Nuclear spins were among the first physical platforms to be considered for quantum information processing [1, 2], because of their exceptional quantum coherence [3] and atomic-scale footprint. However, their full potential for quantum computing has not yet been realized, due to the lack of methods to link nuclear qubits within a scalable device combined with multi-qubit operations with sufficient fidelity to sustain fault-tolerant quantum computation. Here we demonstrate universal quantum logic operations using a pair of ion-implanted \(^{31}\)P nuclei in a silicon nanoelectronic device. A nuclear two-qubit controlled-Z gate is obtained by imparting a geometric phase to a shared electron spin [4], and used to prepare entangled Bell states with fidelities up to 94.2(2.7)\%.

The quantum operations are precisely characterised using gate set tomography (GST) [5], yielding one-qubit gate fidelities up to 99.93(3)\%, two-qubit gate fidelity of 99.21(14)\% and two-qubit preparation/measurement fidelities of 98.95(4)\%. These three metrics indicate that nuclear spins in silicon are approaching the performance demanded in fault-tolerant quantum processors [6]. We then demonstrate entanglement between the two nuclei and the shared electron by producing a Greenberger-Horne-Zeilinger three-qubit state with 92.5(14)\% fidelity. Since electron spin qubits in semiconductors can be further coupled to other electrons [7, 8, 9] or physically shuttled across different locations [10, 11], these results establish a
viable route for scalable quantum information processing using nuclear spins.

Nuclear spins are the most coherent quantum systems in the solid state [3] [12], owing to their extremely weak coupling to the environment. In the context of quantum information processing, the long coherence is associated with record single-qubit gate fidelities [13]. However, the weak coupling poses a challenge for multi-qubit logic operations. Using spin-carrying defects in diamond [14] and silicon carbide [15], this problem can be addressed by coupling multiple nuclei to a common electron spin, thus creating quantum registers that can sustain small quantum logic operations and error correction [16]. Exciting progress is being made on linking several such defects via optical photons [17] [18].

Still missing, however, is a pathway to exploit the atomic-scale dimension of nuclear spin qubits to engineer scalable quantum processors, where densely-packed qubits are integrated and operated within a semiconductor chip [19]. This requires entangling the nuclear qubits with electrons that can either be physically moved, or entangled with other nearby electrons. It also requires interspersing the electron-nuclear quantum processing units with spin readout devices [20]. Here we show experimentally that silicon - the material underpinning the whole of modern digital information technology - is the natural system in which to develop dense nuclear spin based quantum processors [1].

One electron – two nuclei quantum processor

The experiments are conducted on a system of two $^{31}$P donor atoms, introduced in an isotopically purified $^{28}$Si substrate by ion implantation (see Methods). A three-qubit processor is formed by using an electron (e) with spin $S = 1/2$ (basis states $|\uparrow\rangle, |\downarrow\rangle$) and two nuclei (Q1, Q2) with spin $I = 1/2$ (basis states $|\uparrow\rangle, |\downarrow\rangle$). Metallic structures on the surface of the chip provide electrostatic control of the donors, create a single-electron transistor (SET) charge sensor, and deliver microwave and radiofrequency signals through a broadband antenna (Fig. 1a, Extended Data Fig. 1). With this setup, we can perform single-shot electron spin readout [20], and high fidelity ($\approx 99.9\%$) single-shot quantum nondeletion readout of the nuclear spins [21], as well as nuclear magnetic resonance (NMR) and electron spin resonance (ESR) [22] on all spins involved (see Methods).

The ESR spectra in Fig. 1c exhibit four resonances. This means that the ESR frequency depends upon the state of two nuclei, to which the electron is coupled by contact hyperfine interactions, $A_1 \approx 95$ MHz and $A_2 \approx 9$ MHz. We adopt labels where, for instance, $\nu_{e\downarrow\uparrow\downarrow}$ represents the frequency at which the electron spin undergoes transitions conditional on the two nuclear spin qubits being in the $|Q_1Q_2\rangle = |\downarrow\downarrow\rangle$ state, and so on. In a two-donor system, this could either mean that all electrons have been removed from the donor pair, or that two electrons are left in a singlet state with total spin zero, yielding $A_1 = A_2 = 0$. However, the spin relaxation time $T_{1e}$ on the hyperfine-coupled electron is three orders of magnitude shorter than expected from a one-electron system (Extended Data Fig. 3). Therefore, we interpret the ESR spectrum in Fig. 1c as describing the response of the third electron bound to a 2P donor system.

An effective-mass calculation of the wavefunction of the third electron in a 2P system (see Methods) reproduces the observed values of $A_1$ and $A_2$ by assuming donors spaced 6.5 nm apart, and subjected to an electric field 2 mV/nm that pulls the electron wavefunction more strongly towards donor 1 (Fig. 1a). The $^{31}$P nuclei in this 2P cluster are spaced more widely than those produced by scanning probe lithography [8] [23], where the sub-nanometre inter-donor spacing causes a strongly anisotropic hyperfine coupling, which randomizes the nuclear spin state each time the electron is removed from the cluster for spin readout [24]. Here, instead, the probability of flipping a nuclear spin by electron ionisation is of order $10^{-6}$ (Extended Data Fig. 3), meaning that our nuclear readout is almost perfectly quantum nondemolition.

