar expansion $\theta = 3\frac{\ddot{a}}{a}$.

Now, let us assume that the universe is described by the homogeneous, isotropic and spatially flat FLRW metric given by,

$$ds^2 = -dt^2 + a^2(t) \delta_{ij} dx^i dx^j. \tag{13}$$

where $a(t)$ is the scale factor of the Universe. Moreover, assume that the cosmic fluid possesses a bulk viscosity. The energy-momentum tensor can be written as

$$T_{\mu\nu} = \rho u_\mu u_\nu + (p + \Pi) H_{\mu\nu}. \tag{14}$$

where in the co-moving coordinates, $u_\mu = (1, 0)$, and $H_{\mu\nu} = g_{\mu\nu} + u_\mu u_\nu$. Also, the non-metricity function $Q$ for such a metric is calculated as $Q = 6H^2$. By defining the effective pressure as $\tilde{p} = p + \Pi$, the Einstein’s field equations using the metric and (11) are expressed as

$$3H^2 = \frac{f}{4F} - \frac{4\pi}{F} \left((1 + \tilde{G})\rho + \tilde{G}\tilde{p}\right), \tag{15}$$

and

$$2H + 3H^2 = \frac{f}{F} - \frac{2\dot{F}H}{F} + \frac{4\pi}{F} \left[(1 + \tilde{G})\rho + (2 + \tilde{G})\tilde{p}\right]. \tag{16}$$

Here (·)dot represents a derivative with respect to time, besides $F = f Q$, and $8\pi \tilde{G} = f T$ denote differentiation with respect to $Q$, and $T$, respectively.

The cold dark matter has been assumed to be highly non-relativistic. So, we can take pressure $p = 0$ and assume that the effect of dark energy on universe evolution is included in the viscous term $\Pi = -\zeta \theta$ which has the dimension of pressure.

We assume the simplest functional form $f(Q, T) = \alpha Q + \beta T$, where $\alpha$ and $\beta$ are constants. Therefore, we get $F = f_Q = \alpha$ and $8\pi \tilde{G} = f_T = \beta$.

Solving (15) and (16), we get the following differential equation.

$$H + k_1 H + k_2 H^2 = 0. \tag{17}$$
where

\[ k_1 = \frac{1}{8\alpha} \left( 15\beta + 96\pi + 3\beta \left( \frac{\beta + 16\pi}{3\beta + 16\pi} \right) \right) \tilde{\zeta}_0, \quad (18) \]

and

\[ k_2 = \frac{1}{8\alpha} \left( 6\alpha + (15\beta + 96\pi)\tilde{\zeta}_1 + \left( \frac{\beta + 16\pi}{3\beta + 16\pi} \right) (6\alpha + 3\beta\tilde{\zeta}_1) \right) \]

We consider \( \frac{dH}{dt} = H \frac{dH}{dzdt} \) and using \( a = \frac{1}{1+z} \) (taking \( a(t_0) = 1 \), we obtained the solution of (17) as

\[ H(z) = H_0 \left[ (C(1+z))^{k_2} - k_1 \right]. \quad (20) \]

where \( H(0) = H_0 \), the present value of Hubble constant and \( C \) is an integrating constant. As the Hubble parameter contains model parameters \( \tilde{\zeta}_0, \tilde{\zeta}_1, \alpha, \beta, \) and \( C \), we try to constrain these with the two different datasets in the following section.

IV. OBSERVATIONAL CONSTRAINTS

We studied \( f(Q,T) \) gravity with the bulk viscosity formalism in the preceding sections and obtained an exact solution for the derived field equations. The solution contains four model parameters \( \tilde{\zeta}_0, \tilde{\zeta}_1, \alpha, \beta, \) and a constant \( C \). To validate our approach, we must constrain these model parameters with some observational datasets that will also yield the best fit values for these model parameters. In this study, we have considered two datasets: the observational Hubble datasets consisting of 57 data points and the newly released Pantheon samples with 1048 data points. To constrain the model parameters, firstly, we employed Python’s scipy optimization approach and estimated the global minima for the Hubble function in equation (20). The considerable variances in the diagonal elements of the covariance matrix pertaining to the parameters are noticed. Then, we used Python’s emcee module for the numerical analysis and considered the above estimates as means and a Gaussian prior with a fixed \( \sigma = 1.0 \) as the dispersion. As a result, we investigated the parameter space surrounding the local minima (or estimates). The method employed with two datasets is explored in greater detail below, with the findings displayed as two-dimensional contour plots with \( 1 - \sigma \) and \( 2 - \sigma \) errors.

