SUPER-RIGIDITY AND BIFURCATIONS OF EMBEDDED CURVES IN CALABI–YAU 3-FOLDS

SHAOYUN BAI AND MOHAN SWAMINATHAN

ABSTRACT. We study certain bifurcations of moduli spaces of embedded pseudo-holomorphic in symplectic Calabi–Yau 3-folds and associated obstruction bundles. As a corollary, we give a direct definition of the Gopakumar–Vafa invariant in a special case.

1. Introduction

Let \((X, \omega)\) be a symplectic Calabi–Yau 3-fold, i.e., it is a closed symplectic manifold of (real) dimension 6 with \(c_1(TX, \omega) = 0 \in H^2(X, \mathbb{Z})\). After choosing an \(\omega\)-compatible almost complex structure \(J \in J(X, \omega)\), the genus \(g\) Gromov–Witten invariant of \((X, \omega)\) of class \(0 \neq A \in H_2(X, \mathbb{Z})\) with no marked points, denoted by \(GW_{A,g}(X)\), is defined by certain counts of \(J\)-holomorphic maps into \(X\) and it is independent of \(J\). In general, \(GW_{A,g}(X) \in \mathbb{Q}\) because of the non-triviality of the automorphism groups of certain \(J\)-holomorphic maps. Nonetheless, they are determined by the \(\mathbb{Z}\)-valued BPS numbers \(n_{A,h}(X)\) via the formula

\[
\sum_{A \neq 0} \sum_{g \geq 0} GW_{A,g}(X)t^{2g-2}q^A = \sum_{A \neq 0} n_{A,h}(X) \sum_{h \geq 0} \left( \sum_{k=1}^{\infty} \frac{1}{k} \left( \frac{2\sin \left( \frac{kt}{2} \right)}{kt} \right)^{2h-2} q^{kA} \right),
\]

(1.1)

conjectured by Gopakumar–Vafa [GV98] and proved by Ionel–Parker [IP18].

However, Ionel–Parker’s proof of \(n_{A,h}(X) \in \mathbb{Z}\) does not illustrate the meaning of these Gopakumar–Vafa invariants. When \((X, \omega)\) is further assumed to be a smooth projective variety, Maulik–Toda [MT18] propose a sheaf-theoretic definition of the Gopakumar–Vafa invariants, based on earlier works of Hosono–Saito–Takahashi [HST01] and Kiem–Li [KL12]. Despite the beauty of the definition, it is not known how to prove the deformation invariance of Maulik–Toda’s ansatz and the proof of formula (1.1) using this definition seems to be out of reach in general. Moreover, the sheaf-theoretic definition relies crucially on the algebraicity of \(X\), making it hard to generalize it to general symplectic Calabi–Yau 3-folds (equipped with not necessarily integrable almost complex structures).

There are several pieces of evidence indicating that the BPS numbers \(n_{A,h}(X)\) should be related to certain counts of embedded \(J\)-holomorphic curves in \(X\). The following is Conjecture 7.4.5 in Cox–Katz’s book [CK99].

**Conjecture 1.1.** Suppose \((X, \omega)\) is a symplectic Calabi–Yau 3-fold. For a generic almost complex structure \(J\) tamed by \(\omega\), we have:

1. For any homology class \(A \in H_2(X, \mathbb{Z})\), there are finitely many immersed \(J\)-holomorphic curves of genus 0 and class \(A\). These curves are embedded, and no two intersect.
(2) All $J$-holomorphic maps $\Sigma \to X$ of genus 0 are multiple covers of the above embeddings.

(3) For each $A \in H_2(X, \mathbb{Z})$, the BPS number $n_{A,0}(X)$ satisfies
\[ n_{A,0}(X) = n'_{A,0}(X) + \sum_{k \in \mathbb{Z}_{\geq 2}} \sum_{B \in M_0^c(X, J, B)} c(k, C), \]
where $n'_{A,0}(X)$ is the signed count of embedded $J$-curves of genus 0 and class $A$ and each $c(k, C)$ is an integer determined by degree $k$ covers of the embedded curve $C$.

In fact, Katz proposes an algebro-geometric counterpart of the above conjecture in [Kat08] using Donaldson–Thomas invariants. For a second piece of evidence, Ionel–Parker [IP18, Equation (8.1)] prove that the Gromov–Witten generating function satisfies
\[ \sum_{A \neq 0, g \geq 0} GW_{A,g}(X) t^{2g-2} q^A = \sum_{A \neq 0, g \geq 0} e_{A,g}(X) \cdot GW^{\text{elem}}_g(q^A, t) \tag{1.2} \]
where $GW^{\text{elem}}_g$ is some universal generating series and $e_{A,g}(X) \in \mathbb{Z}$ is regarded as a “virtual count of embedded clusters in $X$”. They also show that $n_{A,h}(X)$ and $e_{A,g}(X)$ actually determine each other via the formula [IP18, Equation (8.9)]
\[ n_{A,h}(X) = \sum_{B \in \mathbb{Z}_{\geq 2}} \sum_{g=0}^h n_{d,h}(g) \cdot e_{B,g}(X) \tag{1.3} \]
where $n_{d,h}(g) \in \mathbb{Z}$ are certain universal coefficients determined by $d, h, g$. In other words, Ionel–Parker’s proof hints that $n_{A,h}(X)$ should be a weighted sum of counts of embedded $J$-holomorphic curves. As a third piece of evidence, results of Zinger [Zin11] and Doan–Walpuski [DW19] show that $n_{A,h}(X)$ indeed comes from counts of embedded $J$-holomorphic curves when $A$ is a primitive homology class.

In view of these results, it is natural to ask the following pair of questions.

**Question 1.2.** Given a symplectic Calabi–Yau 3-fold $(X, \omega)$ and $J \in \mathcal{J}(X, \omega)$, how to define symplectic invariants by counting embedded $J$-holomorphic curves in $X$? How to related these counts to the Gromov–Witten invariants and the Gopakumar–Vafa invariants?

The analogous question in real dimension 4 for all symplectic 4-manifolds was answered using Taubes’ Gromov invariants in [Tau00]. Taubes’ construction is generalized to immersed curves by Ionel–Parker in [IP97] and the comparison with Gromov–Witten invariants is made in the same paper.

Question 1.2 seemed to be out of reach until Wendl’s recent breakthrough [Wen19] on the generic super-rigidity (see Definition 2.13) conjecture. Wendl shows that for a generic $J \in \mathcal{J}(X, \omega)$, all $J$-holomorphic maps $\Sigma \to X$ have no non-trivial (first order) normal deformations. As a result, (1) and (2) of Conjecture 1.1 are answered affirmatively for all genera.

The finiteness result is a necessary preliminary for counts of embedded $J$-curves. But the naive count of embedded $J$-curves, even after taking into account the signs coming from the orientations of relevant moduli spaces, fails to be an invariant independent of $J$ in general since bifurcations may occur. Indeed, given a generic 1-parameter family of $\{J_t\}_{t \in [-1,1]}$, super-rigidity could fail over a discrete subset
Given $t_0 \in \mathcal{F}$ and a sequence $t_i \to t_0$, there could be a sequence of embedded $J_{t_i}$-holomorphic curves $\Sigma_{t_i}$ that converges to a multiply-covered $J_{t_0}$-holomorphic map $\Sigma_{t_0} \to X$. Similar problems arise in special Lagrangian geometry [Joy02] and the study of associative submanifolds in Riemannian manifolds with holonomy group $G_2$ [Joy16].

Based on a detailed analysis of local Kuranishi models, our first main result shows that bifurcations of embedded $J$-holomorphic curves do occur for any generic 1-parameter family $\{J_t\}_{t \in [-1,1]}$ passing through the codimension 1 locus in $\mathcal{J}(X,\omega)$ where super-rigidity fails to hold. Moreover, the change of the signed count of the corresponding embedded curves is computed.

**Theorem 1.3** (see Theorem 3.4). Let $\{J_t\}_{t \in [-1,1]}$ be a generic path in $\mathcal{J}(X,\omega)$. Assume that there exists an embedded rigid $J_0$-curve $\Sigma \hookrightarrow X$ along with a $d$-fold genus $h$ branched multiple cover $\varphi: \Sigma' \to \Sigma$ which has non-trivial normal deformations. If this cover determines an elementary wall type (see Definition 3.1), then $\text{Aut}(\varphi) \subset \mathbb{Z}/2\mathbb{Z}$ and, moreover, the change in the signed count of embedded curves of genus $h$ and class $[\Sigma]$ near $\varphi$ is given by $\pm 2/|\text{Aut}(\varphi)|$.

**Remark 1.4.** The technical condition of “elementary wall type” is satisfied in practice by a large class of examples (see Example 3.3).

As far as we know, this is the first general result studying equivariant bifurcations of pseudo-holomorphic curves in dimension 6. The result applies to branched covers, which generalizes Taubes' study of bifurcations of embedded pseudo-holomorphic tori in dimension 4 arising from unbranched covers [Tau00]. We point out that our setup and arguments have many formal similarities with other moduli problems of calibrated submanifolds [Don19], see Remark 3.5.

Wendl’s result on generic super-rigidity also allows one to compute the Gromov–Witten invariants as the sum of the so-called local Gromov–Witten invariants from $J$-holomorphic maps with images contained in a fixed embedded curve. Our second main result computes the variations of these local contributions in a precise form.

**Theorem 1.5** (see Theorem 5.4). Suppose $N \to C$ is a rank 2 complex vector bundle of degree $2g - 2$ on a curve $C$ of genus $g$. Let $\mathcal{D} = \{D_t\}_{t \in [-1,1]}$ be a generic 1-parameter family of Cauchy–Riemann operators on $N$. Fix integers $d \geq 2$, $h \geq g$ and consider the moduli stack $\mathcal{M}_{h}(C,d)$ of stable genus $h$ maps to $C$ of degree $d$. Assume further that $\mathcal{D}$ is $(d,h)$-rigid (see Definition 5.2) except over a finite set $\Delta \times \{0\} \subset \mathcal{M}_{h}(C,d) \times [-1,1]$.

Then, the assignment

$$\Delta \times \{0\} \subset \mathcal{M}_{h}(C,d) \times [-1,1]. \quad (1.4)$$

Then, the assignment

$$[f: C' \to C] \in \mathcal{M}_{h}(C,d) \mapsto \text{coker} (f^*D_t) \quad (1.5)$$

gives a well-defined vector bundle on $\mathcal{M}_{h}(C,d)$, equipped with a natural orientation, for small $t \neq 0$. Denote the Euler number of this bundle by $e_{d,h}(C,D_{\pm})$ for small $\pm t > 0$. Then, we have

$$e_{d,h}(C,D_+) - e_{d,h}(C,D_-) = \sum_{p \in \Delta} \frac{2 \cdot \text{sgn}(D,p)}{|\text{Aut}(p)|} \quad (1.6)$$

where $\text{sgn}(D,p) \in \{-1, +1\}$ are determined by the local behavior of $D$ near $p$. 

The proof of Theorem 1.5 relies on certain formal properties of virtual fundamental cycles of spaces equipped with an implicit atlas in the sense of [Par16] (Lemma 5.5) and a concrete local computation (Lemma 5.6).

The third main result of this paper proves part (3) of Conjecture 1.1 when the homology class is two times a primitive homology class.

**Theorem 1.6** (See Theorems 6.11 and 6.14). Given any primitive homology class $A \in H_2(X, \mathbb{Z})$, the Gopakumar–Vafa invariant $n_{2A,0}(X)$ of genus 0 and class $2A$ is a virtual count of embedded $J$-holomorphic curves when $J$ is super-rigid.

We remark that the ideas of the construction of the weight function $w_2(\cdot)$ in Definition 6.10 have been used in various gauge-theoretic problems before, including the construction of the SU(3)–Casson invariants [BH98] and the definition of the Seiberg–Witten invariants for homology $S^1 \times S^3$ [MRS11].

We do not give a full solution to Conjecture 1.1 or Question 1.2 because of the following obstacles. Although the statement of the bifurcation result Theorem 1.3 includes essentially all places where an equivariant bifurcation could occur, the conclusion is concerned with minimal covers. It is not a priori clear whether embedded curves could be constructed from a larger cover. Moreover, our Kuranishi analysis is carried out for curves with smooth domains, but it is possible that embedded curves could be constructed from suitably perturbing nodal curves. Considering the second half of Question 1.2, the geometric meaning of the invariants $GW_{A,g}(X)$ as an enumeration of $J$-holomorphic curves is difficult to understand due to the existence of multiply-covered $J$-holomorphic maps and maps with ghost components. Regarding the contributions from multiple covers to $GW_{A,g}$, the Aspinwall–Morrison formula [Voi96] gives a complete answer for $g = 0$. As for separating out the contribution of $J$-holomorphic maps with ghost components, Zinger’s reduced Gromov–Witten invariants [Zin08] give the solution when $g = 1$. General multiply-covered formulas and ghost contribution formulas are needed to make comparisons of various conjectural/existing invariants. We hope to address these issues in future work.

We end the introduction by outlining the structure of this paper. In Section 2, we recall the necessary background from Wendl’s paper [Wen19] adapted to our setting. Section 3 states our main bifurcation result Theorem 1.3 and gives examples to which the bifurcation analysis can be applied. The proof of Theorem 1.3 is carried out in Section 4. Section 5 analyzes the change of Euler numbers while Section 6 defines the invariant $n_{2A,0}(X)$ and makes the expected comparisons.

**Acknowledgements.** The authors thank their advisor John Pardon for his constant support and encouragement. We also thank Aleksander Doan, Eleny Ionel, Thomas Walpuski and Chris Wendl for useful discussions and correspondences. The second named author would also like to thank Sridhar Venkatesh for the constructions in Example 3.3.

2. **Background**

In this section, we will summarize the background on super-rigidity in a form relevant for our discussion. The notation closely follows that of [Wen19, §2]. We will begin by recalling some basic facts about branched covers of curves and Cauchy–Riemann operators (in §2.1) and then move onto super-rigidity (in §2.2).
2.1. Cauchy–Riemann operators and Galois covers. We will consistently use the word ‘curve’ to mean ‘irreducible smooth projective algebraic curve over \(\mathbb{C}\)’ (i.e. a closed connected smooth Riemann surface). A ‘morphism’ between curves will mean a ‘non-constant holomorphic map’.

**Definition 2.1** (Function field). Let \(\Sigma\) be a curve. Define \(\mathbb{C}(\Sigma)\) to be the function field of \(\Sigma\) (i.e., the field of meromorphic functions on \(\Sigma\)). Given a degree \(d \geq 1\) morphism of curves \(\varphi : \Sigma' \to \Sigma\), we get the associated degree \(d\) field extension \(\varphi^* : \mathbb{C}(\Sigma) \to \mathbb{C}(\Sigma')\). It is a basic fact from algebraic geometry that this is a contravariantly functorial one-to-one correspondence (i.e. an equivalence of categories) between curves and fields of transcendence degree 1 over \(\mathbb{C}\).

**Definition 2.2** (Galois closure). Let \(\varphi : \Sigma' \to \Sigma\) be a morphism of curves. We say that \(\varphi\) is Galois if and only if the associated field extension is Galois. In general, \(\varphi\) may not be Galois and we can form the Galois closure, a morphism \(\tilde{\Sigma} \to \Sigma'\), by taking the Galois closure of the function field extension \(\varphi^* : \mathbb{C}(\Sigma) \to \mathbb{C}(\Sigma')\). For a Galois cover \(\tilde{\Sigma} \to \Sigma\), we define the Galois group \(\text{Gal}(\tilde{\Sigma}/\Sigma)\) to be the group of automorphisms of \(\tilde{\Sigma}\) over \(\Sigma\) (or equivalently the Galois group of the associated function field extension).

Given a morphism \(\varphi : \Sigma' \to \Sigma\) of curves, we call its critical points as ramification points and its critical values as branch points. Away from the ramification points, \(\varphi\) restricts to a covering map with connected domain over the complement of the branched points, which is called the associated covering space. It is a basic fact that \(\varphi : \Sigma' \to \Sigma\) is Galois if and only if the associated covering space is normal. Also, the associated covering space of the Galois closure of \(\varphi\) is the normal closure of the associated covering space of \(\varphi\).

**Definition 2.3** (Branched covers and Galois groups). Let the following data be given: integers \(g \geq 0\) and \(d \geq 2\) and branching data \(b = (b_1, \ldots, b_r)\) where each \(b_i = (b^{(1)}_i, \ldots, b^{(r)}_i)\) is a tuple of positive integers adding up to \(d\) with at least one \(b^j_i \geq 2\). Define

\[
b = \sum_{i=1}^{r} \sum_{j=1}^{q_i} (b^j_i - 1)\tag{2.1}
\]

and define \(h\) using the formula \(2h - 2 = b + d(2g - 2)\). Assume that \(h\) is a non-negative integer. Now, let \(\varphi : \Sigma' \to \Sigma\) be a morphism of curves of type \((g, b)\), i.e., \(h = \text{genus}(\Sigma'), g = \text{genus}(\Sigma), d = \text{deg}(\varphi)\) and \(\varphi\) has exactly \(r\) critical values \(w_1, \ldots, w_r \in \Sigma\) with \(\varphi^{-1}(w_i) = \{\zeta^1_i, \ldots, \zeta^r_i\}\) and \(\varphi\) is \(b^j_i\)-to-1 in a punctured neighborhood of each \(\zeta^j_i \in \Sigma'\). We define the generalized automorphism group of \(\varphi\) to be the Galois group of the Galois closure of \(\varphi\).

Given a finite group \(G\) and a genus \(g\) curve \(\Sigma\), define \(\mathcal{M}^g_{\Sigma,G}(\Sigma)\) to be the orbifold of pairs \((\varphi : \Sigma' \to \Sigma, i)\), up to isomorphism, where \(\varphi\) is a morphism of type \((g, b)\) and \(i\) is an isomorphism of \(G\) with the generalized automorphism group of \(\varphi\).