Nuclear two-qubit operations

We first consider the two $^{31}$P nuclear spins as the qubits of interest. One-qubit logic operations are trivially achieved by NMR pulses [21] (see Methods), where $A_1 \neq A_2$ provides the spectral selectivity to address each qubit individually (Fig. 1d). Two-qubit operations are less trivial, since the nuclei are not directly coupled to each other (Supplementary Information S1 and S9). They are, however, hyperfine-coupled to the same electron. This allows the implementation of a geometric two-qubit controlled-Z (CZ) gate [4] [16].

When a quantum two-level system is made to trace a closed trajectory on its Bloch sphere, its quantum state acquires a geometric phase equal to half the solid angle enclosed by the trajectory [25]. Fig. 1d illustrates how an electron $2\pi$-pulse at the frequency $\nu_{e\downarrow\uparrow\downarrow}$ (see Fig. 1c) constitutes a nuclear CZ 2-qubit gate. Starting from the state $|\downarrow\rangle \otimes (|\downarrow\rangle + |\uparrow\rangle)/\sqrt{2} \equiv (|\downarrow\downarrow\rangle + |\downarrow\uparrow\rangle + |\uparrow\downarrow\rangle)/\sqrt{2}$, the electron $X_{2\pi}$ pulse at $\nu_{e\downarrow\uparrow\downarrow}$ introduces a phase factor $e^{i\pi} = -1$
to the $|\downarrow\downarrow\rangle$ branch of the superposition, resulting in the state $(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)/\sqrt{2} = |\downarrow\rangle \otimes (|\downarrow\rangle + |\uparrow\rangle)/\sqrt{2}$, i.e. a rotation of Q2 by 180 degrees around the $z$-axis of its Bloch sphere, which is the output of a CZ operation. Conversely, if the initial state of Q1 were $|\uparrow\rangle$, the pulse at $\nu_{[\uparrow\uparrow]}$ would have no effect on the electron, leaving the nuclear qubits unaffected.

A nuclear controlled-NOT (CNOT) gate is obtained by sandwiching the CZ gate between a nuclear $X_{2\pi}$ pulse (Extended Data Fig. 6d). Applying an ESR $X_{2\pi}$ pulse at $\nu_{[\uparrow\uparrow]}$ transforms the sequence in a zero-CNOT gate, i.e. a gate that flips Q2 when Q1 is in the $|0\rangle = |\uparrow\rangle$ state (Extended Data Fig. 6b, and Supplementary Information S2).

We apply this universal gate set (Fig. 2) to produce each of the four maximally-entangled Bell states of the two nuclear spins, $|\Phi^\pm\rangle = (|\downarrow\downarrow\rangle \pm |\uparrow\uparrow\rangle)/\sqrt{2}$ and $|\Psi^\pm\rangle = (|\downarrow\uparrow\rangle \pm |\uparrow\downarrow\rangle)/\sqrt{2}$. We reconstruct the full density matrices of the Bell states using maximum likelihood quantum state tomography [23] (Supplementary Information S3). The reconstructed states (Fig. 2f) have fidelities of up to 94.2(2.7)%, and concurrences as high as 0.93(4), proving the creation of genuine two-qubit entanglement. Here and elsewhere, error bars indicate $1\sigma$ confidence intervals. Bell fidelities and concurrences are calculated without removing state preparation and measurement (SPAM) errors (Extended Data Fig. 10).

Gate set tomography

We used a customized, efficient gate set tomography (GST) [27, 28, 6] analysis (see Methods, and Supplementary Information S4, S5, S8) to investigate the quality of 6 logic operations on both qubits: $X_{\pi/2}$ and $Y_{\pi/2}$ rotations on Q1 and Q2, an additional $Y_{-\pi/2}$ rotation on Q2, and the entangling CZ gate. During operations on a sin-
Quantum state tomography results for (b) quantum circuit, only varying the initial spin state. The error bars are estimated using Monte Carlo bootstrap re-sampling and represent 1σ confidence level.

Table of Bell state fidelities and concurrences. No corrections have been applied to compensate readout errors. Hollow, black boxes indicate the outcome of an ideal measurement for each Bell state. We found that each gate’s behavior could be described using just 13-14 elementary errors: 3 local S errors and 3 local H errors acting on each of Q1 and Q2, and 1-2 entangling H errors (discussed in detail below). Extended Data Figure 8 shows those errors’ rates, along with the process matrices and full EGs used to derive them. To get a higher-level picture of gate quality, we aggregate related errors’ rates together (see Methods) to measure total stochastic and coherent rates on each qubit and on the entire 2-qubit system. We present two overall figures of merit in Figure 3a,c: infidelity and total error. We choose a definition of infidelity closely related to entanglement infidelity, appropriate to predict gate performance in realistic large-scale quantum processors, and to compare to fault-tolerance thresholds (see Methods and Supplementary Information S8). Total error is a bound on worst-case gate performance in any circuit, including structured
Fig. 3 | Precise tomographic characterization of 1- and 2-qubit gate quality. Process matrices for all 6 gates (e.g., the CZ gate shown in b) were estimated using gate set tomography (GST) and represented as error generators with associated rates. a, Each gate’s total error rate (columns) can be partitioned into coherent (blue) and stochastic (orange) components, then further into components acting on Q1 (left), Q2 (right), and on both at once (wide). Coherent errors are further partitioned into intrinsic (dark) and relational (light), which were assigned to specific gates by gauge-fixing. Infidelities on the whole 2-qubit system (hollow pins) and the target qubit only (black pins) are shown. The CZ gate’s total infidelity is only 0.79(14)%. Single-qubit gates have on-target infidelities of 0.07(3)-0.79(6)%, but their total error budgets are uniformly dominated by crosstalk errors on the spectator qubit. Significant unexpected entangling coherent (ZZ) errors were detected on 1-qubit gates.