A. Hz datasets

The Hubble parameter, \( H = \frac{\ddot{a}}{a} \), where (\( \ddot{a} \)) represents derivative with respect to cosmic time \( t \). The Hubble parameter is used to analyse the expansion of the universe in observational cosmology. The Hubble parameter can be stated as \( H(z) = -\frac{1}{1+z} \frac{dz}{dt} \) as a function of redshift, where \( dz \) is obtained through spectroscopic surveys. In contrast, the measurement of \( dt \) gives the model-independent value of the Hubble parameter. For estimating the value of the \( H(z) \) at a specific redshift, two approaches are extensively used. The extraction of \( H(z) \) from the line-of-sight BAO data is one, while another is the differential age methodology [55]-[73]. Here, we use the revised set of 57 data points from the reference, which includes 31 points from the differential age (DA) approach and the left 26 points measured using BAO and other methods of redshift range \( 0.07 \leq z \leq 2.42 \) [74]. In addition, we used \( H_0 = 67.8 \text{ km/s/Mpc} \) for our analysis. We also used the chi-square function to find the mean values of the model parameters \( \tilde{\zeta}_0, \tilde{\zeta}_1, \alpha, \beta, \) and \( C \) (equivalent to the maximum likelihood analysis).

\[
\lambda_H^2(\tilde{\zeta}_0, \tilde{\zeta}_1, \alpha, \beta, C) = \sum_{i=1}^{57} \frac{[H_{th}(z_i, \tilde{\zeta}_0, \tilde{\zeta}_1, \alpha, \beta, C) - H_{obs}(z_i)]^2}{\sigma_{H(z_i)}^2},
\]

where \( H_{th} \) represents the theoretical value of the Hubble parameter and \( H_{obs} \) represents the observed value. The standard error in the observed value of the Hubble parameter is represented by \( \sigma_{H(z_i)} \). Here, Table-1 contains the 57 points of Hubble parameter values \( H(z) \) with errors \( \sigma_{H(z)} \) from differential age (31 points), and BAO and other (26 points) approaches, along with references.

We obtained the best fit values of the model parameters $\zeta_0$, $\zeta_1$, $\alpha$, $\beta$, and $C$ as a two dimensional contour plots with $1 - \sigma$ and $2 - \sigma$ errors in fig. 3 using the above stated Hubble datasets consisting of the 57 points as tabulated in Table-1. The best fit obtained values are $\zeta_0 = 10.8^{+1.10}_{-1.10}$, $\zeta_1 = 0.051^{+0.017}_{-0.046}$, $\alpha = -1.6^{+0.74}_{-0.30}$, $\beta = -9.38^{+0.27}_{-1.30}$, and $C = 7.66^{+0.95}_{-1.10}$. In addition, we have observed the curve fit of the model with error bars for the aforementioned Hubble datasets in fig 1 as well as our resulting model compared to the $\Lambda$CDM model (with $\Omega_{\Lambda 0} = 0.7$ and $\Omega_{m0} = 0.3$). Our model fits the observational Hubble datasets well, as shown in the plot.
FIG. 1. The plot shows the evolution of the Hubble function $H(z)$ vs. redshift $z$. The red line shown in the curve is our obtained model. The blue dots shown are the Hubble datasets consisting of 57 data points with their corresponding error bars, and also the black dashed line depicts the $\Lambda$CDM model with $\Omega_{\Lambda 0} = 0.7$ & $\Omega_{m0} = 0.3$.