We will next discuss Cauchy–Riemann operators on curves and their pullbacks along Galois covers. Denote by \(E\) a complex vector bundle over a curve \(\Sigma\).

**Definition 2.4** (Serre dual). Let \(D : \Omega^0(\Sigma, E) \to \Omega^{0,1}(\Sigma, E)\) be an \(\mathbb{R}\)-linear Cauchy–Riemann operator. Define the Serre dual bundle of \(E\) to be

\[
E^\dagger = \Lambda^{1,0}T^*_\Sigma \otimes_{\mathbb{C}} E^*\tag{2.2}
\]
and the Serre dual operator $D^\dagger$ to be the $\mathbb{R}$-linear Cauchy–Riemann operator on $E^\dagger$ determined by the following condition: for all $s \in \Omega^0(\Sigma, E)$ and $s^\dagger \in \Omega^0(\Sigma, E^\dagger)$,
\[
\int_\Sigma \langle Ds, s^\dagger \rangle + \langle s, D^\dagger s^\dagger \rangle = 0.
\] (2.3)

The pairing $\langle \cdot, \cdot \rangle$ followed by integration gives the Serre duality isomorphisms
\[
\ker D^\dagger = (\coker D)^* \quad \text{(2.4)}
\]
\[
\ker D = (\coker D^\dagger)^* \quad \text{(2.5)}
\]

**Definition 2.5** (Twisted operators). Let $D : \Omega^0(\Sigma, E) \to \Omega^{0,1}(\Sigma, E)$ be an $\mathbb{R}$-linear Cauchy–Riemann operator on the curve $\Sigma$ and let $\psi : \tilde{\Sigma} \to \Sigma$ be a Galois cover with Galois group $G = \text{Gal}(\tilde{\Sigma}/\Sigma)$. We can then form the pullback operator
\[
\psi^* D : \Omega^0(\tilde{\Sigma}, \psi^* E) \to \Omega^{0,1}(\tilde{\Sigma}, \psi^* E)
\] (2.6)
which is $G$-equivariant with respect to the natural linear $G$-actions on the source and target. Let $\theta$ be a linear $G$-representation over $\mathbb{R}$. We define the twisted operator $D_{\psi, \theta}$ to be the one obtained by applying $\text{Hom}^G(\theta^*, -)$ to the operator (2.6). The operator $D_{\psi, \theta}$ is naturally linear over the endomorphism algebra $\mathbb{K}_\theta = \text{End}^G(\theta)$.

**Remark 2.6.** This definition is easily seen to be equivalent to the twisted operators from [Wen19, §2.2 and §3.4] since taking $G$-invariant sections of $\theta \otimes \psi^* E$ on $\tilde{\Sigma}$ amounts to taking sections of $(\tilde{\Sigma} \times V)/G$ on the orbifold $\Sigma/G$ (which has a natural map to $\Sigma$ being an isomorphism except over the branch points).

**Remark 2.7.** Suppose $G \to G'$ is a quotient map between groups, corresponding to a factorization $\tilde{\Sigma} \xrightarrow{\varphi} \Sigma' \xrightarrow{\psi} \Sigma$ of $\psi$ as the composition of two Galois covers $\varphi$, $\psi'$ and $G' = \text{Gal}(\Sigma'/\Sigma)$. Also, suppose that $\theta'$ is a $G'$-representation and that $\theta$ is its pullback to $G$. Then, $\varphi^*$ gives a natural map of complexes from $D_{\psi, \theta}$ to $D_{\psi', \theta}$ and this map is easily seen to be a quasi-isomorphism (using the removable singularity theorem near the branch points of $\varphi$ for $D$ and $D^\dagger$). Similarly, if $H \subset G$ is any subgroup and $\Sigma' = \tilde{\Sigma}/H$ with the associated morphism $\psi' : \Sigma' \to \Sigma$, then the natural pullback map from $(\psi')^* D$ to $(\psi^* D)^H$ is also a quasi-isomorphism (i.e. an isomorphism on kernels and cokernels).

The following result, which appears in [DW20, Remark 1.4.15] in a slightly different form, will also be useful for the discussion below.

**Lemma 2.8.** Let $\theta_i$ for $i = 1, \ldots, p$ be an enumeration of all the irreducible representations of $G$ over $\mathbb{R}$ with $\mathbb{K}_i = \text{End}^G(\theta_i)$. Then, the tautological map
\[
\bigoplus_i \theta_i^* \otimes_{\mathbb{K}_i} D_{\psi, \theta_i} \to \psi^* D
\] (2.7)
of $G$-equivariant two term complexes is a quasi-isomorphism.

**Proof.** This is because for any finite dimensional $\mathbb{R}[G]$-module $V$, the tautological map $\bigoplus_i \Theta_i^* \otimes_{\mathbb{K}_i} \text{Hom}^G(\theta_i^*, V) \to V$ is an isomorphism of $\mathbb{R}[G]$-modules by Maschke’s theorem. We apply this to the (co)kernels of the operators in question. \qed

Given a family of curves and a corresponding family of Cauchy–Riemann operators, we introduce the following definition which measures the variation of the Cauchy–Riemann operators on a particular finite-dimensional vector space. It will be used later in the analysis of Kuranishi maps.
**Definition 2.9.** Let $\pi : C \to B$ be a smooth family of curves, i.e., $\pi$ is a proper submersion with fibers of $\mathbb{R}$-dimension 2 along with a smooth endomorphism $j$ of $\ker(d\pi) = T_C|_B$ satisfying $j^2 = -1$. Let $E \to C$ be a $\mathbb{C}$-vector bundle and set

$$F = \Lambda^{0,1}T^*_C/B \otimes \mathbb{C} E.$$  

Assume that we have a smooth family $D = \{D_b\}_{b \in B}$ of Cauchy–Riemann operators

$$D_b : \Omega^0(C_b, E_b) \to \Omega^0(C_b, F_b)$$

where $C_b = \pi^{-1}(b)$, $E_b = E|_{C_b}$ and $F_b = F|_{C_b}$ for $b \in B$. For any point $a \in B$, define the linearized map at a associated to the family $D$

$$D'|_a : T_a B \to \text{Hom}(\ker D_a, \text{coker } D_a)$$

as follows. Given $\sigma \in \ker D_a$, extend it arbitrarily to a section $\tilde{\sigma} \in \Omega^0(C, E)$. Then, the section $\tilde{\tau} = D(\tilde{\sigma}) \in \Omega^0(C, F)$ defined by $\tilde{\tau}|_{C_b} = D_b(\tilde{\sigma}|_{C_b})$ for $b \in B$ vanishes along $C_a$ and thus, has a well-defined normal derivative

$$\nabla \tilde{\tau}|_a \in \text{Hom}(N(C_a/C), F_a) = \text{Hom}(T_aB, \Omega^0(C_a, F_a))$$

(2.11)

where we have used the identification $N(C_a/C) = \pi^*(T_aB)$ in the last equality. Now, for any $v \in T_aB$ we set $D'|_a(v) \cdot \sigma \in \text{coker } D_a$ to be the projection of the section $\nabla \tilde{\tau}|_a \cdot v = \nabla \tilde{\tau}|_a \cdot v$ for all $v \in T_aB$. If a finite group $G$ acts compatibly on $B$, $C$, $E$, $F$, with the action on $B$ being trivial, such that the family $D$ is $G$-equivariant, then (2.10) factors through $\text{Hom}^G(\ker D_a, \text{coker } D_a)$.

**Remark 2.10.** It is easily seen from Definition 2.9 that we can define the linearized map $D'|_a$ by first choosing suitable trivializations to regard $D$ as a family of $G$-equivariant operators

$$b \mapsto D_b : \Omega^0(C_b, E_b) \to \Omega^0(C_b, F_b)$$

(2.13)

and setting $D'|_a(v) \cdot \sigma$ to be the projection of $\left[\frac{d}{dt} D_{\gamma(t)}(\sigma)|_{t=0}\right]$ onto $\text{coker } D_a$, where $\gamma$ is any smooth path in $B$ with $\gamma(0) = a$ and $\dot{\gamma}(0) = v$.

### 2.2. Review of super-rigidity.

**Definition 2.11** (Normal deformation operator). Let $J \in \mathcal{J}(X, \omega)$ and let $C \subset X$ be a smooth closed embedded $J$-curve, i.e. the tangent bundle of $C$, written as $T_C$, is invariant under the $J$–action. The normal bundle $N_C = T_X|_C/T_C$ is then naturally a complex vector bundle. The linearized Cauchy–Riemann operator on $T_X|_C$ descends to an operator

$$D_{C,J}^N : \Omega^0(C, N_C) \to \Omega^{0,1}(C, N_C)$$

(2.14)

called the normal deformation operator of the embedded curve $C$.

**Remark 2.12.** It is a basic fact (see [DW20, Theorem 2.1.18] for example) that away from a codimension 2 subset of $\mathcal{J}(X, \omega)$, all simple $J$-curves are embedded and pairwise disjoint. Thus, along generic paths $\gamma \subset \mathcal{J}(X, \omega)$, we may assume that all simple curves are embedded and pairwise disjoint.
Definition 2.13 (Super-rigidity). Given an embedded $J$-curve $C \subset X$ as in Definition 2.11, we say that it is super-rigid if for all holomorphic (possibly branched) covers $\varphi : C' \to C$, the pullback operator
\[ \varphi^* D^N_{C,J} : \Omega^0(C', \varphi^* N_C) \to \Omega^0(\Sigma, \varphi^* N_C) \]
(2.15)
is injective. We say that a given almost complex structure $J \in \mathcal{J}(X, \omega)$ is super-rigid if and only if every simple $J$-curve is embedded and every embedded $J$-curve is super-rigid.

Definition 2.14 (Loci of failure of super-rigidity). Fix $g, d, b$ as in Definition 2.3 and a finite group $G$. Now, given $A \in H_2(X, \mathbb{Z})$, define the universal moduli space
\[ \mathcal{M}^b_{g,G} (\mathcal{M}^*_g(X, A)) \]
(2.16)
to consist of tuples $(J, \Sigma, \varphi : \Sigma' \to \Sigma, \iota)$ up to isomorphism where $J \in \mathcal{J}(X, \omega)$, $\Sigma \subset X$ is an embedded $J$-curve of genus $g$ in class $A$ and $\varphi$ is a branched cover of type $(g, b)$ along with an isomorphism $\iota$ between $G$ and its generalized automorphism group (this is clearly a purely ineffective smooth Fréchet orbifold). Given any such point, we can then form the associated Galois closure $\psi : \overline{\Sigma} \to \Sigma$ and consider the $G$-equivariant operator $\psi^* D^N_{\Sigma, J}$. Its kernel and cokernel are finite dimensional real $G$-representations. Thus, given two nonzero finite dimensional $G$-representations $k$ and $\mathfrak{c}$ over $\mathbb{R}$, define
\[ \mathcal{M}^b_{g,G} (\mathcal{M}^*_g(X, A); k, \mathfrak{c}) \]
(2.17)
to be the subset of $\mathcal{M}^b_{g,G} (\mathcal{M}^*_g(X, A))$ consisting of those tuples $(J, \Sigma, \varphi : \Sigma' \to \Sigma, \iota)$, with associated Galois cover $\psi : \overline{\Sigma} \to \Sigma$, for which we have isomorphisms $\ker \psi^* D^N_{\Sigma, J} \cong k$ and $\coker \psi^* D^N_{\Sigma, J} \cong \mathfrak{c}$ of $G$-representations.

We now state the version of [Wen19, Theorem D] that we will need for the rest of the article. Some immediate corollaries are also explained below.

Theorem 2.15 (Stratification). In the setting of Definition 2.14, away from an exceptional subset of infinite codimension of $\mathcal{J}(X, \omega)$, the subspace
\[ \mathcal{M}^b_{g,G} (\mathcal{M}^*_g(X, A); k, \mathfrak{c}) \subset \mathcal{M}^b_{g,G} (\mathcal{M}^*_g(X, A)) \]
(2.18)
is a Fréchet sub-orbifold of codimension given by $\dim_{\mathbb{R}} \text{Hom}^G(k, \mathfrak{c})$.

Remark 2.16. Recall that a subset (of a separable metrizable Fréchet or Banach manifold) is said to have codimension $\geq m$ if it can be covered by the images of countably many Fredholm maps of index $\leq -m$. In the statement of Theorem 2.15, we are using the fact that the Petri condition (see [Wen19, §5] for more details) holds on $\mathcal{J}(X, \omega)$ away from an exceptional subset which has infinite codimension. In practice, we can ignore this exceptional set as in the next corollary.

Corollary 2.17. Let $P$ be a second countable manifold and let $\mathcal{J}_P(X, \omega)$ denote the space of smooth $\omega$-compatible almost complex structures parametrized by $P$ with the $C^\infty$ topology. Let $\mathcal{P} = \{ J_s \}_{s \in P}$ be a point in $\mathcal{J}_P(X, \omega)$ for which the associated map $P \to \mathcal{J}(X, \omega)$ is transverse to the forgetful map
\[ \mathcal{M}^b_{g,G} (\mathcal{M}^*_g(X, A); k, \mathfrak{c}) \to \mathcal{J}(X, \omega) \]
(2.19)
over a closed submanifold $Q \subset P$. Define $\mathcal{J}(X, \omega)_{P,Q}$ to be the Fréchet manifold of $P' \in \mathcal{J}_P(X, \omega)$ which coincide with $P$ over $Q \subset P$. Then, the subset of $\mathcal{J}(X, \omega)_{P,Q}$
consisting of those $P'$ for which the associated map $P \to J(X,\omega)$ is transverse to (2.19) is a Baire set, and therefore, dense.

**Definition 2.18** (Wall). Let $\mathcal{W}_{\text{emb}} \subset J(X,\omega)$ be the subset of almost complex structures $J$ for which there exists either a simple and non-embedded $J$-curve or two simple $J$-curves with distinct but intersecting images. For $\delta = (g,d,b,G,k,c,A)$ as in Definition 2.14 define

$$\mathcal{W}_{\text{emb}}^{\delta}(g,A,k,c) \subset J(X,\omega) \quad (2.20)$$

to be the image of the forgetful map (2.19). Define the wall $\mathcal{W} \subset J(X,\omega)$ to be the set of all $J$ which are not super-rigid. Clearly, we have

$$\mathcal{W} = \mathcal{W}_{\text{emb}} \cup \bigcup_{\delta} \mathcal{W}_{\text{emb}}^{\delta}(g,A,k,c) \quad (2.21)$$

by passing to Galois covers in Definition 2.13. We refer to each term in the union in (2.21) as a stratum of the wall $\mathcal{W}$.

We will now determine a way to separate $\mathcal{W}$ into those strata which have codimension 1 in $J(X,\omega)$ and those which have codimension $\geq 2$. We do this essentially by rewording the proof of [Wen19, Theorem A] for $X$ and following the remarks from [Wen19, §2.4].

**Lemma 2.19** (Wall: codimension 1 strata). Away from a codimension 2 subset of $J(X,\omega)$, the codimension 1 strata of $\mathcal{W} \subset J(X,\omega)$ is a union of those strata $\mathcal{W}_{\text{emb}}^{\delta}(g,A,k,c)$ which are non-empty such that

(i) each $b^i_j \in \{1,2\}$, i.e., each ramification point is simple and,

(ii) the $G$-representation $k$ is faithful, irreducible and of real type, i.e., its equivariant endomorphism algebra $\text{End}^G(k)$ is isomorphic to $\mathbb{R}$.

**Proof.** Begin by noting that $\mathcal{W}_{\text{emb}}$ is of codimension 2 in $J(X,\omega)$ by Remark 2.12. Now, take $J$ in $\mathcal{W} \setminus \mathcal{W}_{\text{emb}}$ and not in the exceptional set from Theorem 2.15. This means that we can find a minimum possible $d \geq 1$, an embedded $J$-curve $\Sigma \subset X$ and a $d$-fold branched cover $\varphi: \Sigma' \to \Sigma$ such that $\ker \varphi^* D_{\Sigma,J}^N \neq 0$. Let $\psi: \Sigma \to \Sigma'$ be the Galois closure of $\varphi$ and let $G = \text{Gal}(\Sigma/\Sigma')$ while $H = \text{Gal}(\Sigma'/\Sigma)$. Let $\theta_i$ for $i = 1, \ldots, p$ denote the complete list of irreducible representations of $G$ over $\mathbb{R}$. For each $i$, recall that we have the twisted operators $D_{\Sigma,J}^N$, as in [Wen19, §2.2 and §3.4] and Definition 2.5, whose kernels (and similarly cokernels) are related to $\psi^* D_{\Sigma,J}^N$ by the following formulas

$$\ker D_{\psi,\theta_i}^N = \text{Hom}^G(\theta_i^*, \ker \psi^* D_{\Sigma,J}^N) \quad (2.22)$$

$$\ker \psi^* D_{\Sigma,J}^N = \bigoplus_i \theta_i^* \otimes_{K_i} \ker D_{\psi,\theta_i}^N \quad (2.23)$$

where $K_i = \text{End}^G(\theta_i)$, and (2.22), (2.23) are isomorphisms of $K_i$-modules and $G$-representations respectively. Now, the assumption implies that we can find an $1 \leq j \leq p$ such that $(\theta_j^*)^H \neq 0$ and $\ker D_{\psi,\theta_j}^N \neq 0$. We contend that $\theta_j$ must be a faithful $G$-representation. If not, let (1) $\neq K \subset G$ be such that $\theta_j$ descends to $G/K$. Note that $K \not\subset H$ (since $H$ has trivial normal core) and thus, $D_{\Sigma,J}^N$ pulled back to $\Sigma/HK$ has a non-trivial kernel (contradicting the minimality of $d$). Now that we know that $\theta_i$ is faithful, we can use [Wen19, Lemma 2.10] to get

$$\text{ind}_{K_i} D_{\psi,\theta_j}^N \leq -2r \quad (2.24)$$
where \( r \) is the number of distinct branch points of \( \varphi \). Moreover, this estimate is strict in case \( K_j = \mathbb{R} \) unless all the ramification points of \( \varphi \) are simple (i.e., they’re all locally 2-to-1). Now, set \( t_i = \dim_{\mathbb{R}} K_i, \ k_i = \dim_{\mathbb{R}} \ker D^N_{\psi_i, \theta_i} \) and \( c_i = \dim_{\mathbb{R}} \text{coker} \ D^N_{\psi_i, \theta_i} \) and note that the codimension of \( \mathcal{W}^d_{b,G}(g,A,k,c) \) near \( J \) is

\[
\geq -2r + \sum_i t_i k_i c_i \geq -2r + t_j k_j (k_j + 2r) \geq 1
\]  

(2.25)

using Theorem 2.15. Note that the shifting \(-2r\) comes from the dimension of the moduli space of branched covers. (Here, \( b \) is constructed using \( \varphi, A = [\Sigma], g = \text{genus}(\Sigma), k = \ker \psi^* D^N_{\Sigma,j} \) and \( c = \text{coker} \ \psi^* D^N_{\Sigma,j} \)) Moreover, to obtain the equality in the last estimate, we must have \( t_j = k_j = 1, k_i = 0 \) for all \( j \neq i \) (this last part follows since \( \text{ind}_K D^N_{\psi_i, \theta_i} \leq 0 \) by [Wen19, Lemma 2.10]) and \( \text{ind}_K D^N_{\psi_i, \theta_i} = -2r \) [Wen19, Lemma 2.10] now implies that all the ramification points of \( \varphi \) must be locally 2-to-1. \( \square \)

3. Bifurcation analysis: statement and examples

We begin by describing the class of bifurcations that we will treat in this article.