Because estimated gate sets have a gauge symmetry [34, 5], we separate coherent errors into intrinsic, which commute with the target operation and are gauge-invariant, and relational, which can be shifted from one gate to another by changing gauge (Fig. 3a, c). Intrinsic
errors include over/under-rotation and coherent rotation of the spectator qubit during single-qubit gates. Relational errors include axis tilt, e.g. that the rotation axes of a qubit’s $X_{\pi/2}$ and $Y_{\pi/2}$ gates are not perpendicular. The amount of relational error between any pair of gates is gauge-invariant, as shown in Figure 4.

All 6 gates achieved on-target fidelities > 99%, with fidelities as low as 0.907(3)% on Q1 and 0.968(7)% on Q2. However, we observed significant crosstalk on the spectator qubit during 1-qubit gates, resulting in full logic operations (1-qubit gate and spectator idle operation in parallel) with higher fidelities of 0.68(6)% − 3.5(2)%.

SPAM errors were estimated by GST as 1.05(4)% on average, and as low as 0.25(3)% for the $|\uparrow\uparrow\rangle$ state (Extended Data Figure 10). This is a unique feature of nuclear spin qubits, afforded by the quantum nondemolition nature of the measurement process [21] (Methods and Extended Data Fig. 5).

GST provided unambiguous evidence for a surprising relational error: weight-2 (entangling) coherent errors on 1-qubit gates, i.e. coherent $H_{ZZ}$ and/or $H_{GZ}(ZZ)$, with amplitudes from 1.8 − 5.0% (Extended Data Figure 8). These errors are consistent with an intermittent $ZZ$ Hamiltonian during the gate pulses. After ruling out a wide range of possible error channels, we propose that the observed $H_{ZZ}$ error arises from the spurious accumulation of geometric phase by the electron spin, caused by off-resonance leakage of microwave power near the ESR frequencies (Supplementary Information S9). This observation illustrates the diagnostic power of GST, which revealed an error channel we had not anticipated. It also shows GST’s ability to unveil correlated and entangling errors, whose detection and prevention is of key importance for the realization of fault-tolerant quantum computers [35].

Three-qubit entanglement
The nuclear logic gates shown above would not scale beyond a single, highly localised cluster of donors. To address this concern, we demonstrate the ability to entangle the $^{31}P$ nuclei with their hyperfine-coupled electron. We produce the maximally entangled three-qubit Greenberger-Horne-Zeilinger (GHZ) state $|\psi_{GHZ}\rangle = (|\uparrow\uparrow\uparrow\rangle + |\downarrow\downarrow\downarrow\rangle)/\sqrt{2}$ using the pulse sequence shown in Fig. 2a. Starting from $|\downarrow\downarrow\rangle$, an NMR $Y_{\pi/2}$ pulse at $\nu_{Q2}$ creates a coherent superposition state of nucleus 2, followed by a nuclear $z$CNOT gate (as in Fig. 2a) to produce a nuclear $|\Phi^+\rangle$ state, and an ESR $X_{\pi}$ pulse at $\nu_{e\downarrow\downarrow}$ to arrive at $|\psi_{GHZ}\rangle$. Since the ESR frequency directly depends on the state of both nuclei, the latter pulse constitutes a natural 3-qubit Toffoli gate, making the creation of 3-qubit entanglement particularly simple. A similar method has been used with nitrogen-vacancy in diamond [36], whereas other solid-state system such as electrons in quantum dots [37] or superconducting qubits [38] require significantly more complex sequences in order to execute a Toffoli gate.

Measuring the populations of the eight electron-nuclear states (Supplementary Information S7) after each step confirms the expected evolution from $|\downarrow\downarrow\rangle$ to $|\psi_{GHZ}\rangle$ (Fig. 4b). The evolution can be undone by applying the sequence in reverse, yielding a return probability to $|\downarrow\downarrow\rangle$ of 89.6(9)%%, including SPAM errors. As in the two-qubit case, measuring the populations is a useful sanity check but does not prove multipartite entanglement, which requires knowing the off-diagonal terms of the density matrix $\rho_{GHZ} = |\psi_{GHZ}\rangle\langle\psi_{GHZ}|$.

The hybrid electron-nuclear nature of our three-qubit system complicates quantum state tomography of this GHZ state. Standard tomography methods require measuring the target state in different bases, obtained by rotating the qubits prior to measurement. However, the superposition of $|\downarrow\downarrow\rangle$ and $|\uparrow\uparrow\rangle$ dephases at a rate dominated by the electron dephasing time $T_{2e}^* \approx 10 \mu s$ (Extended Data Fig. 5), which is only marginally longer than the nuclear spin operation time $\approx 10 − 20 \mu s$. Therefore, the GHZ state will have significantly dephased by the time it is projected onto each measurement basis.