B. Pantheon datasets

The pantheon sample, which contains 1048 data points, is the most recently released supernovae type Ia datasets. We used this sample [75] of spectroscopically confirmed SNe Ia data points covering the redshift range $0.01 < z < 2.26$. These data points give the estimation of the distance modulus $\mu_i = \mu^{\text{obs}}_i$ in the redshift range $0 < z_i \leq 1.41$. We compare the theoretical $\mu^\text{th}_i$ value and observed $\mu^{\text{obs}}_i$ value of the distance modulus to find the best fit for our model parameters of the derived model. The distance moduli are the logarithms $\mu^\text{th}_i = \mu(D_L) = m - M = 5 \log_{10}(D_L) + \mu_0$ where $m$ and $M$ denote apparent and absolute magnitudes, respectively, and $\mu_0 = 5 \log(H_0^{-1}/Mpc) + 25$ is the marginalised nuisance parameter. The luminosity distance is considered to be

$$D_L(z) = \frac{c(1+z)}{H_0} S_k \left( H_0 \int_0^z \frac{1}{H(z')} dz' \right),$$

where $S_k(x) = \begin{cases} \sinh(x\sqrt{\Omega_k})/\Omega_k, & \Omega_k > 0 \\ x, & \Omega_k = 0 \\ \sin x\sqrt{|\Omega_k|}/|\Omega_k|, & \Omega_k < 0 \end{cases}$.

Here, $\Omega_k = 0$ (flat space-time). We estimated distance $D_L(z)$ and chi square function to measure the difference between the SN Ia observational data and the predictions of our model. The $\chi^2_{5N}$ function for the Pantheon datasets is taken to be,

$$\chi^2_{5N}(\mu_0, \zeta_0, \zeta_1, \alpha, \beta, C) = \sum_{i=1}^{1048} \frac{[\mu^\text{th}(\mu_0, z_i, \zeta_0, \zeta_1, \alpha, \beta, C) - \mu^{\text{obs}}(z_i)]^2}{\sigma^2_{\mu(z_i)}},$$

(22)

$\sigma^2_{\mu(z_i)}$ is the standard error in the observed value. We have determined the best fit values of the model parameters $\zeta_0$, $\zeta_1$, $\alpha$, $\beta$, and $C$ using the aforementioned Pantheon datasets as two dimensional contour plots with $1 - \sigma$ & $2 - \sigma$ errors in fig. 3. The obtained best fit values are $\zeta_0 = 11.0^{+1.0}_{-0.9}$, $\zeta_1 = 0.0504^{+0.0098}_{-0.008}$, $\alpha = -1.36^{+0.84}_{-0.44}$, $\beta = -9.88^{+0.77}_{-1.10}$, and $C = 7.4^{+1.0}_{-1.2}$ with 1048 points of Pantheon datasets. Furthermore, in fig 2, we observed our derived model curve fitting for the mentioned Pantheon datasets along with the error bars and compared to the $\Lambda$CDM model (with $\Omega_{\Lambda 0} = 0.7$ and $\Omega_{m0} = 0.3$). The plot depicts a good match of our model to the Pantheon observational datasets.
FIG. 2. The plot depicts the variation of $\mu(z)$ vs. $z$ for our model shown in red line. The black dotted line is the curve for the $\Lambda$CDM model. Both show a nice fit to the Pantheon sample consisting of 1048 data points with the corresponding error bars.
FIG. 3. The two dimensional contour plots for the model parameters $\zeta_0, \zeta_1, \alpha, \beta,$ and $C$ with $1 - \sigma$ and $2 - \sigma$ errors. It also includes the best fit values of the model parameters obtained from the Hubble datasets consisting of 57 points and the Pantheon samples of 1048 points.

V. COSMOLOGICAL PARAMETERS

The behavior of energy density $\rho$ and effective pressure $\tilde{p}$ is shown in plots 4 and 5. It is observed that energy density is an increasing function of $z$, and the effective pressure is strongly negative. The negative pressure is due to the bulk viscosity considered, which
indicates the expanding accelerated phase of the universe.