**Definition 3.1** (Elementary wall type). Given any \( \delta = (g,d,b,G,k,c,A) \) as in Definition 2.14, let \( r, h \) and \( H \subset G \) be the number of branch points, domain genus and the (conjugacy class of) subgroup corresponding to the \( d \)-fold covers in question.

Say that \( \delta \) is an elementary wall type if it satisfies conditions (1)-(2) below. Call an elementary wall type \( \delta \) trivial if it violates condition (3) below.

1. \( d \geq 2 \) and either \( r = 0 \), i.e. unbranched covers, or for each \( 1 \leq i \leq r \), we have \( b^1_i = 2 \) and \( b^1_j = 1 \) for \( 1 < j \leq q_i \).
2. The \( G \)-representation \( k \) is faithful, irreducible and of real type.
3. We have \( k^H \neq 0 \).

**Remark 3.2.** Note that condition (1) in Definition 3.1 is just a strengthening of condition (i) in Lemma 2.19 while condition (2) of Definition 3.1 is the same as condition (ii) of Lemma 2.19. Condition (3) is a necessary condition for the desired bifurcation to occur based on Lemma 2.8.

**Example 3.3.** Definition 3.1 covers many cases, including the following.

1. Any degree 2 morphism \( \Sigma' \to \Sigma \) of curves gives an elementary wall type \( \delta \), with \( G = \mathbb{Z}/2\mathbb{Z} \) and \( k \) being the unique one-dimensional non-trivial representation of \( \mathbb{Z}/2\mathbb{Z} \). A result analogous to Theorem 3.4 below in the case of unbranched double covers of tori in dimension 4 appears in [Tan00].
2. For any \( d \geq 2 \), consider a degree \( d \) morphism \( \Sigma' \to \Sigma \) with distinct simple branch points with generalized automorphism group being the whole symmetric group \( S_d \). Such covers always exist provided

\[
2h - 2 - d(2g - 2) = r \geq 2d - 2
\]

(3.1)

where \( h = \text{genus}(\Sigma') \) and \( g = \text{genus}(\Sigma) \) and they give rise to elementary wall types with \( G = S_d \) and \( k \) being the subrepresentation \( \{(x_1, \ldots, x_d) : \sum x_i = 0\} \) of the tautological representation of \( S_d \) on \( \mathbb{R}^d \). The subgroup \( H \subset G \) in this case is given by \( S_{d-1} \).
(3) For any $n \geq 1$, take $d = 2n + 1$ and consider a degree $d$ unbranched cover $\Sigma' \to \Sigma$ of a genus $g \geq 2$ curve given by the permutation representation

$$\rho : \pi_1(\Sigma_g) = \langle a_1, b_1, \ldots, a_g, b_g : [a_1, b_1] \cdots [a_g, b_g] = 1 \rangle \to S_{2n+1}$$  \hspace{1cm} (3.2)

$$\rho(a_1) = \rho(b_1) = (1 2)(3 4) \cdots (2n - 12n)$$  \hspace{1cm} (3.3)

$$\rho(a_2) = \rho(b_2) = (23)(45) \cdots (2n 2n + 1)$$  \hspace{1cm} (3.4)

and $\rho(a_i) = \rho(b_i) = 1$ for $i > 2$. Note that the generalized automorphism group $\text{im } \rho = G \subset S_{2n+1}$ of this cover is isomorphic to the dihedral group

$$D_{2n+1} = \langle \tau, \theta : \tau^2 = \theta^{2n+1} = 1, \tau \theta \tau^{-1} = \theta^{-1} \rangle$$  \hspace{1cm} (3.5)

with $\tau = (1 2)(3 4) \cdots (2n - 12n)$ and $\tau \theta = (23)(45) \cdots (2n 2n + 1)$. The subgroup $H$ is given by $\langle \tau \rangle \subset D_{2n+1}$. The standard 2-dimensional representation $k$ which realizes $D_{2n+1}$ as the isometry group of a regular $(2n + 1)$-gon in $\mathbb{R}^2$ gives rise to a non-trivial elementary wall type.

(4) Let $n \geq 2$ be an integer and let $d = 2n$. For integers $g, s \geq 1$, define a degree $d$ branched cover $\Sigma' \to \Sigma$ of a genus $g$ curve with $2s$ distinct simple branch points $\{q_1, \ldots, q_{2s}\} \subset \Sigma$ by the permutation representation

$$\rho : \pi_1(\Sigma \setminus \{q_1, \ldots, q_{2s}\})$$  \hspace{1cm} (3.6)

$$= \langle a_1, b_1, \ldots, a_g, b_g, c_1, \ldots, c_{2s} : [a_1, b_1] \cdots [a_g, b_g]c_1 \cdots c_{2s} = 1 \rangle \to S_d$$  \hspace{1cm} (3.7)

$$\rho(a_i) = \rho(b_i) = (1 2 \cdots n)(n + 1 \cdots 2n), \quad \rho(c_j) = (1 n + 1)$$  \hspace{1cm} (3.8)

for all $1 \leq i \leq g$ and $1 \leq j \leq 2s$. Note that the generalized automorphism group $\text{im } \rho = G \subset S_d$ is isomorphic to $(\mathbb{Z}/2\mathbb{Z})^n \times \mathbb{Z}/n\mathbb{Z}$ via

$$(0, 0, \ldots, 0) \mapsto (1 \cdots n)(n + 1 \cdots 2n)$$  \hspace{1cm} (3.9)

$$(1, 0, \ldots, 0) \mapsto (1 n + 1)$$  \hspace{1cm} (3.10)

and the subgroup $H \subset G$ is given by $(\mathbb{Z}/2\mathbb{Z})^{n-1} \times \{0\}$. The group $G$ has a representation $k = \mathbb{R}^n$, where $\mathbb{Z}/n\mathbb{Z}$ acts by cyclically permuting the coordinates while $(\alpha_1, \ldots, \alpha_n) \in (\mathbb{Z}/2\mathbb{Z})^n$ acts by the matrix $\text{diag}(-1)^{\alpha_1}, \ldots, (-1)^{\alpha_n}$, and this gives rise to a non-trivial elementary wall type.

We freely make use of the notation from Definition 3.1 in the statement of our main result on bifurcations below.

**Theorem 3.4** (Elementary bifurcations). Fix super-rigid almost complex structures $J_-, J_+ \in \mathcal{J}(X, \omega)$. For a generic, in the sense of Baire, path $\gamma : [-1, 1] \to \mathcal{J}(X, \omega)$ avoiding $\mathcal{W}_\text{emb}$ with $\gamma(\pm 1) = J_{\pm}$, the following is true.

Let $t_0 \in \{ -1, 1 \}$, write $J = \gamma(t_0)$ and suppose there is a point

$$p = (J, \Sigma, \varphi : \Sigma' \to \Sigma, \iota) \in \mathcal{M}_G^\delta(\mathcal{M}^\varphi_g(X, A); k, c)$$  \hspace{1cm} (3.11)

with $\delta = (g, d, b, G, k, c, A)$ being an elementary wall type.

Assume that the maps $\gamma$ and (2.19) are transverse at $t = t_0$ and $p$ respectively and define $\text{sgn}(\gamma, t_0 ; p) \in \{-1, +1\}$ to be the sign of the associated isomorphism

$$T_{\delta} \gamma \otimes \text{Hom}(\ker \varphi^* D, \text{coker } \varphi^* D) / T_{\varphi} \mathcal{M}_h(\Sigma, d)$$  \hspace{1cm} (3.12)

where we orient the left side of (3.12) by the obvious identification with $\mathbb{R}$, and the right side of (3.12), which is the normal space of $\mathcal{W}_G^d(b, A, k, c) \subset \mathcal{J}(X, \omega)$ at $p$, using the standard Cauchy–Riemann orientation on the determinant line $\text{det}(\varphi^* D)$.
and the complex structure on the moduli stack $\mathcal{M}_h(\Sigma, d)$ of $d$-fold genus $h$ branched covers of $\Sigma$. Here, $D = D^N_{\Sigma; \gamma(t_0)}$ is the normal deformation operator of $\Sigma$.

We can then find an arbitrarily small Gromov neighborhood $\mathcal{O}$ of $\varphi : \Sigma' \to X$ and an arbitrarily small $\epsilon > 0$ such that the parametrized moduli space

$$(t_0 - \epsilon, t_0 + \epsilon) \times \mathcal{O} \cap \mathcal{M}_h^0(X, \gamma, dA)$$

(3.13)

of embedded $\gamma(t)$-curves, with $|t - t_0| < \epsilon$, of genus $h$ and class $dA$, which lie in $\mathcal{O}$ has the following properties. The fiber of (3.13) over $t = t_0$ is empty and, moreover, (3.13) is a smooth oriented 1-dimensional manifold, with the projection to $(t_0 - \epsilon, t_0) \cup (t_0, t_0 + \epsilon)$ being a proper submersion. Let $m_\pm$ and $n_\pm$ denote the unsigned and signed number, respectively, of points in the fiber of (3.13) over $t$ for $\pm(t - t_0) > 0$.

(i) If $\delta$ is trivial, then $m_\pm = 0$. If $r = 0$ and $H \subset G$ is not a maximal subgroup such that $k^H \neq 0$, then also we have $m_\pm = 0$.

(ii) If we’re not in either of the cases from (i), then we have $\Gamma = \text{Aut}(\varphi) \subset \mathbb{Z}/2\mathbb{Z}$, the estimate $|\Gamma| \cdot |m_\pm| \leq 2$ and the identity

$$n_+ - n_- = -2 \cdot \text{sgn}(\gamma, t_0; p) \frac{|\Gamma|}{|\Gamma|}.$$  

(3.14)

Moreover, if $\Sigma'_t \subset X$ is any sequence of points in (3.13), lying over $t_i \to t_0$, then the Gromov limit of this sequence exists and is given by $\varphi : \Sigma' \to X$.

**Remark 3.5.** Note that an element $v \in \ker(\varphi^* D_{\Sigma,j}^N)$ can be viewed as a $d$-valued holomorphic section of the bundle $N_\Sigma$ over the curve $\Sigma$ with singular points given by the branched points of the cover $\varphi : \Sigma' \to \Sigma$. Theorem 3.4 asserts that by varying $J$ along a generic path, we can obtain a 1-parameter family of solutions to the nonlinear Cauchy–Riemann equations which give rise to embedded pseudo-holomorphic curves of class $d[\Sigma]$. We expect the analysis of Kuranishi models in Section 4 to be useful in other relevant problems. For instance, it is speculated in [Don19, Section 1] that a 2-valued harmonic 1-form defined over a special Lagrangian submanifold $M$ in a Calabi–Yau manifold $(X, \omega, \Omega)$ should give rise to a 1-parameter family of special Lagrangian immersions $t_i : M \to M$, where $M$ is the branched double cover of $M$ branching along the singular set of the given harmonic 1-form. The similarity is quite transparent, though the analysis needed to carry out the program in [Don19] is still under development.

### 4. Bifurcation analysis: Proofs

In this section, we will prove Theorem 3.4.

#### 4.1. Simplifications

We are given two super-rigid almost complex structures $J_-, J_+ \in J(X, \omega)$. Using Corollary 2.17, a generic path $\gamma : [-1, 1] \to J(X, \omega)$, with $\gamma(\pm 1) = J_\pm$, is transverse to all the maps (2.19) and disjoint from $W_{\text{emb}}$.

For notational simplicity, assume $t_0 = 0$. Let $r, h$ and $H \subset G$ be as in Definition 3.1. We will study what happens to the moduli space of embedded genus $h$ curves of class $dA$ near $\varphi : \Sigma' \to X$ as we go from $t < 0$ to $t > 0$.

Write $k = \theta^*$ for some irreducible faithful representation $\theta$ of $G$ of real type. At the point $p = (J, \Sigma, \varphi : \Sigma' \to \Sigma, \iota) \in \mathcal{M}_{b,c}(\mathcal{M}_g^0(X, A); k, c)$, with associated Galois closure $\psi : \tilde{\Sigma} \to \Sigma$, we have dimension $\ker D_{\psi, \theta} = 1$ and

$$\ker \psi^* D_{\Sigma,j}^N = \theta^* \otimes \ker D_{\psi, \theta}.$$  

(4.1)
For (3.13) to be non-empty for arbitrarily small $O$ and $\epsilon$, we must have $\ker \varphi^* D_{\Sigma, J}^N \neq 0$. This follows from a standard argument involving rescaling in the directions normal to $\Sigma$ (see, for example, [Wen19, Appendix B]). This proves the first half of assertion (i) from Theorem 3.4.

Taking $H$-invariants in (2.23), we see that requiring $\ker \varphi^* D_{\Sigma, J}^N \neq 0$ is the same as requiring $k^H = (\theta^*)^H \neq 0$. Let us henceforth make the following assumption.

**Assumption 4.1** ($\delta$ is not trivial). We have $\theta^* \neq 0$.

Let us note an important consequence of this assumption.

**Lemma 4.2.** Under Assumption 4.1, the point $p = (J, \Sigma, \varphi : \Sigma' \to \Sigma, \iota) \in \mathcal{M}_{b, G}(\mathcal{M}_{\gamma}^d(X, A); k, c)$ satisfies the following.

(i) We have $\dim_k (\theta^*)^H = 1$.

(ii) For each irreducible representation $\rho$ of $G$ over $R$ with $\rho \ncong \theta$, we have either $\text{ind}_R D_{\psi, \rho}^N = 0$ or $(\rho^*)^H = 0$.

As a consequence, we have the identifications

$$\ker \varphi^* D_{\Sigma, J}^N = (\theta^*)^H \otimes \ker D_{\psi, \theta}^N \quad (4.2)$$

$$\text{coker} \varphi^* D_{\Sigma, J}^N = (\theta^*)^H \otimes \text{coker} D_{\psi, \theta}^N. \quad (4.3)$$

**Proof.** We use Lemma 2.8 to deduce the quasi-isomorphism

$$\bigoplus_i (\theta_i^*)^H \otimes_{K_i} D_{\psi, \theta_i}^N \to \varphi^* D_{\Sigma, J}^N, \quad (4.4)$$

which implies that we have the identity

$$\text{ind}_R (\varphi^* D_{\Sigma, J}^N) = \sum_i \dim_k (\theta_i^*)^H \cdot \text{ind}_{K_i} D_{\psi, \theta_i}^N. \quad (4.5)$$

Now, a simple computation using the Riemann–Roch formula (combined with the Riemann–Hurwitz formula for $\varphi$ and condition (1) of Definition 3.1) shows that the left side of (4.5) is $-2r$. On the other hand, using [Wen19, Lemma 2.10], we have $\dim_k (\theta^*)^H \cdot \text{ind}_R (D_{\psi, \theta}^N) \leq -2r$ while each summand on the right side of (4.5) is $\leq 0$. Thus, we must have equality in all these inequalities. This immediately gives us (i), (ii) as well as (4.2), (4.3).

□

Since $d = [G : H] \geq 2$, it follows that $G$ is non-trivial. Thus, taking $G$-invariants in (4.1) implies that $\ker D_{\Sigma, J}^N = 0$. We can thus choose $\epsilon > 0$ with the following property: there is a unique embedded $\gamma(t)$-curve $\Sigma_\epsilon$ close to $\Sigma$ for each $|t| < \epsilon$ (obtained using the inverse function theorem).