We circumvent this problem by adopting a tomography method that minimizes the time spent in the GHZ state. An extension of a method first introduced for the measurement of electron-nuclear entanglement in spin ensembles [39], it is related to the parity scan commonly used in trapped ions [40]. We repeat the reversal of the GHZ state (Fig. 4b) $N = 100$ times, each time introducing phase shifts $\theta_{1,2,3}$ to the rotation axes of the three reversal pulses, with $\theta_1 = 3\theta_2 = 9\theta_3 = 9N/125$. The return probability to $|\downarrow\downarrow\rangle$ oscillates with $N$: the amplitude and phase of the oscillations yield the off-diagonal element $\langle\downarrow\downarrow|\rho_{GHZ}|\uparrow\uparrow\rangle = \rho_{18}$.

Since the ideal $\rho_{GHZ}$ has nonzero elements only on its four corners, the populations $\rho_{11}, \rho_{88}$ and the coherence $\rho_{18}$ are sufficient to determine the GHZ state fidelity $F_{GHZ} = 92.5(1.0)\%$. Also here, SPAM errors remain included in total infidelity.

Outlook
The demonstration of 1-qubit, 2-qubit and SPAM errors at or below the 1% level highlight the potential of
nuclear spins in silicon as a credible platform for fault-tolerant quantum computing. An often-quoted example, based on surface code quantum error correction, sets a fault-tolerance threshold of 0.56% for the entanglement fidelity of 1- and 2-qubit gates and the SPAM errors [6].

Several avenues are available to harness the high-fidelity operations demonstrated here. Replacing the $^{31}$P donors with the higher-spin group-V analogues such as $^{123}$Sb ($I = 7/2$) or $^{209}$Bi ($I = 9/2$) would provide access to a much larger Hilbert space in which to encode quantum information. For example, a cluster of two $^{123}$Sb donors contains the equivalent of six qubits in the nuclear spins, plus an electron qubit. An error-correcting code can be efficiently implemented in high-spin nuclei [41], where our method would provide a pathway for universal operations between the logical qubits encoded in each nucleus.

Moving to heavier group-V donors also allows the electrical control of the nuclear spins [42]. Combined with the electrical drive of the electron-nuclear ‘flip-flop’ transition [43], this implies the ability to control electron and nuclei by purely electrical means. In a two-donor system as shown here, the entangling CZ gate could similarly be obtained by an electrical $2\pi$-pulse on a flip-flop transition.

The electron-nuclear entanglement we have demonstrated can be harnessed to scale up beyond a pair of nuclei coupled to the same electron. Neighbouring donor electrons can be entangled via exchange interaction by performing controlled-rotation resonant gates [8] or iSWAP gates [8]. Wider distances could be afforded by physically shuttling the electron across lithographic quantum dots [44, 45], while preserving the quantum information encoded in it [11]. Our methods would apply equally to isoelectronic nuclear spin centres like $^{73}$Ge and $^{29}$Si, where it has been shown that the nuclear qubit coherence is preserved while shuttling the electron across neighbouring dots [10]. Furthermore, electron spins can mediate the coherent interaction between nuclear spin qubits and microwave photons [46, 47]. A recent experiment on electron

---

**Fig. 4 | Creation and tomography of an electron-nuclear three-qubit GHZ state.** a, Starting from $|\downarrow\downarrow\downarrow\rangle$, the first three gates generate an entangled three-qubit GHZ state. All eight state populations are read out (b) at each circuit step (red dashed lines), and estimated without correcting for SPAM errors (Supplementary Information S7). The final three gates $R(\theta_i)$ reverse the operations of the first three if the rotation angles are $\theta_1 = \theta_2 = \theta_3 = 0$, returning to the initial state in the absence of errors. The two gates that are conditional on extrema of the GHZ state. The state populations of the GHZ components are composed of multiple pulses (Supplementary Information S6). The coherence between the GHZ components $|\downarrow\downarrow\downarrow\rangle$ and $|\uparrow\uparrow\uparrow\rangle$ is probed by incrementing the phases $\theta_i$ of the reversal pulses. This induces oscillations at frequency $f = 2\pi/(\theta_1 + \theta_2 + \theta_3)$ whose amplitude and phase correspond to the purity and phase relation between $|\downarrow\downarrow\downarrow\rangle$ and $|\uparrow\uparrow\uparrow\rangle$. b, Density-matrix elements $(\theta_1, \theta_2, \theta_3) = (3\pi/125, 9\pi/125, 9\pi/125)$ provide the off-diagonal entries, while the oscillation amplitude and phase (c) provide the off-diagonal entries. From these values, the fidelity to the nearest GHZ state is estimated as 92.5(1.0)% including SPAM.
spin qubits in silicon reports 1- and 2-qubit gate fidelities above 99% \cite{48}. Therefore, the fidelity of electron qubit operations will not constitute a bottleneck for the performance of electron-nuclear quantum processors. These examples illustrate the significance of universal high-fidelity two-qubit operations with nuclear spins in a platform like silicon, which can simultaneously host nuclear and electron spin qubits, lithographic quantum dots, and dense readout and control devices \cite{19}.