The deceleration parameter as a function of Hubble parameter $H(z)$ is given by

$$q = -1 - \frac{H}{H_0^2}. \quad (23)$$

It describes the rate of expansion and acceleration or deceleration of the universe. If $q < 0$, the universe is at a decelerated phase, else $q < 0$ corresponds to an accelerated phase. The deceleration parameter $q$ is obtained from the eq. (23) contains the model parameters $\zeta_0, \zeta_1, \alpha, \beta, \rho$, and $C$. The following plot shows the behavior of $q$ with respect to redshift $z$, explaining the evolution from past to present. Considering the constrained values of model parameters from the two considered datasets, $q$ transit from positive in the past, i.e., early deceleration, to negative at present, indicating the present acceleration. The present value of $q$ obtained from Hubble dataset and Pantheon sample is $q_0 = -0.55^{+1.32}_{-2.52}$ and $q_0 = -0.64^{+1.45}_{-4.87}$ respectively[52, 53]. So, the value obtained from the Pantheon sample is consistent with the $\Lambda$CDM model at $1 - \sigma$ level.
representing the quintessence phase whereas $\omega$ below $-1$ is known as phantom regime.

According to constrained values of model parameters $\zeta_0, \zeta_1, \alpha, \beta$ and $C$ from Hubble data and Pantheon sample, the behavior of the EoS parameter is shown in fig. 7. It is observed that the EoS parameter remains in the quintessence phase supporting the acceleration in the universe. The present value of $\omega$ is obtained as $\omega_0 = -0.86^{+0.41}_{-0.62}$ and $\omega_0 = -0.90^{+0.41}_{-0.79}$ [54] for Hubble data and Pantheon sample respectively.

VI. CONCLUSIONS

This article examined the evolution of the universe in the FLRW framework with the non-relativistic bulk viscous matter in modified $f(Q, T)$ gravity theory. We have considered the bulk viscosity term as $\xi = \zeta_0 + \zeta_1 H$, where $H$ is the Hubble parameter, $\zeta_0$ and $\zeta_1$ are constants. In the presence of bulk viscosity and assuming the function form $f(Q, T) = \alpha Q + \beta T$, where $\alpha$ and $\beta$ are constants, we obtained the exact solutions to field equations. The solution in the form of Hubble parameter contains $\zeta_0$, $\zeta_1$, $\alpha$, $\beta$ and $C$ parameters. Further, we use 57 Hubble data points and 1048 Pantheon samples to constrain the model parameters $\zeta_0$, $\zeta_1$, $\alpha$, $\beta$ and $C$. As a result, MCMC techniques is used to find the best values for these model parameters. The best values are

Hubble datasets:

\[ \zeta_0 = 10.8^{+1.10}_{-1.10}, \quad \zeta_1 = 0.051^{+0.017}_{-0.046}, \quad \alpha = -1.69^{+0.74}_{-0.50}, \quad \beta = -9.38^{+0.77}_{-1.30}, \quad C = 7.66^{+0.95}_{-1.10} \]

Pantheon datasets:

\[ \zeta_0 = 11.0^{+1.0}_{-1.0}, \quad \zeta_1 = 0.0504^{+0.0098}_{-0.0500}, \quad \alpha = -1.36^{+0.84}_{-0.44}, \quad \beta = -9.88^{+0.77}_{-1.10}, \quad C = 7.4^{+1.0}_{-1.2} \]

It is found that our model agrees well with the $\Lambda$CDM model as shown in fig 1 and fig 2.

We investigated the behavior of cosmological parameters for the above best fit-values of model parameters. The density shows the increasing positive behavior, whereas effective pressure is highly negative due to the bulk viscosity. The deceleration parameter depicts a transition from positive in the past to negative in the present showing the current accelerated expansion of the universe. The present value of $q$ is obtained as $q_0 = -0.55^{+1.32}_{-2.55}$ and $q_0 = -0.64^{+1.45}_{-4.87}$ for Hubble data and Pantheon samples respectively. The EoS parameter, on the other hand, is in the quintessence region, indicating that the universe is accelerating. We obtained $\omega_0 = -0.86^{+0.41}_{-0.62}$ and $\omega_0 = -0.90^{+0.41}_{-0.79}$ for Hubble data and Pantheon samples respectively. According to the obtained values of cosmological parameters and behavior, it can be said that the model considered here is stable and the bulk viscosity theory is a viable choice for describing the late-time acceleration of the universe in $f(Q, T)$ gravity. This encourages us to investigate the cosmic implications and stability of the newly proposed $f(Q, T)$ gravity in different aspects.