4.2. **Preparation.** Let us clarify the transversality hypothesis (of the intersection of $\gamma$ and (2.19) in Theorem 3.4) a little further. Define

$$\mathcal{M}_{b, G}^d(\Sigma, \gamma) \to (-\epsilon, \epsilon) \quad (4.6)$$

to be the smooth bundle of orbifolds whose fibre over a point $\tau \in (-\epsilon, \epsilon)$ is the stack $\{\tau\} \times \mathcal{M}_{b, G}^d(\Sigma_\tau)$ as in Definition 2.3. We have a natural short exact sequence

$$0 \to T_{\varphi} \mathcal{M}_{b, G}^d(\Sigma) \to T_{(0, \varphi)} \mathcal{M}_{b, G}^d(\Sigma, \gamma) \to \mathbb{R}_t \to 0 \quad (4.7)$$

and transversality says that the natural map

$$T_{(0, \varphi)} \mathcal{M}_{b, G}^d(\Sigma, \gamma) \xrightarrow{\varphi^*} \text{Hom}^G(\ker \psi^* D, \text{coker} \psi^* D) \quad (4.8)$$
is an isomorphism, where $\psi : \tilde{\Sigma} \to \Sigma$ is the Galois closure of $\varphi$ and $D = D_{\Sigma, j}^N$. The map (4.8) is the linearized map, in the sense of Definition 2.9, associated to the family of $G$-equivariant Cauchy–Riemann operators on $\mathcal{M}_{h,G}^d(\Sigma, \gamma)$ given by

$$p = (\tau, \varphi'' : \Sigma'' \to \Sigma, \iota) \mapsto \psi^*(D_{\Sigma, \gamma(\tau)})$$ (4.9)

where $p \mapsto (\psi_p : \tilde{\Sigma}'' \to \Sigma'' \to \Sigma)$ is a continuous family of Galois closures.

Next we will study the stable map moduli space $M_h(X, \gamma, dA)$ locally near $(0, \varphi)$ as an intermediate step to understanding (3.13). The strategy is to use the implicit function theorem to first produce a Kuranishi model and then explicitly analyze the resulting Kuranishi map. Before proceeding to this, let us establish the notations for the domain and target of the Kuranishi map (which are respectively the kernel and cokernel of the corresponding linearized equation).

4.2.1. Domain. To describe the domain explicitly, let us denote the inclusion of $\Sigma$ in $X$ by $\iota$ and the linearized Cauchy–Riemann operator on $\iota^*TX$ (resp. $\varphi^*TX$) by $\tilde{D}$ (resp. $\tilde{D}_\varphi = \varphi^*\tilde{D}$). Moreover, write $K = \dot{\gamma}(0)$. The domain of the Kuranishi map is then an open neighborhood of 0 in the vector space

$$T_{(0, \varphi)}^{Zar} M_h(X, \gamma, dA).$$

which consists of “cocycle” triples $(\xi, y, t)$, where $\xi \in \Omega^0(\Sigma', \varphi^*TX)$, $y \in \Omega^{0,1}(\Sigma', T\Sigma')$ and $t \in \mathbb{R}$ are such that

$$\tilde{D}_\varphi \xi + \frac{1}{2} (J \circ d\varphi \circ y + tK \circ d\varphi \circ j_{\Sigma'}) = 0$$ (4.10)

modulo the “coboundary” triples $(\frac{1}{2} d\varphi(V), j_{\Sigma'} \cdot \bar{\partial} V, 0)$ where $V \in \Omega^0(\Sigma', T\Sigma')$ and $\bar{\partial}$ stands for the Cauchy-Riemann operator on $\Omega^0(\Sigma', T\Sigma')$. This vector space contains the domain

$$T_{\varphi}^{Zar} M_h(X, J, dA)$$

of the corresponding Kuranishi model for $M_h(X, J, dA)$, which is the subspace of $T_{(0, \varphi)}^{Zar} M_h(X, \gamma, dA)$ defined by $t = 0$.

Similarly, we can consider the parametrized moduli space of $d$-fold genus $h$ branched covers of $\{\Sigma\}_{\tau \in [-1, 1]}$, denoted by $M_h(\Sigma, \gamma, d)$ and its (Zariski) tangent space $T_{(0, \varphi)} M_h(\Sigma, \gamma, d)$ at $(0, \varphi)$ by considering the vector bundle $\varphi^*T\Sigma$, instead of $\varphi^*TX$, and the corresponding cohomology group. The specialization of the space $M_h(\Sigma, \gamma, d)$ at $\tau = 0$ is denoted by $M_h(\Sigma, d)$ and its tangent space at $\varphi$, written as $T_{\varphi} M_h(\Sigma, d)$, is constructed accordingly.

These vector spaces fit into the following commutative diagram with exact rows and columns (recall $D = D_{\Sigma, j}^N$).
The exactness of the first row is obvious and the exactness of the second row follows from construction. The exactness of the left and middle columns follow by using the long exact sequence associated to \( 0 \rightarrow \varphi^*T_{\Sigma} \rightarrow \varphi^*T_X \rightarrow \varphi^*N_{\Sigma} \rightarrow 0 \). The exactness of the right column now follows formally.

In view of condition (1) of Definition 3.1, the natural map from the short exact sequence (4.7) to the upper row short exact sequence in this diagram is an isomorphism. In fact, the following diagram

\[
\begin{array}{c}
\text{T}_{(0,\varphi)}M_{b,h}(\Sigma,\gamma,d) \\
\text{ker}(\varphi^*D) \\
\end{array} \xrightarrow{\cong} \text{Hom}^G(\ker \psi^*D, \coker \psi^*D) \xrightarrow{\cong} \text{Hom}(\ker \varphi^*D, \coker \varphi^*D)
\]

(4.11)

is commutative and, because of Lemma 4.2, all its arrows are isomorphisms. Indeed, the isomorphism given by the left vertical arrow is induced by inclusion, the right vertical arrow comes by restricting to the \( H \)-fixed subspace while the horizontal arrows come by considering the families of operators (4.9) and (\( \tau, \varphi'' : \Sigma'' \rightarrow \Sigma \)) \( \mapsto \varphi''_{\tau}(D^N_{\Sigma''}) \) on \( M_{b,G}^d(\Sigma,\gamma,d) \) and \( M_h(\Sigma,\gamma,d) \) respectively. For future reference, we will label the bottom horizontal arrow of this commutative diagram as \( w_{\varphi} \).

Observe that both sides of the isomorphism \( w_{\varphi} \) have natural orientations.

(1) \( M_h(\Sigma,\gamma,d) \) is fibered over the oriented interval \((-\epsilon, \epsilon)\) with complex fibers.

(2) An orientation of the vector space

\[
\text{Hom}(\ker \varphi^*D, \coker \varphi^*D) = (\ker \varphi^*D)^* \otimes \coker \varphi^*D
\]

(4.12)

is the same as an orientation of its determinant line

\[
(\ker \varphi^*D)^{\otimes 1+2r} \otimes \det(\coker \varphi^*D)
\]

(4.13)

where we recall that \( \dim \ker \varphi^*D = 1 \). Since the tensor square of a 1-dimensional space is canonically oriented, it follows that we simply need an orientation of the determinant line

\[
\det(\varphi^*D) = \det(\ker \varphi^*D) \otimes \det(\coker \varphi^*D)^*
\]

(4.14)

of the Cauchy–Riemann operator \( \varphi^*D \). This can be defined in the usual manner by comparing \( D \) with a \( C \)-linear Cauchy–Riemann operator.
Thus, the isomorphism \( w_\varphi \) has a well-defined sign. Notice that the isomorphism (3.12) from Theorem 3.4 is derived by passing to the quotient \( \mathbb{R} \), using the short exact sequence (4.7), in the map \( w_\varphi \). In particular, we have

\[
\text{sgn}(w_\varphi) = \text{sgn}(\gamma, 0; p).
\]  (4.15)

For convenience, let us make the following assumption.

**Assumption 4.3.** \( w_\varphi \) is orientation-preserving, i.e., \( \text{sgn}(w_\varphi) = \text{sgn}(\gamma, 0; p) = +1 \).

This assumption can be achieved by reversing the direction of \( \gamma \) if it is not already satisfied.

4.2.2. **Target.** The target of the Kuranishi map is the space \( E_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA) \) of all \( \eta \in \Omega^{0,1}(\Sigma', \varphi^*TX) \) modulo all elements of the kind that appear on the left side of (4.10). In fact, in view of the surjectivity of \( T^\text{bar}_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA) \to \mathbb{R} \), we can restrict attention to just elements as in the left side of (4.10) for which \( t = 0 \). Using the long exact sequence associated to \( 0 \to \varphi^*T\Sigma \to \varphi^*TX \to \varphi^*N\Sigma \to 0 \), it now follows that we have a natural identification

\[
E_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA) = \text{coker} \varphi^*D.
\]  (4.16)

4.3. **Implicit function theorem.** We will now explain how to construct the Kuranishi model for \( \mathcal{M}_h(X, \gamma, dA) \) near \( (0, \varphi) \) using the implicit function theorem on an appropriate map \( \Phi : X \to \mathcal{Y} \) of Banach spaces (defined on a neighborhood of 0). Let \( m \geq 2 \) be an integer. Define \( \mathcal{Y} \) to be the space of sections of \( \Lambda^{0,1}T\Sigma'_\Sigma \otimes \varphi^*TX \) of class \( L^2_m \) (i.e. \( m \) derivatives in \( L^2 \)). Note that \( \mathcal{Y} \) has a natural action of

\[
\Gamma = \text{Aut}(\varphi) = N_G(H)/H
\]  (4.17)

We define \( \mathcal{X} = \mathcal{X}_{\text{ct}} \oplus \mathcal{X}_{\text{acs}} \oplus \mathbb{R}_t \), where the summands are defined as follows. Choose a \( \Gamma \)-invariant set \( M \subset \Sigma' \) where \( \varphi \) is unramified such that \( \Sigma' \) has no automorphisms fixing \( M \). For each \([z] \in M/\Gamma \), choose a complement \( D_{[z]} \subset T_{\varphi(z)}X \) for \( d\varphi_z(T_{\Sigma'}\Sigma) \). Define \( \mathcal{X}_{\text{ct}} \) to be the kernel of the \( \Gamma \)-equivariant evaluation map

\[
L^2_{m+1}(\Sigma', \varphi^*TX) \to \bigoplus_{z \in M} (T_{\varphi(z)}X)/D_{[z]}.
\]  (4.18)

Define \( \mathcal{X}_{\text{acs}} \) to be a (finite dimensional) \( \Gamma \)-invariant complement of the map

\[
\Omega^0_M(\Sigma', T_{\Sigma'}) \xrightarrow{\partial} \Omega^{0,1}(\Sigma', T_{\Sigma'})
\]  (4.19)

consisting of sections compactly supported in \( \Sigma' \setminus M \). Here, \( \Omega^0_M(\Sigma', T_{\Sigma'}) \) is the space of vector fields on \( \Sigma' \) which vanish on \( M \).

To define the map \( \Phi : X \to \mathcal{Y} \), we need to fix the following choices.

1. A metric on \( X \) with its associated exponential map.
2. A \( J \)-linear connection \( \nabla \) on \( TX \).
3. A smooth 1-parameter family of complex vector bundle isomorphisms

\[
I_{X,t} : (TX, J) \xrightarrow{\sim} (TX, J_t)
\]  (4.20)

with \( I_{X,t} = \text{id} + \frac{1}{2}JA_{X,t} \), where \( A_{X,0} = 0 \) and \( A_{X,t} \) is \( J \)-antilinear for all \( t \in \mathbb{R} \) with \( |t| \) small. In this case, we have \( \dot{\gamma}(0) = \frac{d}{dt}|_{t=0}J_t = \frac{d}{dt}|_{t=0}A_t = K. \)
(4) A smooth family \( y \mapsto j_y \) of almost complex structures on \( \Sigma' \) parametrized by \( y \in \mathcal{X}_{acs} \) with \( \frac{\partial}{\partial z} |_{z=0} j_y = y \) and \( j_0 = j_{\Sigma'} \) being the given almost complex structure on \( \Sigma' \). The concrete choice we shall work with is given by declaring the following to be an isomorphism of complex vector bundles

\[
I_{\Sigma', y} = \text{id} + \frac{i}{2} j_{\Sigma'} : (T_{\Sigma', y}) \to (T_{\Sigma', y})
\]

for \( y \in \mathcal{X}_{acs} \) with small \( |y| \).

We can now define the smooth map \( \Phi : \mathcal{X} \to \mathcal{Y} \) for small \((\xi, y, t) \in \mathcal{X} \) as

\[
\Phi(\xi, y, t) = P T_{\nabla} \left[ I_{\Sigma', y}^{-1} \circ (\bar{\partial}_{j_{\Sigma'}, \exp y} \xi) \right].
\]

The symbol \( \exp y \xi \) denotes the \( L^2 \) map \( z \mapsto \exp y(\xi(z)) \), the symbol \( \bar{\partial}_{j_{\Sigma'}, \exp y} \xi \) denotes the non-linear Cauchy–Riemann operator

\[
u \mapsto \frac{1}{2} (du + J_t \circ du \circ j_y)
\]

and \( P T_{\nabla} \) denotes the backward parallel transport along the paths \( \tau \mapsto \exp y(\tau \xi) \) induced by the connection \( \nabla \). Clearly, \( \Phi \) is \( \Gamma \)-equivariant, \( \Phi(0) = 0 \) and it is immediate that a neighborhood of \((0, \varphi) \in \mathcal{M}_h(X, \gamma, dA) \) is identified with a neighborhood of \([0] \in \Phi^{-1}(0)/\Gamma \).

To apply the implicit function theorem to \( \Phi \), we first note that the linearization \( \hat{D} = D\Phi(0) : \mathcal{X} \to \mathcal{Y} \) is given by the following formula (compare (4.10) from §4.2.1).

\[
(\xi, y, t) \mapsto \hat{D}_\Phi \xi + \frac{1}{2}(J_t \circ d\varphi \circ y + tK \circ d\varphi \circ j_{\Sigma'}).
\]

We can now readily see that we have natural identifications

\[
\ker \hat{D} = T_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA)
\]

\[
coker \hat{D} = E_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA).
\]

Split the maps \( \ker \hat{D} \to \mathcal{X} \) and \( \mathcal{Y} \to \ker \hat{D} \) by choosing a \( \Gamma \)-invariant complement \( \mathcal{X}' \subset \mathcal{X} \) for \( \ker \hat{D} \) and a \( \Gamma \)-invariant lift \( E \subset \mathcal{Y} \) of \( \ker \hat{D} \).

**Lemma 4.4.** There are \( \Gamma \)-invariant neighborhoods \( 0 \in U \subset \ker \hat{D} \) and \( 0 \in V \subset \mathcal{X}' \) such that \( \Phi^{-1}(E) \cap (U \times V) \) is given by the graph of a \( \Gamma \)-equivariant smooth function \( \Psi : U \to \mathcal{X}' \) satisfying \( \Psi(0) = 0 \) and \( D\Psi(0) = 0 \).

**Proof.** Apply the implicit function theorem to the \( \Gamma \)-equivariant map \( \Phi \).

**Definition 4.5** (Kuranishi map). Define the \( \Gamma \)-equivariant map \( F : U \to E \) by

\[
F(\kappa) = \Phi(\kappa + \Psi(\kappa)).
\]

This map \( F \) yields the germ at 0 of a \( \Gamma \)-equivariant smooth map from \( \ker \hat{D} \) to \( \ker \hat{D} \) or equivalently

\[
T^{\text{Zar}}_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA) \to E_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA)
\]

which we call a Kuranishi map for \((0, \varphi) \in \mathcal{M}_h(X, \gamma, dA) \).

**Remark 4.6.** It is clear from Lemma 4.4 that a neighborhood of \([0] \in F^{-1}(0)/\Gamma \) describes a neighborhood of \((0, \varphi) \in \mathcal{M}_h(X, \gamma, dA) \). We may assume that this neighborhood is of the form

\[
((-\epsilon, \epsilon) \times \mathcal{O}) \cap \mathcal{M}_h(X, \gamma, dA)
\]

for a Gromov neighborhood \( \mathcal{O} \) of \( \varphi : \Sigma' \to X \), after shrinking \( \epsilon \) if needed.
4.4. Analysis of the Kuranishi map. All ‘functions’ in this subsection are to be understood to be germs near 0 of smooth functions which vanish at 0.

Definition 4.7. Given two finite dimensional vector spaces $W_1, W_2$, two functions $F', F'': W_1 \to W_2$ and an integer $l \geq 1$, we write

$$F' \equiv_l F''$$

(4.30)

to mean that the $i^{th}$ derivatives of $F' - F''$ vanish at 0 for all $0 \leq i \leq l$. Clearly, $\equiv_l$ is an equivalence relation.

We will now analyze the Kuranishi map $F$ from Definition 4.5. From Lemma 4.4, it follows that $F(0) = 0$ and $DF(0) = 0$. We fix some notations first. Let

$$\epsilon : \ker \tilde{D} \to \ker(\varphi^*D)$$

(4.31)

$$t : \ker \tilde{D} \to \mathbb{R}_t$$

(4.32)

be the natural projections (see the exact commutative diagram in §4.2.1 for more details). Fix $0 \neq \sigma \in \ker(\varphi^*D)$. Using $\sigma$, we will sometimes regard $\epsilon$ as an $\mathbb{R}$-valued linear functional on $\ker \tilde{D}$ (with $\sigma$ corresponding to 1). Finally, let $z : \ker \tilde{D} \to \mathbb{C}_r$ be a $\mathbb{R}$-linear map such that its restriction to $T_{\varphi}M_h(\Sigma, d)$ is a $\mathbb{C}$-linear isomorphism. Thus, we now have explicit coordinates

$$\ker \tilde{D} = T_{(0, \varphi)}M_h(X, \gamma, dA) \xrightarrow{(t, z, \epsilon)} \mathbb{R}_t \oplus \mathbb{C}_r^r \oplus \mathbb{R}_c.$$

(4.33)

We also obtain (non-canonical) splittings $\ker \tilde{D} = T_{(0, \varphi)}M_h(\Sigma, \gamma, d) \oplus \ker \varphi^*D$ and $T_{(0, \varphi)}M_h(\Sigma, \gamma, d) = \mathbb{R}_t \oplus T_{\varphi}M_h(\Sigma, d)$ which we will use without further comment in some of the proofs below.