**Methods**

**Device fabrication**

The quantum processor is fabricated using methods compatible with standard silicon MOS processes. We start from a high quality silicon substrate (p-type (100); 10-20 Ωcm), on top of which a 900 nm thick epilayer of isotopically enriched $^{28}$Si has been grown using low-pressure chemical vapour deposition (LPCVD). The residual $^{29}$Si concentration is 730 ppm. Heavily-doped n$^+$ regions for Ohmic contacts and lightly-doped p regions for leakage prevention are defined by thermal diffusion of phosphorus and boron, respectively. A 200 nm thick SiO$_2$ field oxide is grown in a wet oxidation furnace. In the centre of the device, an opening of 20 $\mu$m × 40 $\mu$m is etched in the field oxide using HF acid. Immediately after, a 8 nm thick, high quality dry SiO$_2$ gate oxide is grown in this opening. In preparation for ion implantation, a 90 nm × 100 nm aperture is opened in a PMMA mask using electron-beam lithography (EBL). The samples are implanted with P$^+$ ions at an acceleration voltage of 10 keV per ion. During implantation the samples were tilted by 8 degrees and the fluence was set at 1.4 × 10$^{12}$/cm$^2$. Donor activation and implantation damage repair is achieved through the process of a rapid thermal annealing (5 seconds at 1000 °C). The gate layout is patterned around the implantation region in three EBL steps, each followed by aluminium thermal deposition (25 nm thickness for layer 1; 50 nm for layer 2; 100 nm for layer 3). Immediately after each metal deposition, the sample is exposed to a pure, low pressure (100 mTorr) oxygen atmosphere to form an Al$_2$O$_3$ layer, which electrically insulated the overlapping metal gates. At the last step, samples are annealed in a forming gas (400 °C, 15 min, 95% N$_2$ / 5% H$_2$) aimed at passivating the interface traps.

**Experimental setup**

The device was wire-bonded to a gold-plated printed circuit board and placed in a copper enclosure. The enclosure was placed in a permanent magnet array \cite{49}, producing a static magnetic field of 1.33 T at the device (see Extended Data Fig. 1 for field orientation). The board was mounted on a Bluefors BF-LD400 cryogen-free dilution refrigerator, reaching a base temperature of 14 mK, while the effective electron temperature was ≈ 150 mK.

DC bias voltages were applied to all gates using Stanford Research Systems (SRS) SIM928 voltage sources. A room-temperature resistive combiner was used for the fast donor gates (Extended Data Fig. 1) to add DC voltages to AC signals produced by the LeCroy Arbstudio 1104, which then passed through an 80 MHz low-pass filter; all other gates passed through a 20 Hz low-pass filter. All filtering takes place at the mixing chamber plate. The wiring includes graphite-coated flexible coaxial cables to reduce triboelectric noise \cite{50}.

Microwave pulses to induce ESR transitions were applied to an on-chip broadband antenna \cite{51} using a Rohde & Schwarz SGS100A vector microwave source combined with an SGU100A upconverter. The microwave carrier frequency remained fixed at 37.1004125 GHz, while the output frequency was varied within a pulse sequence by mixing it with a radiofrequency (RF) signal using double-sideband modulation, i.e. by applying RF pulses to the in-phase port of the SGS100A IQ mixer (the quadrature port was terminated by a 50 Ω load). The carrier frequency was chosen such that whenever one sideband tone was resonant with an ESR pulse, the second sideband was off-resonant with all other ESR frequencies. To suppress microwave signals when not needed, 0 V was applied to the in-phase port of the IQ mixer. Under these circumstances, the carrier frequency is expected to be suppressed by 35 dB, according to the source data sheet. The RF pulses used for double-sideband modulation were generated by one of the two channels of the Agilent 81180A arbitrary waveform generator; the second channel delivered RF pulses to the microwave antenna to drive NMR transitions. The microwave signal for ESR and RF signal for NMR were combined in a Marki Microwave DPX-1721 diplexer.

The SET current passed through a Femto DLPCA-200 transimpedance amplifier (10$^7$ V/A gain, 50 kHz bandwidth), followed by an SRS SIM910 JFET post-amplifier (10$^2$ V/V gain), SRS SIM965 analog filter (50 kHz cutoff low-pass Bessel filter), and acquired via an AlazarTech ATS9440 PCI digitizer card. The instruments were trig-
The readout of the two nuclear spin qubits is an extension of the well-known method developed for a single donor [21], based on the excitation of the electron bound to the nuclei, conditional on a particular nuclear state, followed by electron spin readout [20]. In the present system, consisting of an electron coupled to two 31P donors with different hyperfine couplings $A_1 \gg A_2$, we find four well-separated electron spin resonance (ESR) frequencies (Fig. 1), conditional on the $|\downarrow\downarrow\rangle$, $|\downarrow\uparrow\rangle$, $|\uparrow\downarrow\rangle$, $|\uparrow\uparrow\rangle$ nuclear states. An electron in the $|\downarrow\rangle$ state is initially drawn from a cold charge reservoir onto the donor cluster (independently of nuclear states). We then apply a microwave $\pi$-pulse at a particular ESR frequency, for instance $\nu_{\downarrow\downarrow}$ corresponding to the $|\downarrow\downarrow\rangle$ nuclear spin state, and then measure the electron spin. If it is found in the $|\uparrow\rangle$ state, then the nuclear spins are projected to the $|\downarrow\downarrow\rangle$, $|\downarrow\uparrow\rangle$, $|\uparrow\downarrow\rangle$, $|\uparrow\uparrow\rangle$ state. This constitutes a nuclear spins single-shot readout, with a fidelity given by the product of the electron single-shot readout fidelity (typically $\approx 80\%$) and the electron $\pi$-pulse fidelity ($\geq 99\%$).

This nuclear readout is a projective, approximately quantum non demolition (QND) process [21]. The ideal QND measurement relies on the observable $I_z$ to commute with the Hamiltonian $H_{\text{int}}$ describing an interaction between the observable and the measurement apparatus $[I_z, H_{\text{int}}] = 0$ [50]. In our case the hyperfine terms $A_1 S_z I_{z1}$ and $A_2 S_z I_{z2}$ constitute $H_{\text{int}}$. The observation of nuclear spin quantum jumps originating from the electron measurement by spin-dependent tunnelling (ionization shock) hints at a deviation from QND nature of the readout process [21]. It implies the presence of terms of the form $A_{\|}/2(S_+ I_- + S_- I_+) \approx 0$ in the Hamiltonian. In our experiment, the deviation from the ideal QND measurement is extremely small, of order $10^{-6}$, as shown in Extended Data Figure 5.

We exploit the near-perfect QND nature of the nuclear spin readout by repeating the cycle [load $|\downarrow\rangle$ – ESR $\pi$-pulse – electron readout] between 7 and 40 times, to substantially increase the nuclear single-shot readout fidelity. This is the fundamental reason why our average SPAM errors are $\approx 1\%$ (Extended Data Fig. 10), and we have thus reported Bell and GHZ state fidelities without removing SPAM errors from the estimate.
ESR and NMR frequency recalibration

To keep the system tuned throughout the measurements, the NMR frequencies $\nu_{Q1\uparrow}$ and $\nu_{Q2\uparrow}$ and ESR frequency $\nu_{Q1\downarrow\downarrow}$ were calibrated every ten circuits. The ESR frequency was calibrated by measuring the ESR spectrum and selecting the frequency of the ESR peak. The NMR frequencies were measured by a variant of the Ramsey sequence, consisting of an $X_{\pi/2}$ and $Y_{\pi/2}$ separated by a wait time $\tau$. An off-resonant RF pulse was applied during the wait time to mitigate any frequency shift caused by the absence of an RF drive. Since nuclear readout has a near-unity fidelity, this measurement should result in a nuclear flipping probability $P_{\text{flip}} = 0.5$ if the RF frequency $f_{\text{RF}}$ matches the average NMR frequency $f_{\text{NMR}}$ throughout the measurement. Therefore, any deviation of $P_{\text{flip}}$ from 0.5 provides a direct estimate of the frequency mismatch $\Delta f = f_{\text{NMR}} - f_{\text{RF}} = \arcsin((2P_{\text{flip}} - 1))/(2\pi\tau)$, provided that $|\Delta f/\tau| < 0.25$. A higher $\tau$ more accurately estimates $\delta f$, while a lower $\tau$ results in the condition $|\Delta f/\tau| < 0.25$ being valid for a broader range of $\Delta f$. The NMR recalibration then iteratively increased the wait time $\tau = 40 \mu s \rightarrow 100 \mu s \rightarrow 160 \mu s$ to ensure that the condition $|\Delta f/\tau| < 0.25$ remains satisfied while increasing the accuracy at which the NMR frequency is estimated. For each $\tau$, the NMR frequency was estimated by repeating this sequence and updating the RF frequency until $P_{\text{flip}}$ fell within the range [0.4, 0.6].

Effective mass theory simulations of the hyperfine interaction

To simulate the wave function of the third electron in the 2P system, the effective mass theory (EMT) model of the neutral 2P system in Ref. [57] is extended in a mean-field approach.

For short donor separations, the two inner electrons are tightly bound in a magnetically inactive singlet orbital. The third electron only interacts with the inner ones to the extent that it experiences the Coulomb repulsion of their fixed charge distribution

$$V(\vec{r}) = \frac{e^2}{4\pi\varepsilon_{\text{Si}}} \int \rho_{\text{Si}}(\vec{r}') |\vec{r} - \vec{r}'|^3 d^3r'.$$

(3)

Here, only 2P configurations along the [100] crystal axis with distances $d \leq 7$ nm and realistic fields $E \leq 2$ mV/nm are considered. In this regime the inter-donor exchange dominates the on-site exchange and the mean-field approach is justified.

The chosen basis is a combination of two STO-3G [57] orbitals, one variationally optimized at $d = 0.5$ nm and the other at $d = 7$ nm.

To compute the hyperfine interaction strength, the electron density at the nucleus is rescaled by a bunching factor of 440 [58]. The experimentally found hyperfine configuration is found for donors spaced 6.5 nm apart, and subjected to an electric field 2 mV/nm.