Now, observe that $F^{-1}(0) \subset \ker \tilde{D} = T_{(0, \varphi)}Zar M_h(X, \gamma, dA)$ contains a $\Gamma$-invariant submanifold $Z$ (passing through 0) corresponding to $M_h(\Sigma, \gamma, d)$ with

$$T_0Z = T_{\varphi}M_h(\Sigma, \gamma, d) \subset \ker \tilde{D}.$$  

(4.34)

Thus, if $\epsilon' : \ker \tilde{D} \to \ker(\varphi^*D) \simeq \mathbb{R}$ is a smooth function with $Z$ as its transverse zero locus near 0, then we can find a smooth function

$$F_1 : \ker \tilde{D} \to (\ker \varphi^*D)^* \otimes \coker \tilde{D} = \text{Hom}(\ker \varphi^*D, \coker \varphi^*D)$$

(4.35)

such that $F = \langle \epsilon', F_1 \rangle$, where

$$\langle \cdot, \cdot \rangle : \ker \varphi^*D \otimes \text{Hom}(\ker \varphi^*D, \coker \varphi^*D) \to \coker \varphi^*D$$

(4.36)

is the natural pairing. In view of (4.34), $Z$ is given by the graph of a function $f : T_0Z \to \ker(\varphi^*D) \text{ with } f(0) = 0$ and $Df(0) = 0$. As a result, we can take $\epsilon' = \epsilon - f$ and, in particular, we have the relation

$$\epsilon' \equiv_1 \epsilon.$$  

(4.37)

Since $DF(0) = 0$, it follows that $F_1(0) = 0$. Let $F'_1$ denote the function obtained by restricting $F_1$ to the subspace $T_0Z \subset \ker \tilde{D}$. We then have the following.

Lemma 4.8. The relation

$$F'_1 \equiv_1 w_\varphi$$

(4.38)

holds, where $w_\varphi$ is the isomorphism introduced in diagram (4.11).
Given any $b \in T_0 Z$, we need to show that

$$w_{\varphi}(b) \cdot \sigma = \left( \frac{d}{d\lambda} F_1(b_{\lambda}) \cdot \tilde{\sigma} \right) |_{\lambda=0}$$

where $\tilde{\sigma} \in \ker \tilde{D}$ is the lift of $\sigma \in \ker \varphi^* D$ with $\langle t, \tilde{\sigma} \rangle = \langle z, \tilde{\sigma} \rangle = 0$ and $\lambda \mapsto b_{\lambda}$ is a path in $Z$ with $b_{\lambda}(0) = 0$ and $\dot{b}_{\lambda}(0) = b$. We will make use of the fact that $\Psi(0) = 0$ and $D \Psi(0) = 0$ (Lemma 4.4). Recall that $w_{\varphi}$ comes from linearizing the Cauchy-Riemann operator. Accordingly, we have

$$w_{\varphi}(b) \cdot \sigma \equiv \left( \frac{d}{d\lambda} D \Phi(b_{\lambda} + \Psi(b_{\lambda})) \cdot \tilde{\sigma} \right) |_{\lambda=0} \pmod{\im \tilde{D}}$$

$$\equiv (D^2 \Phi)(0) \cdot b \cdot \tilde{\sigma} \pmod{\im \tilde{D}}$$

where $D^2 \Phi = D(D \Phi)$ denotes the second derivative of $\Phi$. On the other hand,

$$F_1(b_{\lambda}) \cdot \tilde{\sigma} = \frac{\partial}{\partial \mu} F(b_{\lambda} + \mu \tilde{\sigma}) |_{\mu=0}$$

for each $\lambda$, by the definition of $F_1$. We now compute

$$\left( \frac{d}{d\lambda} F_1(b_{\lambda}) \cdot \tilde{\sigma} \right) |_{\lambda=0} = \frac{\partial^2}{\partial x \partial \mu} F(b_{\lambda} + \mu \tilde{\sigma}) |_{\lambda=0} = (D^2 \Phi)(0) \cdot b \cdot \tilde{\sigma} \pmod{\im \tilde{D}}$$

which proves (4.39). 

**Corollary 4.9.** $Z' = F_1^{-1}(0) \subset \ker \tilde{D}$ is a $\Gamma$-invariant submanifold passing through 0 and its natural projection to $\ker \varphi^* D$ is a local diffeomorphism at 0. In other words, $Z'$ is given by the graph of a smooth function $g : \ker \varphi^* D \to T_{\Gamma(\varphi)} M_\Sigma(\Sigma, \gamma, d)$ such that $g(0) = 0$ and $g$ is $\Gamma$-equivariant.

**Proof.** Apply the implicit function theorem to the $\Gamma$-equivariant map $F_1$, noting that $DF_1(0)|_{T_0 Z} = w_{\varphi}$ is an isomorphism. 

The normal bundle $N_{\Sigma}$ admits an almost complex structure such that the projection $N_{\Sigma} \to \Sigma$ is pseudo-holomorphic and for any element $\sigma \in \ker(\varphi^* D)$, its graph in $N_{\Sigma}$ defines a pseudo-holomorphic curve. For details, see [Wen19, Lemma B.4]. Our analysis will differ based on whether $\sigma$ is simple or a non-trivial multiple cover, when regarded as a pseudoholomorphic curve in $N_{\Sigma}$. To proceed further, let us make the following additional assumption.

**Assumption 4.10.** $\Sigma' \to N_{\Sigma}$ is a simple curve.

**Remark 4.11.** We will see in §4.4.2 that Assumption 4.10 can fail only if $r = 0$ and $H \subset G$ is not a maximal subgroup with $(\theta^*)^H \neq 0$. This is the case covered by the second half of assertion (i) from Theorem 3.4 and we will prove it in §4.4.2.

**Lemma 4.12.** Under Assumption 4.10, we have $\Gamma \subset \mathbb{Z}/2\mathbb{Z}$.

**Proof.** It suffices to show that $\Gamma$ acts faithfully on the 1-dimensional space $(\theta^*)^H$. Suppose to the contrary that there is an element $h' \in N_G(H) \setminus H$ which acts trivially on $(\theta^*)^H$. Letting $H'$ be the subgroup of $N_G(H)$ generated by $H$ and $h'$, we find that $(\theta^*)^{H'} = (\theta^*)^H \neq 0$. This implies that $\Sigma' \xrightarrow{\varphi} N_{\Sigma}$ factors through the morphism $\Sigma' = \bar{\Sigma}/H \to \bar{\Sigma}/H'$ which has degree $[H' : H] > 1$, where $\bar{\Sigma} \to \Sigma'$ is the Galois closure of $\varphi$. This contradicts Assumption 4.10.
Under Assumption 4.10, note that each point in \( Z' \setminus \{0\} \) which is sufficiently close to 0 represents an embedded pseudoholomorphic curve. Indeed, let \( \lambda : \sigma \mapsto \mathcal{C}_\lambda \) be the section of \( Z' \to \ker \varphi^* D \), defined for small \( |\lambda| \) using Corollary 4.9. Rescaling \( \mathcal{C}_\lambda \) by \( \lambda^{-1} \) (in the normal direction to \( \Sigma \)) and taking the Gromov limit as \( \lambda \to 0 \) gives the simple curve \( \Sigma' \to \mathbb{R} \). Thus, for small \( \lambda \neq 0 \), the curve \( \mathcal{C}_\lambda \subset X \) is simple and therefore embedded (recall that \( \gamma \) misses \( \mathcal{W}_{\text{emb}} \)).

To complete the bifurcation analysis, we need to understand the natural projection \( Z' \subset \ker \mathcal{D} \to \mathbb{R}_t \), which is the same as the smooth map

\[
\ker \varphi^* D \xrightarrow{\mathcal{D}} T_{(0, \varphi)} \mathcal{M}_\lambda (\Sigma, \gamma, d) \xrightarrow{\mathcal{L}} \mathbb{R}_t.
\]

(4.46)

Orient the 1-dimensional space \( \ker \varphi^* D \) using \( \sigma \). Then the natural orientation on \( \text{Hom}(\ker \varphi^* D, \text{coker} \mathcal{D}) \) gives rise to an orientation on \( \text{coker} \varphi^* D \). Using the isomorphism \( \mathbf{w}_\varphi \), the element \( \sigma \) and the coordinates (4.33), we can identify

\[
\text{coker} \varphi^* D = \mathbb{R}_t \oplus \mathbb{C}_z^r.
\]

(4.47)

This isomorphism preserves orientation by Assumption 4.3. With these choices of coordinates, we can write the Kuranishi map as

\[
F(t, z, \epsilon) = (id + A(t, z, \epsilon)) \cdot (\epsilon - f(t, z)) \cdot ((t, z) - g(\epsilon))
\]

with \( f \equiv 1 \) and \( A(\cdot) \) is a \((1 + 2r)(1 + 2r)\) real matrix valued function with \( A(0) = 0 \). The zeros of \( F \) are exactly the zeros of the second factor (corresponding to \( Z \)) and the zeros of the third factor (corresponding to \( Z' \)).

**Lemma 4.13.** If \( \gamma \) is generic, there exists an integer \( n \geq 1 \) and a real number \( c \neq 0 \) such that

\[
(t \circ g)(\epsilon) = n c \epsilon^n.
\]

(4.49)

The proof of Lemma 4.13 is completed in the end of §4.4.1. Assuming this result for now, we will determine the signed count of the zeros of \( F \) in \( Z' \) for small \( t \neq 0 \). We divide into cases based on the sign of \( c \) and the parity of \( n \). (Clearly, if \( \Gamma = \mathbb{Z}/2\mathbb{Z} \), then \( n \) must be even.)

1. \( c \neq 0, n \text{ odd} \). The Taylor expansion (4.49) shows that for each small \( t_0 \neq 0 \), we have a unique \( \epsilon_0 \) such that \( t_0 = (t \circ g)(\epsilon_0) \). Moreover, since \( z \) is a complex coordinate, the sign of this zero can be determined by looking at the unique nonzero solution \( \epsilon = \epsilon_0 = (c^{-1} t_0)^{1/n} \) of the simplified equation

\[
\epsilon(t_0 - c \epsilon^n) = 0.
\]

(4.50)

We compute of the derivative at this point

\[
d \frac{d}{d\epsilon}(t_0 - c \epsilon^n)|_{\epsilon = \epsilon_0} = t_0 - (n + 1) c \epsilon_0^n = -n t_0
\]

(4.51)

and find that the sign of the zero is +1 for \( t < 0 \) and −1 for \( t > 0 \).

2. \( c > 0, n \text{ even} \). The Taylor expansion (4.49) shows that for small \( t_0 > 0 \), there are exactly two distinct solutions \( \epsilon_0 \sim \pm (c^{-1} t_0)^{1/n} \) to \( t_0 = (t \circ g)(\epsilon_0) \) while there are no solutions for small \( t_0 < 0 \). Again, we can compute the signs of these zeros, by considering the model equation (4.50), and we find that both of these zeros have the sign −1.

3. \( c < 0, n \text{ even} \). Arguing exactly as in the previous case, we find that there are exactly two zeros \( \epsilon_0 \sim \pm (c^{-1} t_0)^{1/n} \) for small \( t_0 < 0 \) (both with sign +1) and no zeros for small \( t_0 > 0 \).
Taking the $\Gamma$-symmetry into account and shrinking $O$ and $\epsilon$ if necessary, we find that in all cases (under Assumption 4.3) the signed number of embedded curves in a sufficiently small Gromov neighborhood $O$ of $\varphi : \Sigma' \to \Sigma$ reduces by the amount $2/|\Gamma| \in \mathbb{Z}$ when $\gamma$ goes from $-\epsilon < t < 0$ to $0 < t < \epsilon$. Modulo the result of §4.4.1 and Assumption 4.10 (whose negation will be examined in §4.4.2), we have finished the proof of Theorem 3.4. □

4.4.1. Generic non-vanishing of Taylor expansion. The analysis above depends crucially on the existence of the nonzero Taylor expansion (4.49). In view of the expression (4.48) for $F$, this is the same as saying that $\chi(\epsilon) = (t \circ F)(0, 0, \epsilon)$ has a nonzero Taylor expansion

$$\chi(\epsilon) + c\epsilon^{n+1} \equiv n+1 \ 0$$

for some integer $n \geq 1$ and real number $c \neq 0$. For any $n \geq 0$, if we assume that $\chi(\epsilon) \equiv n$, then the next Taylor coefficient of $\chi$ is defined invariantly as a homomorphism

$$T^{(n)}_{\varphi,J} : (\ker \varphi^* D)^{\otimes n+1} \to (\coker \varphi^* D)/W_\varphi$$

where $W_\varphi$ is the codimension 1 subspace of $\coker \varphi^* D$ spanned by the image of $T_{\varphi, M_0(\Sigma, d)}$ under $w_\varphi \cdot \sigma$. If $T^{(i)}_{\varphi,J} = 0$ for $0 \leq i < n$, then for any smooth path $\gamma' : [-1, 1] \to \mathcal{J}(X, \omega)$ satisfying

(i) $\gamma'(0) = J$,
(ii) $|\gamma'(s) - J| = O(|\nu_\Sigma|^{n+1})$ for all $s$, where $\nu_\Sigma = \text{dist}(\Sigma, \cdot)$ denotes the distance to $\Sigma$ induced by the given Riemannian metric,
we have the equality $D^N_{\Sigma,j} = D^N_{\Sigma,\gamma'(s)}$ of normal operators and the vanishing of the Taylor coefficients $T^{(i)}_{\sigma,\gamma'(s)}$ for $0 \leq i < n$. Moreover, the element

$$DT^{(n)}_{\sigma,j} \cdot K' = \frac{d}{ds}T^{(n)}_{\sigma,\gamma'(s)}|_{s=0}$$

(4.54)

is well-defined, where $K' = \gamma'(0)$.

**Lemma 4.14.** The Taylor expansion of $K'$ normal to $\Sigma$ begins with an $\mathbb{R}$-linear bundle homomorphism

$$K_{n+1}' : \text{Sym}^{n+1}_\mathbb{R} N_\Sigma \to \text{End}_J(T_X|_\Sigma)$$

(4.55)

from the symmetric $(n+1)^{st}$ power of $N_\Sigma$ to the bundle of $J$-antilinear endomorphisms of $T_X$. This can be projected to an element

$$\tilde{K}_{n+1}' : \text{Sym}^{n+1}_\mathbb{R} N_\Sigma \to \text{Hom}_J(T_\Sigma; N_\Sigma) = \Lambda^{0,1}T^{*}_\Sigma \otimes \mathbb{C} N_\Sigma.$$  

(4.56)

Moreover, we have the following identity:

$$\langle (DT^{(n)}_{\sigma,j} \cdot K') \cdot \sigma^{\otimes n+1}, \sigma^\dagger \rangle = -\frac{1}{2} \int_{J'} (\varphi^*(i\tilde{K}_{n+1}') \cdot \sigma^{\otimes n+1}, \sigma^\dagger).$$

(4.57)

Here $\sigma^\dagger \in \ker \varphi^* D^\dagger = (\text{coker} \varphi^* D)^*$ is a nonzero solution of the Serre dual operator (see Definition 2.4) which vanishes on $W_\varphi$ and $i$ denotes the multiplication by $\sqrt{-1}$ on the fibres of $N_\Sigma$.

**Proof.** It is clear that from conditions (i) and (ii) on $\gamma'$ that $K'$ is given, in a tubular neighborhood of $\Sigma$, by $K_{n+1}'$ plus terms which are $o(|\nu_\Sigma|^{n+1})$. To get (4.57), we inspect the expression for the non-linear Cauchy–Riemann operator

$$(J', \varphi, j') \mapsto \bar{\partial}_{J'} \cdot (\varphi') = \frac{1}{2} (d\varphi' + J'(\varphi') \cdot d\varphi' \cdot j')$$

(4.58)

and differentiate it at $(J, \varphi, j_\Sigma)$ once with respect to the $J'$ (in the direction $K'$) and $n+1$ times with respect to $(\varphi', j')$ (in the direction $(\delta_{\text{vf}}, \delta_{\text{acs}})$, which is a lift of $\sigma \in \ker \varphi^* D$ to $\ker \tilde{D}$) and use the fact that $J'(\varphi) \cdot d\varphi \cdot j = J(\varphi) \cdot J'(\varphi') \cdot d\varphi$. By assumption, $T^{(i)}_{\sigma,j} = 0$ for $0 \leq i < n$ and thus, the only term which can survive the pairing with $\sigma^\dagger$ is the one from (4.57).

Now, assume that we have $T^{(n)}_{\sigma,j} = 0$ for all $n \geq 1$ (since otherwise we are already done). We then have the following result.

**Lemma 4.15.** For some $1 \leq n \leq d$, there exists a point $p \in \Sigma$ over which $\varphi$ is unramified and the element

$$\sum_{q \in \varphi^{-1}(p)} (\sigma^{\otimes n+1} \otimes \sigma^\dagger)(q) \in \text{Sym}^{n+1}_\mathbb{R} N_\Sigma \otimes \mathbb{R} N^{\dagger}_\Sigma$$

(4.59)

is nonzero. In particular, we can find $K'$ as in Lemma 4.14, supported near $p$, such that the right side of (4.57) is nonzero.