Gate set tomography experiments

We designed a customized GST experiment for a set of 6 logic gates: $X_{\pi/2}$ and $Y_{\pi/2}$ rotations on each qubit, an additional $Y_{-\pi/2}$ rotation on Q2, and the symmetric CZ gate between them. A basic 2-qubit GST experiment for this gate set comprises a list of quantum circuits defined by: (1) choosing a set of 75 short “germ” circuits that, when repeated, collectively amplify every error rate; (2) repeating each germ several times to form “germ power” circuits whose lengths are approximately $L = 1, 2, 4, \ldots L_{\text{max}}$; and (3) prefacing and appending each germ power with each of 16 “preparation fiducial” circuits and each of 11 “measurement fiducial” circuits. We used $L_{\text{max}} = 8$, yielding a set of 20606 circuits (this is not a simple multiplication because germ circuits with depth > 1 do not appear at shorter $L$). We eliminated 92% of these circuits using two techniques from [5]. First, we identified a subset of 18 germs that amplify any dominant errors in each gate (if $L_{\text{max}}$ was very large, subdominant errors would get echoed away by dominant errors). This yielded a total of 50 germ powers. Second, for the $L > 1$ germ powers, we identified and eliminated pairs of fiducial circuits that provided redundant information. This trimmed the circuits per germ power from 176 to as few as 16, and the total number of circuits from 8800 to just 1592. Each of those circuits was repeated 300-500 times to gather statistics. We used maximum likelihood estimation (MLE) implemented in the pyGSTi software [59] to estimate $16 \times 16$ 2-qubit process matrices $\{G_i : i = 1 \ldots 6\}$ for all six operations.

Constructing and selecting reduced models

Process matrices are a comprehensive but not especially transparent, representation of gate errors. So we used each
gate’s ideal target (unitary) operation $G_i$ to construct an error generator \[ L_i = \log(G_i G_i^{-1}) \] that presents the same information more usefully. Representing noisy gates this way enables us to split each gate’s total error into parts that act on Q1 only, Q2 only, or both qubits together – and then further into coherent and stochastic errors – to reveal those errors’ sources and consequences. It also enables the construction of simple, efficient “reduced models” for gate errors, by identifying swaths of elementary error generators whose rates are indistinguishable from zero.

Pinning the coefficients of $k$ elementary error generators to zero yields a reduced model with $k$ fewer parameters, whose likelihood ($\mathcal{L}$) can be found by MLE. We evaluate the statistical significance of error rates that were pinned by seeing how much $\mathcal{L}$ declines. If a given error’s true rate is zero, then pinning it to zero in the model reduces $2 \log \mathcal{L}$, on average, by 1 \cite{61}. So when we pin $k$ rates, we compute the “evidence ratio” $r = 2 \Delta \log \mathcal{L} / k$, where $\Delta \log \mathcal{L}$ is the difference between the two models’ likelihood \cite{62}. If $r \leq 1$, the pinned rates are strictly negligible; if $r \leq 2$, then the smaller model is preferred by Akaike’s information criterion (AIC) \cite{63}; other criteria (e.g. the Bayesian BIC) impose higher thresholds. We used a slightly higher $r$, only $\epsilon_{\text{agg}}$ and $\theta_{\text{agg}}$ have nonzero rates.

Because H error rates correspond to amplitudes and S error rates correspond to probabilities, they add in different ways when aggregated. Aggregated S generators add directly ($\epsilon_{\text{agg}} = \sum_i \epsilon_i$), while those of H generators add in quadrature ($\theta_{\text{agg}} = (\sum_i \theta_i^2)^{1/2}$). There is no unique way to combine a gate’s H and S error rates into a single overall error rate, because the impact of coherent errors depends on how they interfere over the course of a circuit. We therefore report two quantities in Figure 3: total error $\epsilon_{\text{tot}} = \epsilon_{\text{agg}} + \theta_{\text{agg}}$ and infidelity $\bar{\epsilon} = \epsilon_{\text{agg}} + \theta_{\text{agg}}$. Total error approximates the maximal rate at which errors could add up in any circuit; infidelity quantifies the impact of errors on an average, random circuit.

For example, in Figure 3b, the total stochastic error on the $X_{\pi/2} \otimes I$ gate is computed by aggregating the rates of all stochastic error rates on that gate (as shown in Figure 8 only $S_{X1}$ and $S_{I2}$ have nonzero rates).

There are two alternative and widely used definitions for gate “infidelity”: the entanglement infidelity ($\epsilon_e$) and the average gate infidelity ($\bar{\epsilon}$), defined by \cite{64}

\begin{equation}
\epsilon_e = 1 - \langle \phi | \mathbb{I} \otimes G_i G_i^{-1} (|\psi\rangle \langle \phi|) |\phi\rangle,
\end{equation}

where $\phi$ is any maximally entangled state over a doubled state space (here, a 4-qubit state space) and $\mathbb{I}$ is the identity operator, and

\begin{equation}
\bar{\epsilon} = 1 - \int d\psi \ \text{Tr} \ [G_i(|\psi\rangle \langle \psi|) G_i(|\psi\rangle \langle \psi|)],
\end{equation}

Aggregated error rates and metrics

Gate errors cause unintended changes in the state of the system. S error generators produce stochastic errors that transfer probability to erroneous states; H generators produce coherent errors that transfer amplitude to erroneous states. We can interpret the rate of an error generator, to first order, as the amount of erroneous probability (denoted $\epsilon$ for S generators) or amplitude (denoted $\theta$ for H generators) transferred by a single use of the gate when acting on one half of a maximally entangled state.