**Proof.** Using Assumption 4.10, it follows that for all points $p \in \Sigma$, outside of a closed and at most countable set, $\sigma(\varphi^{-1}(p)) \subset N_{\Sigma,p}$ has $d$ distinct nonzero elements. Choose such a point $p$ and, by perturbing it slightly if necessary, assume also that $\sigma^\dagger(q) \neq 0$ for some $q \in \varphi^{-1}(p)$. Enumerate the pre-images of $p$ under $\varphi$ as $q_1, \ldots, q_d \in \Sigma$. Choose linear functionals

$$\Lambda : N_{\Sigma,p} \to \mathbb{R}$$

(4.60)
\[
\Lambda^1 : N_{\Sigma, p}^{\Lambda} \to \mathbb{R}
\] (4.61)
such that the \(d\) numbers \(x_i = \Lambda(\sigma(q_i))\) are all distinct and nonzero and the \(d\) numbers \(y_j = \Lambda^1(\sigma^1(q_i))\) are not all zero. This implies that the product

\[
\begin{pmatrix}
x_1^2 & x_2^2 & \cdots & x_d^2 \\
x_1 & x_2 & \cdots & x_d \\
\vdots & \vdots & \ddots & \vdots \\
x_1^{d+1} & x_2^{d+1} & \cdots & x_d^{d+1}
\end{pmatrix}
\begin{pmatrix}
y_1 \\
y_2 \\
\vdots \\
y_d
\end{pmatrix}
\] (4.62)
cannot be zero, since the matrix is invertible and the column vector is nonzero. Take \(n\) to be such that the \(n\)th entry of this product is nonzero. This \(n\) then suffices, since applying \(\text{Sym}^{n+1}_n \Lambda \otimes \mathbb{R} \Lambda^1\) to (4.59) yields a nonzero result.

Define \(K'\) explicitly as follows. Identify a tubular neighborhood of \(\Sigma \subset X\) with a neighborhood \(U\) of the zero section in \(\pi : N_\Sigma \rightarrow \Sigma\). Choose smooth \(\mathbb{C}\)-vector bundle isomorphisms \(T_X|_U \simeq \pi^*(T_X|_\Sigma)|_U \simeq \pi^*(T_\Sigma \oplus N_\Sigma)|_U\). Choose

\[
A \in \text{Hom}_\mathbb{C}(\text{Sym}^{n+1}_n N_\Sigma, \mathbb{A}^{0,1}_\mathbb{C} \otimes \mathbb{C} N_\Sigma)
\] (4.63)
which has positive pairing with (4.59) at \(p\). We can now define a deformation \(K'\) of \(J\) at any point \(v \in N_{\Sigma, p'} \cap U\) by

\[
K'_{\lambda}(v) : T_p' \Sigma \oplus N_{\Sigma, p'} \to T_{p'} \Sigma \oplus N_{\Sigma, p'}
\] (4.64)

\[
(w', w'') \mapsto \beta(v) \cdot (0, (iA_p \cdot w'^n+1) \cdot w')
\] (4.65)
where \(\beta : U \rightarrow [0,1]\) is a compactly supported cutoff function which is \(\equiv 1\) near \(\Sigma\). It is clear that \(iK'_{\lambda+1} = -A\). Now, multiplying \(A\) by a cut-off function supported in a sufficiently small neighborhood of \(p \in \Sigma\) gives the result. \(\square\)

**Proof of Lemma 4.13.** Lemmas 4.14 and 4.15 together show that points \((J, \varphi : \Sigma' \rightarrow \Sigma, \iota)\) with \(T_{\varphi|J}^{(n)} \equiv 0\) for all \(n \geq 1\) have codimension at least 1 in the wall \(W_{h, G}(g, A; k, c)\). In particular, they occur in codimension \(\geq 2\) in \(\mathcal{J}(X, \omega)\) and thus, can be avoided if \(\gamma\) is generic. \(\square\)

### 4.4.2. What happens if \(\sigma\) is multiply covered?

In this subsection, we examine what happens if Assumption 4.10 is false.

**Lemma 4.16.** If Assumption 4.10 is false, then \(\varphi\) must be unramified, i.e., \(r = 0\). Moreover, if \(\sigma\) descends to some intermediate cover \(\Sigma' \rightarrow C \rightarrow \Sigma\), then so does \(\sigma^1\).

**Proof.** Suppose \(\sigma\) descends to a \(\Sigma' = \bar{\Sigma}/H \rightarrow \bar{\Sigma}/H' \xrightarrow{\xi} \Sigma\) for some subgroup \(H' \subset G\) which strictly contains \(H\). This implies that \((\theta^*)_H = (\theta^*)_H'\) and so, the (co)kernels of \(\varphi^*D\) and \(\zeta^*D\) are identified, using formulas (4.2) and (4.3). This proves the statement about the descent of \(\sigma^1\). It also follows that the indices of \(\varphi^*D\) and \(\zeta^*D\) are the same, i.e., the number \(n_{\varphi}\) of zeros of \(d\varphi\) is the same as the number \(n_{\zeta}\) of zeros of \(d\zeta\) (counted with multiplicity). This cannot happen with \(|H'| : H| > 1\), unless \(\varphi\) is unramified. \(\square\)

We can now assume that \(\varphi\) is unramified and that both \(\sigma\) and \(\sigma^1\) are pulled back from an intermediate cover \(\Sigma' = \bar{\Sigma}/H \rightarrow C = \bar{\Sigma}/H' \xrightarrow{\xi} \Sigma\) with \(\zeta\) being of degree \(d'\) and genus \(h'\). We can compare the Kuranishi models for \((0, \varphi)\) and \((0, \zeta)\) and find that they are compatible under the natural pullback maps

\[
T^{\text{Zar}}_{(0, \zeta)} \mathcal{M}_{h'}(X, \gamma, d'A) \rightarrow T^{\text{Zar}}_{(0, \varphi)} \mathcal{M}_h(X, \gamma, dA)
\] (4.66)
both of which are isomorphisms. Thus, every curve close to $(0, \varphi) \in \mathcal{M}_h(X, \gamma, dA)$ is a \((d/d')\)-fold cover of a curve close to $(0, \zeta) \in \mathcal{M}_{h'}(X, \gamma, d'A)$. Thus, no embedded curves (of class \(dA\) and genus \(h\)) are created/destroyed (in a Gromov neighborhood of \(\varphi : \Sigma' \to \Sigma \subset X\)) when we go from negative to positive \(t\). This establishes the second half of assertion (i) of Theorem 3.4.

5. Obstruction bundles and their Euler classes

Let \(C\) be a smooth curve of genus \(g\) and let \(h \geq g\) and \(d \geq 2\) be integers such that the integer
\[
r = (2h - 2) - d(2g - 2)
\]
is non-negative. The moduli stack \(\mathcal{M}_h(C, d)\), consisting of stable holomorphic maps \(f : C' \to C\) with the arithmetic genus of \(C'\) being \(h\) and \(f_*[C'] = d[C]\), has complex virtual dimension given by \(r\). Moreover, the non-empty open substack \(\mathcal{M}_h(C, d) \subset \mathcal{M}_h(C, d)\), consisting of those \([f : C' \to C]\) for which the domain \(C'\) is smooth, is a complex orbifold of complex dimension \(r\).

**Definition 5.1 (Virtual fundamental class).** Define the class
\[
[\mathcal{M}_h(C, d)]^{\text{vir}} \in H_{2r}(\mathcal{M}_h(C, d), \mathbb{Q})
\]
to be the virtual fundamental class of this moduli space as in [Par16, Section 9]. Note that \(\mathcal{M}_h(C, d)\) is algebraic and so, we need not distinguish between its Čech and singular cohomologies.

Now, let \(N\) be a rank 2 complex vector bundle on \(C\) with \(\deg(N) = 2g - 2\). Then, for any real Cauchy–Riemann operator \(D\) on \(N\), we have
\[
\text{ind}_C(D) = \deg(N) + (1 - g) \cdot \text{rank}(N) = 0
\]
by the Riemann–Roch theorem. For the Cauchy–Riemann operator \(D\) and a point \([f : C' \to C] \in \mathcal{M}_h(C, D)\), we can consider the vector spaces
\[
\ker(f^*D)' := \text{coker}(\ker D \overset{f^*}{\longrightarrow} \ker(f^*D))
\]
\[
\text{coker}(f^*D)' := \text{coker}(\text{coker} D \overset{f^*}{\longrightarrow} \text{coker}(f^*D)).
\]
Note that these spaces can also be defined as subspaces of \(\ker(f^*D)\) and \(\text{coker}(f^*D)\), when \(C'\) is smooth, using Remark 2.7 and Lemma 2.8.

**Definition 5.2 (Cokernel/obstruction bundle).** The operator \(D\) is said to be \((d, h)\)-rigid if and only if for all \([f : C' \to C] \in \mathcal{M}_h(C, d)\), we have
\[
\ker(f^*D)' = 0.
\]
In this case, the assignment
\[
[f : C' \to C] \mapsto (\mathcal{N}^{d, h}_{C, D})_f = \text{coker}(f^*D)'
\]
defines an oriented rank 2\(r\) vector bundle \(\mathcal{N}^{d, h}_{C, D} \to \mathcal{M}_h(C, d)\), which is called the cokernel/obstruction bundle.
Next, define the canonically oriented determinant line of \((f^*D)\)' to be
\[
\det(f^*D)' = \det \ker(f^*D)' \otimes (\det \coker(f^*D)')^* 
\]
(5.8)
where \(\det(D)\) and \(\det(f^*D)\) are the determinant lines of the Cauchy–Riemann operators \(D\) and \(f^*D\), which are canonically oriented by comparing \(D\) with a \(\mathbb{C}\)-linear Cauchy–Riemann operator. If \(D\) is \((d, h)\)-rigid, this gives rise to an orientation of the corresponding cokernel bundle. Accordingly, we have a well-defined virtual Euler number of the cokernel bundle
\[
e_{d,h}(C, D) = \langle (\overline{M}_h(C, d))^\text{vir}, e(N_{C, D}^h) \rangle \in \mathbb{Q}. 
\]
(5.10)
More generally, suppose \(P\) is a topological space and \(\mathcal{D} = \{D_t\}_{t \in P}\) is a continuous family of real Cauchy–Riemann operators on \(N\). Let \(\Delta \subset \overline{M}_h(C, d) \times P\) be the closed substack over which (5.6) fails, with \(\mathcal{D}\) in place of \(D\). Then, the assignment (5.7), with \(\mathcal{D}\) in place of \(D\), gives a well-defined oriented rank 2\(r\) vector bundle
\[
\mathcal{N}_{C, D}^{d,h} \to (\overline{M}_h(C, d) \times P) \setminus \Delta 
\]
(5.11)
which has an Euler class \(e(\mathcal{N}_{C, D}^{d,h}) \in H^{2r}(\overline{M}_h(C, d) \times P) \setminus \Delta; \mathbb{Q})\).

**Definition 5.3** (Simple wall crossing). Let \(\mathcal{D} = \{D_t\}_{t \in [-1, 1]}\) be a smooth family of real Cauchy–Riemann operators on \(N\). We say that \(\mathcal{D}\) is a simple wall crossing of type \((d, h)\) at \(t = 0\) if \(\ker D_0 = 0\) and there is a finite set \(\Delta \subset \overline{M}_h(C, d)\) such that
\begin{enumerate}[(i)]  
  \item Equation (5.6) holds on \((\overline{M}_h(C, d) \times [-1, 1]) \setminus (\Delta \times 0)\) and the vector bundle \(\mathcal{N}_{C, D}^{d,h}\) is well-defined here;
  \item for each \([f : C' \to C] \in \Delta\), the linearized map
\[
T_f \overline{M}_h(C, d) \otimes \mathbb{R}_t \xrightarrow{\cong} \text{Hom}(\ker(f^*D)', \coker(f^*D)') 
\]
(5.12)
defined in Definition 2.9 is an isomorphism.
\end{enumerate}

By counting dimensions and indices, it follows that we have
\[
\dim_{\mathbb{R}} \ker(f^*D)' = 1 
\]
(5.13)
\[
\dim_{\mathbb{R}} \coker(f^*D)' = 1 + 2r 
\]
(5.14)
over the finite set \(\Delta\). Both sides of (5.12) are canonically oriented by combining the discussion preceding Assumption 4.3 with the orientation on \(\det(f^*D)'\). Thus, to each \([f : C' \to C] \in \Delta\), we can assign a well-defined number
\[
\text{sgn}(\mathcal{D}, [f : C' \to C]) \in \{+1, -1\}. 
\]
(5.15)
which is the sign of the isomorphism (5.12).

We want to compute the change in the virtual Euler number \(e_{d,h}(C, D_t)\) as we go from \(t < 0\) to \(t > 0\) for a simple wall crossing \(\mathcal{D}\) in terms of isotropy groups of the points in \(\Delta\) and the signs \(\{\text{sgn}(\mathcal{D}, p)\}_{p \in \Delta}\). Our main result is the following.

**Theorem 5.4** (Change in Euler number). In the situation of Definition 5.3,
\[
[-1, 1] \setminus \{0\} \to \mathbb{Q} 
\]
(5.16)
\[
t \mapsto e_{d,h}(C, D_t) 
\]
(5.17)
is a locally constant function. Let $e_{d,h}(C, D_{\pm})$ denote the value $e_{d,h}(C, D_t)$ for $\pm t > 0$. Then, we have the identity
\[
e_{d,h}(C, D_{+}) - e_{d,h}(C, D_{-}) = \sum_{p \in \Delta} \frac{2 \cdot \text{sgn}(D, p)}{|\text{Aut}(p)|}.
\] (5.18)

The local constancy assertion is obvious. The remaining assertion will be proved in the next two lemmas. We continue to use the notation from Definition 5.3.

**Lemma 5.5 (Local to global).** For each point $p \in \Delta$, choose an open neighborhood $V_p \subset \mathcal{M}_h(C, d) \times (-1, 1)$ (5.19) whose closure has smooth orbifold boundary $\partial V_p$. Endowing $\partial V_p$ with the boundary orientation from $V_p$ and assuming that the closures of $\{V_p\}_{p \in \Delta}$ are pairwise disjoint, we have the identity
\[
e_{d,h}(C, D_{+}) - e_{d,h}(C, D_{-}) = \sum_{p \in \Delta} \langle [\partial V_p], e(N_{d,h}^C, D) \rangle
\] (5.20)
where $[\partial V_p]$ denotes the standard orbifold fundamental class for each $p \in \Delta$.

**Proof.** It will be enough to show that the identity
\[
[M_h(C, d)^{\text{vir}} \times \{\pm 1\}] - [M_h(C, d)^{\text{vir}} \times \{-1\}] = \sum_{p \in \Delta} [\partial V_p]
\] (5.21)
holds in $H_*(M_h(C, d) \times [-1, 1]) \setminus \bigcup_{p \in \Delta} V_p; \mathbb{Q})$. This will follow from [Par16, Lemmas 5.2.4, 5.2.5 and 5.2.6] applied to the space
\[
(M_h(C, d) \times [-1, 1]) \setminus \bigcup_{p \in \Delta} V_p
\] (5.22)
provided we show that it has an implicit atlas with boundary which, when restricted to the boundary, gives (a) the usual atlas (from section [Par16, Section 9]) on $[M_h(C, d)^{\text{vir}} \times \{\pm 1\}]$ and (b) the standard orbifold atlas on each $V_p$. Constructing such an atlas is straightforward. Indeed, choose open neighborhoods
\[
V_p \subset W_p \subset W'_p \subset M_h(C, d) \times (-1, 1)
\] (5.23)
with $\{W'_p\}_{p \in \Delta}$ still being pairwise disjoint. Endow each $W'_p \setminus V_p$ with the obvious orbifold-with-boundary atlas (with trivial obstruction spaces) as in [Par16, Section 2.1.2] and endow the open subset
\[
(M_h(C, d) \times [-1, 1]) \setminus \bigcup_{p \in \Delta} W_p
\] (5.24)
with the restriction of the product atlas (see [Par16, Definition 6.3.1]) on $M_h(C, d) \times [-1, 1]$. These $1 + |\Delta|$ open sets cover the moduli space in question. Over the open overlaps $W'_p \setminus W_p \subset M_h(C, d) \times (-1, 1)$ – note that there are no triple overlaps – both implicit atlases are equivalent (in the sense of [Par16, Remark 2.1.5]). This is because the standard orbifold atlas on $M_h(C, d)$ is equivalent to the restriction of the implicit atlas on $M_h(C, d)$. Thus, we can combine this cover into an implicit atlas on the space (5.22) with the desired properties. □
Lemma 5.6 (Local contribution). In the situation of Lemma 5.5, the neighborhoods \( V_p \) can be chosen such that their closures are pairwise disjoint and we have

\[
\langle \partial V_p, e(N_{C,D}) \rangle = \frac{2 \cdot \text{sgn}(D, p)}{|	ext{Aut}(p)|}
\]

(5.25)

for each \( p \in \Delta \).

Proof. Fix \( p = [f : C' \to C] \in \Delta \subset \mathcal{M}_h(C, d) \). Since \( \mathcal{M}_h(C, d) \) is a smooth orbifold, we can identify a neighborhood \( U_p \) of \( p \) diffeomorphically with the orbifold \( [V/\Gamma] \), where \( \Gamma = \text{Aut}(C, f) \) is the isotropy group of \( p \) with its natural complex representation on \( V = T_f \mathcal{M}_h(C, d) \) and the point \( p \) is identified with \([0]\). Without loss of generality, we can assume that this neighborhood meets no other points of \( \Delta \).

Assume, for the sake of concreteness, that \( \text{sgn}(D, p) = +1 \). This can be achieved by reparametrizing the interval \([-1, 1]\) in reverse if necessary. The local chart \([V/\Gamma] \) gives a map \( V \xrightarrow{\sim} \mathcal{M}_h(C, d) \) which, in turn, yields the following \( \Gamma \)-equivariant commutative diagram (with the square being a fiber square).

\[
\begin{array}{ccc}
C' & \xrightarrow{j} & C' \\
\downarrow \pi & & \downarrow \pi \\
* & \xrightarrow{0} & V
\end{array}
\]

Here, \( \pi \) is a \( \Gamma \)-equivariant smooth family of curves and \( ev \) is a \( \Gamma \)-invariant smooth map which is holomorphic on each fibre of \( \pi \). The maps \( \pi \) and \( ev \) together with the \( \Gamma \)-action realize the open embedding \([V/\Gamma] \hookrightarrow \mathcal{M}_h(C, d) \) and conclude by noting that \( \langle [S_v], e(TS_v) \rangle = \chi(S_v) = 2 \). It is useful to note that, for this last argument to work, we do not require the isomorphism (5.26) to be \( \Gamma \)-equivariant.

To proceed, let us first make the following auxiliary choices.

1. A Hermitian metric \( \langle \cdot, \cdot \rangle \) and a compatible \( \mathbb{C} \)-linear connection \( \nabla \) on \( N \).
2. A conformal metric (and therefore, an area form) on \( C' \).
3. A smooth trivialization \( C' = C' \times V \) of the bundle \( \pi \). Let \( \tilde{f} : C' \times V \to C \) denote the map induced by \( ev \), and set \( f_v := \tilde{f}(\cdot, v) : C' \to C \) for \( v \in V \). Also, let \( \tilde{j} = (j_v)_{v \in V} \) denote the induced family of almost complex structures on \( C' \).
4. A smooth family of isomorphisms

\[
I_v : (T_{C', j_0}) \xrightarrow{\sim} (T_{C', j_v}).
\]

(5.27)

We now have the following smooth family of Cauchy–Riemann operators on \( N \) parametrized by \((v, t) \in V \times [-1, 1]\)

\[
D_{v,t} : L^2_1(C', f^* N) \to L^2(C', A^{0,1} T^*_{C', j_0} \otimes \mathbb{C} f^* N)
\]

(5.28)
defined by pulling back the operator $D_t$ on $f^*N$ to an operator on $f^*N$ by using the $\nabla$-parallel transport along the paths $\tau \in [0,1] \mapsto f_{\tau}(z) \in C$ for each $z \in C'$ and the isomorphism $I_{f^*}^{-1}$. Obviously, we have $D_{0,0} = f^*D_0$ on smooth sections. Since $\ker D_0 = \coker D_0 = 0$ (and this will continue to hold for small $t$), we have an obvious isomorphism
\[
coker D_{v,t} \simeq (\nu^*\mathcal{N}^{d,h}_{C,D})_{v,t}
\] for small $(v, t) \neq (0, 0)$. Orient $A = \ker (f^*D_0)'$ and $B = \coker (f^*D_0)'$ so that the induced orientation on $\det(f^*D_0)'$ is the canonical one from Definition 5.2. Define the bounded linear map
\[
R : \im D_{0,0} \to (\ker D_{0,0})^\perp
\]
to be the inverse of $D_{0,0}|(\ker D_{0,0})^\perp$, with $(\ker D_{0,0})^\perp \subset L^2_1$ denoting the $L^2$ orthogonal complement of $\ker D_{0,0}$. Let $\Pi_{\im} : L^2 \to \im D_{0,0}$ be the orthogonal projection and let $\Pi_{\coker}$ be the quotient projection onto the cokernel. For small $(v, t)$, the quantity $\|1 - \Pi_{\im} D_{v,t} R\|$ is small on $\im D_{0,0}$ and so, we can define the map
\[
R_{v,t} = R(\Pi_{\im} D_{v,t} R)^{-1} : \im D_{0,0} \to (\ker D_{0,0})^\perp
\]
which is the inverse of $\Pi_{\im} D_{v,t}|(\ker D_{0,0})^\perp$. It is immediate that $\ker(\Pi_{\im} D_{v,t})$ is given by the graph of the map $-R_{v,t}\Pi_{\im} D_{v,t} : \ker D_{0,0} \to (\ker D_{0,0})^\perp$. Define the smooth family of linear maps
\[
L_{v,t} : \ker D_{0,0} \to \coker D_{0,0}
\]
\[
L_{v,t} = \Pi_{\coker} D_{v,t}(1 - R_{v,t}\Pi_{\im} D_{v,t})
\]
for small $(v, t)$. We now observe that that the natural maps $\ker L_{v,t} \overset{\simeq}{\to} \ker D_{v,t}$ and $\coker L_{v,t} \overset{\simeq}{\to} \coker D_{v,t}$ are isomorphisms. It follows (using the identifications $A = \ker D_{0,0}$ and $B = \coker D_{0,0}$) that the oriented vector bundle $\nu^*\mathcal{N}^{d,h}_{C,D}$ is given, on a punctured neighborhood of $(0,0)$, by the assignment
\[
(v, t) \mapsto coker (L_{v,t} : A \to B)
\]
with the bundle orientation derived from the orientations already chosen on $A$ and $B$. Note that $L_{0,0} = 0$ and that the first order Taylor expansion of $L_{v,t}$ about $(0,0)$ is given by the positively oriented linear isomorphism
\[
\mathbb{V} \oplus \mathbb{R}_t \overset{\simeq}{\to} \text{Hom}(A, B)
\]
from (5.12). Fixing a unitary $\Gamma$-invariant metric on $\mathbb{V}$ and restricting to any sufficiently small sphere $S_V \subset \mathbb{V} \times [-1,1]$ centred at the origin, we can discard (i.e. homotope away) the higher order terms from the Taylor expansion of $L_{v,t}$. It follows that the fiber of the vector bundle at a point $(v_0, t_0) \in S_V$ is identified with the quotient of the oriented vector space $\mathbb{V} \oplus \mathbb{R}_t$ by the oriented 1-dimensional space spanned by $(v_0, t_0)$. But this is simply the standard description of the (oriented) tangent bundle of the sphere $S_V \subset \mathbb{V} \oplus \mathbb{R}_t$, once we replace “quotient” by “orthogonal complement” and (5.26) now follows. \hfill $\square$

**Remark 5.7.** A coordinate invariant way of summarizing the above proof is the following. The bundle $\mathcal{N}^{d,h}_{C,D}$, initially defined on $(\overline{\mathcal{M}}_h(C,d) \times [-1,1]) \setminus (\Delta \times 0)$, extends to the real oriented blow-up of $\overline{\mathcal{M}}_h(C,d) \times [-1,1]$ along the smooth points
\[ \Delta \times 0 \text{ as a vector bundle } \mathcal{N}_{C,D}^{d,h}. \] Moreover, for each point \( p \in \Delta \), we have a natural vector bundle isomorphism with orientation \( \text{sgn}(D,p) \)

\[
\mathcal{N}_{C,D}^{d,h}|_{S_p} = TS_p
\]

over \( S_p \), the exceptional boundary component created by blowing up at \( p \). Now, a direct cobordism argument as in Lemma 5.5, applied to the real oriented blow-up \( \text{Bl}^1_{\Delta} \times 0 (\mathcal{M}_h(C,d) \times [-1,1]) \) gives (5.18).

6. Application to the Gopakumar–Vafa invariants

In this section, we describe an application of our bifurcation analysis to the Gopakumar–Vafa invariants in a special case.

**Definition 6.1.** We say that \( A \in H_2(X,\mathbb{Z}) \) is primitive if \( [\omega] \cdot A > 0 \) and we cannot write \( A = dB \) for any \( B \in H_2(X,\mathbb{Z}) \) and integer \( d \geq 2 \).

If we fix a super-rigid \( J \in \mathcal{J}(X,\omega) \), we have a well-defined signed count the number of embedded \( J \)-curves of a given genus \( g \) and homology class \( \beta \). However, this number is not invariant under the change of \( J \) as bifurcations may occur. Thus, we need a suitable correction term to make the count invariant. We will show how to do this for \( g = 0 \) and \( \beta = 2A \), where \( A \) is primitive.

**Definition 6.2.** Let \( C \) be a smooth genus 0 curve and let \( N \) be a complex vector bundle on it with \( \deg(N) = -2 \). Define \( \mathcal{CR}_\mathbb{R}(N) \) to be the affine space of all smooth Cauchy–Riemann operators on \( N \). Let \( \mathcal{CR}_C(N) \) be the subspace of \( \mathbb{C} \)-linear Cauchy–Riemann operators. For \( k \geq 1 \) and \( K \in \{\mathbb{R},\mathbb{C}\} \), define the subsets

\[
\mathcal{W}_{k,K} \subset \mathcal{CR}_K(N)
\]

to be the space of operators \( D \) for which \( \dim_K \ker D = k \). It is easy to show that \( \mathcal{W}_{1,\mathbb{R}} \) has \( \mathbb{R} \)-codimension 1 in \( \mathcal{CR}_\mathbb{R}(N) \) and that \( \mathcal{W}_{k,\mathbb{C}} \) has \( \mathbb{C} \)-codimension \( \geq 1 \) in \( \mathcal{CR}_C(N) \) for all \( k \geq 1 \). Moreover, using Theorem 2.15, we see that \( \mathcal{W}_{k,\mathbb{R}} \) has codimension \( \geq 4 \) in \( \mathcal{CR}_\mathbb{R}(N) \) for \( k \geq 2 \). Finally, define the subset

\[
\mathcal{W}' \subset \mathcal{CR}_\mathbb{R}(N)
\]

to consist of those \( D \) for which there exists a section \( 0 \neq \sigma \in \ker D \) and a point \( z \in C \) with \( \sigma(z) = 0 \).

**Lemma 6.3.** \( \mathcal{W}' \) has codimension \( \geq 3 \) in \( \mathcal{CR}_\mathbb{R}(N) \).

**Proof.** The proof is a direct adaptation of the argument in [IP18, Appendix B]. For each \( k,s \geq 0 \), define \( \mathcal{W}'_{s,k} \) to be the space of tuples \( (z_1,\ldots,z_k,D) \), where \( z_1,\ldots,z_k \in C \) are distinct points and \( D \in \mathcal{CR}_\mathbb{R}(N) \), satisfying the following.

(i) \( V_{(z_1,\ldots,z_k,D)} = \{ \sigma \in \ker D : \sigma(z_1) = \cdots = \sigma(z_k) = 0 \} \) is \( s \)-dimensional.

(ii) There exists a point \( z \in C \setminus \{z_1,\ldots,z_k\} \) such that the map \( V_{(z_1,\ldots,z_k,D)} \to N_z \) given by \( \sigma \mapsto \sigma(z) \) is injective.

Clearly, every \( D \in \mathcal{W}' \) can be lifted to \( \mathcal{W}'_{s,k} \) for some \( (s,k) \) with \( s \geq 1 \) and \( k \geq 1 \) (since \( \ker D \) is finite dimensional). Thus, it suffices to show that the image of \( \mathcal{W}'_{s,k} \to \mathcal{CR}_\mathbb{R}(N) \) is of codimension \( \geq 3 \) for each \( s,k \geq 1 \). Fix a point \( (z_1,\ldots,z_k,D) \in \mathcal{W}'_{s,k} \) and consider the natural linearized map

\[
L : \Omega^0_c(C \setminus \{z_1,\ldots,z_k\},\text{Hom}_\mathbb{R}(N,N)) \to \text{Hom}(V,W)
\]
where \( V, W \) are the kernel, cokernel respectively of \( D : \Omega^0(C, N) \to \Omega^{0,1}(C, N) \) restricted to the space of sections of \( N \) vanishing on \( z_1, \ldots, z_k \). We claim that \( L \) is surjective. To see this, it suffices to show that the Petri map (dual to \( L \))

\[ L^\dagger : V \otimes W^* \to \Omega^0(C \setminus \{z_1, \ldots, z_k\}, N \otimes_R N^\dagger) \tag{6.4} \]

is injective. Indeed, fix a basis \( \kappa_1, \ldots, \kappa_s \) of \( V \) and consider any nonzero element \( \sum_i \kappa_i \otimes c_i \in V \otimes W^* \). Here, each \( c_i \) is a distributional section of the Serre dual \( N^\dagger \) such that \( D^1 c_i \) is a sum of delta distributions supported on \( \{z_1, \ldots, z_k\} \). Without loss of generality, assume that we have \( c_1 \neq 0 \). Then, we can find a point \( z \in C \) such that (ii) above holds and, by perturbing \( z \) slightly if necessary, we also have \( c_1(z) \neq 0 \). We then get

\[ 0 \neq \sum_i \kappa_i(z) \otimes c_i(z) \in N_z \otimes N_z^\dagger. \]

This implies, in particular, that we also have \( L^\dagger (\sum_i \kappa_i \otimes c_i) \neq 0 \).

Since \( L \) is surjective, the image of \( W^\prime_{s,k} \to CR_R(N) \) has codimension

\[ \geq s(s + 4k) - 2k \geq s(s + 2k) \geq 3 \tag{6.5} \]

as desired.

**Definition 6.4.** Continuing in the situation of Definition 6.2, for each \( k,l \geq 0 \) define the subset

\[ W^\mathbb{Z}/2\mathbb{Z}_{k,l} \subset M_0(C,2) \times CR_R(N) \tag{6.6} \]

as follows. First, \( M_0(C,2) \) is the coarse moduli space underlying the (purely ineffective) orbifold \( M_0(C,2) \). Second, say \( ([f : C' \to C], D) \) lies in \( W^\mathbb{Z}/2\mathbb{Z}_{k,l} \) iff

\[ \dim_R \ker(D) = k \tag{6.7} \]

\[ \dim_R \ker(f^*D)' = l \tag{6.8} \]

where we are using the notation of Definition 5.2. Using Theorem 2.15, it follows that \( W^\mathbb{Z}/2\mathbb{Z}_{k,l} \) has codimension \( k^2 + l(l + 4) \) in \( M_0(C,2) \times CR_R(N) \). Finally, also define the subset

\[ W^\mathbb{Z}/2\mathbb{Z}_{s,1} \subset M_0(C,2) \times CR_R(N) \tag{6.9} \]

to be the union of \( W^\mathbb{Z}/2\mathbb{Z}_{k,l} \) for all \( k \geq 0 \).

**Lemma 6.5.** \( W^\mathbb{Z}/2\mathbb{Z}_{s,1} \subset M_0(C,2) \times CR_R(N) \) has codimension 5 and is canonically co-oriented. Moreover, the projection \( W^\mathbb{Z}/2\mathbb{Z}_{s,1} \to M_0(C,2) \) is a fiber bundle.

**Proof.** Let us fix \( p = [f : C' \to C] \in M_0(C,2) \) and prove the result for any point \( D \) in the corresponding subset \( W^\mathbb{Z}/2\mathbb{Z}_{s,1}(p) \subset CR_R(N) \). We then have a linearized map, as in Definition 2.9,

\[ \Omega^0(C, \text{Hom}_R(N,N)) \to \text{Hom}(\ker(f^*D)', \text{coker}(f^*D)') \tag{6.10} \]

which we need to show is surjective. But this follows since it is just a component of the map whose surjectivity is needed show the smoothness of \( W^\mathbb{Z}/2\mathbb{Z}_{s,1} \) for some \( k \geq 0 \). Alternatively, we can take any \( 0 \neq \kappa \in \ker(f^*D)' \) and \( 0 \neq c \in \ker(f^*D)^\dagger \) and note that \( \kappa \otimes c \) is nonzero and \( \mathbb{Z}/2\mathbb{Z} \)-invariant (and therefore, descends along \( f : C' \to C \), away from the branch points). This will show that the map

\[ \ker(f^*D)' \otimes \ker(f^*D)^\dagger \to \Omega^0(C', f^*N \otimes (f^*N)^\dagger)^{\mathbb{Z}/2\mathbb{Z}} \tag{6.11} \]
dual to (6.10) is injective. We now have the desired codimension formula and the co-orientation is simply given by taking canonical orientation on the target of (6.10), coming from Definition 5.2, and the complex orientation on $M_0(C, 2)$. □

**Definition 6.6** (Sign). Continuing with the setup of Definition 6.2, let $D$ be a Cauchy–Riemann operator on $N$ such that $\ker D = \operatorname{coker} D = 0$. Define the sign $\operatorname{sgn}(D) \in \{-1, +1\}$ of $D$ as follows. The determinant line

$$\det(D) = \det \ker D \otimes (\det \operatorname{coker} D)^*$$

of $D$ is, on the one hand, canonically oriented (by deforming $D$ to a complex linear Cauchy–Riemann operator) and, on the other hand, canonically identified with $\mathbb{R}$, since $\ker D = \operatorname{coker} D = 0$. If these two orientations agree, we set $\operatorname{sgn}(D) = +1$. In the remaining case, we set $\operatorname{sgn}(D) = -1$.

**Definition 6.7** (Linear wall crossing invariant). Let $D \in \operatorname{CR}_\mathbb{R}(N)$ be $(2, 0)$-rigid in the sense of Definition 5.2. Choose a generic path $\gamma : [0, 1] \to \operatorname{CR}_\mathbb{R}(N) \setminus W'$ starting from $D$ and ending on $\operatorname{CR}_\mathbb{C}(N) \setminus \bigcup_{k \geq 1} W_{k, \mathbb{C}}$, such that it is transverse to the image of the projection map

$$W_{*, 1}^{\mathbb{Z}/2\mathbb{Z}} \to \operatorname{CR}_\mathbb{R}(N)$$

and avoids $W_{k, \mathbb{C}}^{\mathbb{Z}/2\mathbb{Z}}$ for each $k \geq 0$ and $l \geq 2$. Then, the fiber product of $\gamma$ and (6.13) is a finite oriented, i.e. signed, collection of points and their signed count

$$w_2(D, \gamma) \in \mathbb{Z}$$

is called the linear wall crossing invariant of $D$ along $\gamma$.

**Lemma 6.8.** The linear wall crossing invariant is well-defined and independent of the choice of $\gamma$ and only depends on the starting point $D$.

Proof. Note that $\bigcup_{k \geq 1} W_{k, \mathbb{C}}$ has complex codimension 1 and therefore, the space $\operatorname{CR}_\mathbb{C}(N) \setminus \bigcup_{k \geq 1} W_{k, \mathbb{C}}$ is path connected. Moreover, every operator in the set $\operatorname{CR}_\mathbb{C}(N) \setminus \bigcup_{k \geq 1} W_{k, \mathbb{C}}$ is isomorphic (by Grothendieck’s theorem [Gro57]) to the standard operator on $\mathcal{O}(-1)^{\oplus 2} \to \mathbb{P}^1$, which is super-rigid. Thus, we may disregard the final endpoint of $\gamma$.

By checking the codimensions, we see that we can join any two paths (with the same endpoints) as in Definition 6.7 by a fixed-endpoint path homotopy $\tilde{\gamma}$ which avoids $W'$, is transverse to $W_{*, 1}^{\mathbb{Z}/2\mathbb{Z}}$ and also avoids $W_{k, \mathbb{C}}^{\mathbb{Z}/2\mathbb{Z}}$ for all $k \geq 0$ and $l \geq 2$. We will be done if we show that the fiber product of $\tilde{\gamma}$ with the map (6.13) is a compact oriented 1-manifold with boundary exactly along the two initial paths.

The property of being an oriented 1-manifold with boundary is obvious from the transversality assumptions on $\tilde{\gamma}$. To show compactness, suppose that we have an infinite sequence of points $([f_i : C_i' \to C], D_i) \in W_{*, 1}^{\mathbb{Z}/2\mathbb{Z}}$ with $D_i \to D$. Since we know that the homotopy avoids $W_{k, \mathbb{C}}^{\mathbb{Z}/2\mathbb{Z}}$ for all $k \geq 0$ and $l \geq 2$, it follows that we only need to rule out the possibility when the limit of a subsequence of $[f_i : C_i' \to C]$ is a nodal stable map $f : C \vee_s C \to C$. Indeed, in this case, we must have a section $0 \neq \sigma' \in \ker(f^* D)$ which flips sign under the $\mathbb{Z}/2\mathbb{Z}$ action and thus, there is a section $0 \neq \sigma \in \ker D$ with $\sigma(z) = 0$. But this means $D \in W'$ (which would be a contradiction to the choice of $\tilde{\gamma}$).

**Remark 6.9.** Because of the path independence, we denote the linear wall crossing invariant of an operator $D$ simply by $w_2(D)$. 

Definition 6.10. Let $A \in H_2(X, \mathbb{Z})$ be primitive and $J \in \mathcal{J}(X, \omega)$ be super-rigid. Define the virtual number of embedded curves of genus $0$ and class $2A$ to be

$$n_{2A,0}^{\text{emb}}(J) = \sum_{[C']=2A} \text{sgn}(D_{C',J}^N) + \sum_{[C]=A} \text{sgn}(D_{C,J}^N)w_2(D_{C,J}^N)$$

(6.15)

where the first sum is over all embedded genus $0$ $J$-curves $C' \subset X$ of class $2A$ and the second sum is over all embedded genus $0$ $J$-curves $C \subset X$ of class $A$.

Theorem 6.11 (Invariance). The virtual number of embedded curves of genus $0$ and class $2A$ is independent of the choice of super-rigid $J$.

Proof. The proof essentially follows the ideas in [Tan00]. Let $J_\pm \in \mathcal{J}(X, \omega)$ be two super-rigid almost complex structures. Choose a generic path $\gamma: [-1,1] \to \mathcal{J}(X, \omega)$. Define $b = (b_1, b_2)$ with $b_i = (2)$ for $i = 1, 2$ and let $\theta$ be the sign representation of $\mathbb{Z}/2\mathbb{Z}$. We may assume that $\gamma$ is transverse to the map

$$\mathcal{M}_{b,\mathbb{Z}/2\mathbb{Z}}^2(\mathcal{M}_0(X, A); \theta, \theta^{\pm 5}) \to \mathcal{J}(X, \omega)$$

(6.16)

and that it avoids each $\mathcal{M}_{b,\mathbb{Z}/2\mathbb{Z}}^2(\mathcal{M}_0(X, A); k, c)$ for which $\theta$ is a proper sub-representation of $k$. Also, exactly as in the proof of Lemma 6.8, we may ensure that for each $t \in (-1,1)$, there is no $\gamma(t)$-curve $\Sigma$ along with a point $z \in \Sigma$ and a section $0 \neq \sigma \in \ker D_{\Sigma,\gamma(t)}^N$ satisfying

$$\sigma(z) = 0.$$  

(6.17)

Now, let us consider the moduli space

$$\mathcal{M}_0^*(X, \gamma, 2A) \to [-1,1]$$

(6.18)

consisting, of pairs $(t, \Sigma)$ with $t \in [-1,1]$ and $\Sigma \subset X$ being an embedded $\gamma(t)$-curve in the homology class $2A$. Define $\overline{\mathcal{M}}_0(X, \gamma, A) = \mathcal{M}_0^*(X, \gamma, A)$ analogously. Both of these moduli spaces are oriented 1-dimensional manifolds with boundary over $t = \pm 1$. Moreover, $\mathcal{M}_0^*(X, \gamma, A)$ is proper over $[-1,1]$.

Using the argument from Lemma 6.8 and the genericity of $\gamma$, we find that there are finitely many points in the fiber product of $\gamma$ and (6.16). Let us enumerate the times of the intersections as $-1 < t_1 < \cdots < t_k < 1$. Further, for each $1 \leq i \leq k$, let

$$p_{i,j} = (\gamma(t_i), \Sigma_{i,j} \subset X, \varphi_{i,j}: \Sigma_{i,j}' \to \Sigma_{i,j}) \in \mathcal{M}_{b,\mathbb{Z}/2\mathbb{Z}}^2(\mathcal{M}_0^*(X, A); \theta, \theta^{\pm 5})$$

(6.19)

for $1 \leq j \leq \ell_i$ be an enumeration of the corresponding points in the fibre product. Choose $\epsilon_i > 0$ for $1 \leq i \leq k$ and Gromov neighborhoods $\mathcal{O}_{i,j}$ of $\varphi_{i,j}: \Sigma_{i,j}' \to X$ for $1 \leq j \leq \ell_i$ such that the products

$$U_{i,j} = (t_i - \epsilon_i, t_i + \epsilon_i) \times \mathcal{O}_{i,j}$$

(6.20)

are all pairwise disjoint. The proof now follows from a series of claims.

1. The $\mathbb{Z}$-valued function

$$\quad (t, \Sigma) \mapsto w_2(D_{\Sigma,\gamma(t)}^N)$$

(6.21)

defined on $\mathcal{M}_0(X, \gamma, A)$ away from the complement of the fibres over $\{t_i\}_{1 \leq i \leq k}$ is locally constant.

Proof. Indeed, fix a point $(t_0, \Sigma_0) \in \mathcal{M}_0(X, \gamma, A)$ with $t_0 \neq t_i$ for all $1 \leq i \leq k$. The operator $D_{\Sigma,\gamma(t_0)}^N$ is then $(2,0)$-rigid and thus, any $(t, \Sigma) \in \mathcal{M}_0(X, \gamma, A)$ sufficiently close to $(t_0, \Sigma_0)$ can be joined to it by a path consisting of curves
with \((2,0)\)-rigid normal deformation operators. The definition of \(w_2(\cdot)\) now gives \(w_2(D^{N}_{\Sigma, \gamma(t)}) = w_2(D^{N}_{\Sigma, \gamma(t_0)})\) \(\square\)

2. The moduli space \(\mathcal{M}_0^*(X, \gamma, 2A) \setminus \bigcup_{i,j} \mathcal{U}_{i,j}\) is compact.

**Proof.** Let \((t_n, \Sigma_{i,n}')\) be a sequence in this space. By Gromov compactness, we can pass to a subsequence which converges to a stable map \((t, \varphi : \Sigma' \to X)\). If \(\varphi\) is an embedding, then we are done. If not, then (since \(\gamma(t) \notin \mathcal{W}_{\text{emb}}\) by genericity) we must have a factorization \(\varphi : \Sigma' \to \Sigma \subset X\) for some embedded \(\gamma(t)\)-curve \(\Sigma\) of class \(A\). By Lemma 6.12 below, we must have \(\ker(\varphi^* D^{N}_{\Sigma, \gamma(t)})' \neq 0\). We take two cases.

(i) \(\varphi : \Sigma' = \Sigma \cup_{\gamma} \Sigma \to \Sigma\) is nodal. This implies that there exists a \(0 \neq \sigma \in \ker D^{N}_{\Sigma, \gamma(t)}\) with \(\sigma(\gamma) = 0\), which is a contradiction.

(ii) \(\Sigma'\) is smooth. This means that we must have \(t = t_0\) and \(\varphi \simeq \varphi_{i,j}\) for some \(i, j\) and thus, \((t_n, \Sigma_{i,n}') \in \mathcal{U}_{i,j}\) for large \(n\) which is a contradiction. \(\square\)

3. Let \(t \in [-1, 1]\setminus\{t_1, \ldots, t_k\}\) be a regular value of both (6.18) and the projection \(\mathcal{M}_0^*(X, \gamma, A) \to [-1, 1]\). Then, the formula (6.15) for \(n^{\text{emb}}_{2A,0}\) is well-defined for any \(\gamma(t)\). Moreover, if \(t_i < t' < t'' < t_i+1\) are two such regular values (for some \(1 \leq i < k\)), then we have

\[
n^{\text{emb}}_{2A,0}(\gamma(t')) = n^{\text{emb}}_{2A,0}(\gamma(t'')).
\]  

**Proof.** The argument from claim (2) above shows that the restriction of (6.13) to \([-1, 1]\setminus\{t_1, \ldots, t_k\}\) is proper. Combined with the result of claim (1) and the properness of the projection \(\mathcal{M}_0^*(X, \gamma, A)\), it follows that each of the two summations (appearing in the definition of \(n^{\text{emb}}_{2A,0}\)) gives the same result for \(t'\) and \(t''\). In particular, we get (6.22). \(\square\)

4. Let \(t', t'' \in [-1, 1]\setminus\{t_1, \ldots, t_k\}\) be regular values of both (6.18) and the projection \(\mathcal{M}_0^*(X, \gamma, A) \to [-1, 1]\). If \(1 \leq i \leq k\) is such that

\[
-\epsilon_i < t' - t_i < 0 < t'' - t_i < \epsilon_i
\]  

then we again have (6.22).

**Proof.** In view of claim (3), we can take \(t', t''\) to be arbitrarily close to \(t_i\). For small \(|t-t_i|\) and \(\Sigma \in \{\Sigma_{i,j} : 1 \leq j \leq \ell_i\}\), define \(\Sigma(t)\) to be the unique embedded \(\gamma(t)\)-curve close to \(\Sigma\) (obtained by noting that \(\ker D^{N}_{\Sigma, \gamma(t)} = 0\) and applying the inverse function theorem). For such a \(\Sigma\), let \(I_{\Sigma}(i) = \{1 \leq j \leq \ell_i : \Sigma = \Sigma_{i,j}\}\), and note that we have the identity

\[
\sum_{j \in I_{\Sigma}(i)} \text{sgn}(\gamma, t_i; p_{i,j}) = \text{sgn}(D^{N}_{\Sigma, \gamma(t_i)}) \cdot (w_2(D^{N}_{\Sigma(t''), \gamma(t''_i)}) - w_2(D^{N}_{\Sigma(t'), \gamma(t'_i)}))
\]  

where we check orientations by using the identification

\[
\det(D^{N}_{\Sigma, \gamma(t_i)}) \otimes \det(\varphi_{i,j}^* D^{N}_{\Sigma, \gamma(t_i)})' = \det(\varphi_{i,j}^* D^{N}_{\Sigma, \gamma(t_i)})
\]  

for each \(j \in I_{\Sigma}(i)\). Apply Theorem 3.4 to each pair \((t_i, p_{i,j})\) and note that \(\Gamma = \mathbb{Z}/2\mathbb{Z}\) in all cases. Arguing as in the proof of claim (3), we find that the first sum in the definition of \(n^{\text{emb}}_{2A,0}\) changes by the negative of the left side of (6.24) as we go from \(t'\) to \(t''\), while the second sum in the definition of \(n^{\text{emb}}_{2A,0}\)
changes by the right side of (6.24) when we go from \( t' \) to \( t'' \). These two changes cancel each other out and so, we again have (6.22).

By combining claims (3) and (4), we deduce that \( n_{2A,0}^{\text{emb}}(J_-) = n_{2A,0}^{\text{emb}}(J_+) \).

**Lemma 6.12.** Fix a smooth family \( F : V \to \mathcal{J}(X,\omega) \) defined on a finite dimensional vector space \( V \) with \( J = F(0) \). Let \( \Sigma \subset X \) be an embedded \( J \)-curve of genus 0 and \( \varphi : \Sigma' \to \Sigma \) be a genus 0 double cover, possibly with nodes. If we have

\[
\ker(\varphi^* D^{N}_{C,J})' = 0
\]

then we can find a Gromov neighborhood \( \mathcal{O} \) of \( \varphi : \Sigma' \to X \) and a neighborhood \( U \) of 0 in \( V \) such that \( U \times \mathcal{O} \) contains no pair \((v,f : C' \to X)\), where \( f : C \to X \) is a simple \( F(v) \)-holomorphic genus 0 curve, with \( f_*[C] = 2[\Sigma] \in H_2(X,\mathbb{Z}) \).

**Proof.** Consider the moduli stack

\[
\overline{\mathcal{M}}_0(X,F,2[\Sigma])
\]

of pairs \((v \in V, f : C' \to X)\), where \( f \) is an \( F(v) \)-holomorphic stable map of genus 0 in class \( 2[\Sigma] \). Near the point \((0,\varphi)\), we can describe this moduli stack as \( F^{-1}(0)/\Gamma \), using a local \( \Gamma \)-equivariant Kuranishi model

\[
F : T_{\varphi} \overline{\mathcal{M}}_0(\Sigma,2) \oplus \ker \varphi^* D \oplus V \to \text{coker} \varphi^* D
\]

where \( D = D^N_{C,J} \), \( \Gamma = \text{Aut}(\varphi) = \mathbb{Z}/2\mathbb{Z} \) and \( \overline{\mathcal{M}}_0(\Sigma,2) \) is the orbifold of stable genus 0 maps to \( \Sigma \) of degree 2. When \( \Sigma' \) is smooth, this Kuranishi model can be constructed as usual using the implicit function theorem and \( F \) is smooth. When \( \Sigma' \) is nodal, we first split the space \( T_{\varphi} \overline{\mathcal{M}}_0(\Sigma,2) \) into two complex one dimensional spaces (one corresponding to variations of the nodal branched cover \( \varphi \) among other nodal degree 2 covers and the other being the gluing parameter corresponding to smoothing the node) and then use standard gluing analysis (see for example [Par16, Appendix B]) to construct the Kuranishi model. We recall that when \( \Sigma' \) is nodal, gluing analysis shows that the map \( F \) is continuous but not necessarily smooth.

Now, observe that the \( \Gamma \)-action on the domain of \( F \) is trivial (this is because \( \ker D = \ker \varphi^* D \)). Thus, every point in \( F^{-1}(0) \) corresponds to a stable map in \( \overline{\mathcal{M}}_0(X,F,2[\Sigma]) \) with automorphism group \( \Gamma \). In particular, every stable map near \((0,\varphi)\) is non-simple.

**Remark 6.13.** In view of Theorem 6.11, we drop \( J \) from the notation for \( n_{2A,0}^{\text{emb}} \).

**Theorem 6.14.** The virtual number of embedded curves of genus 0 and class \( 2A \) satisfies the Gopakumar–Vafa formula. More precisely, define, for super-rigid \( J \),

\[
\begin{align*}
GW_{A,0} &= n_{A,0}^{\text{emb}} = \sum_{[C]=A} \text{sgn}(D^N_{C,J}) \\
GW_{2A,0} &= \sum_{[C]=2A} \text{sgn}(D^N_{C,J}) + \sum_{[C]=A} \text{sgn}(D^N_{C,J})e_{2,0}(C, D^N_{C,J})
\end{align*}
\]

where \( e_{2,0} \) denotes the virtual Euler number as defined in 5.2. Then, we have the following relation between \( GW \) and \( n^{\text{emb}} \):

\[
GW_{2A,0} = n_{2A,0}^{\text{emb}} + \frac{1}{23} \cdot n_{A,0}^{\text{emb}}.
\]
Proof. From the definitions, it is clear that it will suffice to prove that
\[ e_{2,0}(\mathbb{C}, D_{\mathbb{C}, J}^N) - \frac{1}{25} = w_2(D_{\mathbb{C}, J}^N). \] (6.32)
Let \( \bar{\partial} \) denote an operator on \( N_{\mathbb{C}} \) which is conjugate to the standard operator on \( \mathcal{O}(-1)^{\mathbb{Z}/2} \to 1 \). The Aspinwall–Morrison formula (see, for example [Voi96]) shows that we have
\[ e_{2,0}(\mathbb{C}, \bar{\partial}) = \frac{1}{25}. \] (6.33)
Thus, we are left to prove that the difference of Euler numbers is given by the wall-crossing invariant. But this is immediate from the definition and Theorem 5.4. Simply choose a generic path \( \gamma \) in \( CR(N_{\mathbb{C}}) \) from \( D_{\mathbb{C}, J}^N \) to \( \bar{\partial} \) which is transverse to all \( W_{k,l}^{\mathbb{Z}/2} \), \( W_{k,R} \) and \( W' \) and apply Theorem 5.4 to each intersection of \( \gamma \) with \( W_{k,l}^{\mathbb{Z}/2} \) and note that \( e_{2,0} \) does not change when \( \gamma \) intersects \( W_{1,0}^{\mathbb{Z}/2} \). \( \square \)