It is often useful to group similar errors together and aggregate their rates. In Figure 3 and the main text, we classify and combine error generators according to:

- Their type (H or S),
- Their support (Q1, Q2, or joint),
- (For H errors) How they transform under gauge transformations (intrinsic to a single gate, or relational between gates).

Extended Data Figure 8 presents each gate’s 13-14 nonzero elementary error rates after projecting the error vector onto the gauge-invariant subspace (column 3), along with the process matrices (column 1) and error generators (column 2) from which they are derived. Here and elsewhere, error bars are 1σ confidence intervals computed using the Hessian of the loglikelihood function.

Extended Data Figure 8 presents each gate’s 13-14 nonzero elementary error rates after projecting the error vector onto the gauge-invariant subspace (column 3), along with the process matrices (column 1) and error generators (column 2) from which they are derived. Here and elsewhere, error bars are 1σ confidence intervals computed using the Hessian of the loglikelihood function.
where $d\psi$ is the Haar measure. They are related by [64]:

$$\epsilon_e = \frac{2^n + 1}{2^n} \epsilon$$

(6)

for an operation on $n$ qubits.

As shown in Supplementary Information S8, our definition for infidelity $\hat{\epsilon}$ is equal to the entanglement infidelity $\epsilon_e$ at lowest order in $\epsilon_{agg}$ and $\theta_{agg}$. This close connection to the underlying gate error rates is one of the reasons for our choice to report entanglement infidelities rather than average gate infidelities. Entanglement infidelities also have a property known as “stability” [65], i.e., they compose nicely upon combination of multiple qubits. If two gates are performed on separate qubits in parallel, the entanglement fidelity of the composite layer is simply the product of the entanglement fidelities of the two individual gates – this is not true of the corresponding average gate fidelities. The stability of the entanglement infidelity partially motivated its adoption in the context of “cycle benchmarking,” which has been used, e.g., for estimating gate errors in a 10-qubit ion-trap quantum processor [65].

Our quoted infidelity $\hat{\epsilon}$ also has the appealing property of being equal to the total error when $\theta_{agg} = 0$, i.e., in the absence of coherent Hamiltonian errors (“perfect gate calibration”). This property is derived from the close connection between $\hat{\epsilon}$ and the entanglement infidelity, which is equal to the diamond distance for Pauli stochastic error channels [67].

The average gate fidelity $\bar{\epsilon}$ is not a stable metric [65], but is nonetheless commonly used to report results from randomized benchmarking [67]. Randomized benchmarking has been broadly adopted to experimentally characterise the performance of quantum gates [68, 69, 13, 29, 30], and the values reported in these experiments should be rescaled according to Eq. [3] as appropriate when compared against the gate fidelities reported here.

Data availability

The experimental data that support the findings of this study are available in Figshare with the identifier doi.org/10.6084/m9.figshare.c.5471706.

Extended data figures and tables

Extended Data Fig. 1 | Device layout. Scanning electron micrograph of a device identical to the one used in this experiment. $^{31}$P donor atoms are implanted in the region marked by the orange rectangle, using a fluence of $1.4 \times 10^{12}/\text{cm}^2$ which results in a most probably inter-donor spacing of approximately 8 nm. Four metallic gates are fabricated around the implantation region, and used to modify the electrochemical potential of the donors. A nearby SET, formed using the SET top gate and barrier gates, enables charge sensing of a single donor atom, as well as its electron spin through spin-to-charge conversion (Methods). The tunnel coupling between the donors and SET is tuned by the rate gate situated between the SET and donor implant region. A nearby microwave (MW) antenna is used for ESR and NMR of the donor electron and nuclear spins, respectively.
Extended Data Fig. 2 | Electrical tunability of the hyperfine interaction and the electron gyromagnetic ratio.  

**a,** Map of the SET current as a function of SET gate and fast donor gates (pulsed jointly). The white dashed line indicates the location in gate space where the 2P donor cluster changes its charge state. The third, hyperfine-coupled electron is present on the cluster in the region to the right of the line. Electron spin readout is performed at the location indicated by the pink star.  

**b,** ESR spectrum of the electron bound to the 2P cluster, acquired while the system was tuned within the blue dashed rectangle in panel **a.** The hyperfine couplings $A_1$, $A_2$ are extracted from ESR frequencies as shown, namely $A_1 = (\nu_e|\uparrow\downarrow + \nu_e|\downarrow\downarrow|)/2 - (\nu_e|\uparrow\uparrow + \nu_e|\downarrow\uparrow|)/2$; $A_2 = \nu_e|\uparrow\uparrow - \nu_e|\downarrow\downarrow$.  

**c-d,** Extracted hyperfine couplings within the marked area. The data shows that $A_1$ decreases and $A_2$ increases upon moving the operation point towards higher gate voltages and away from the donor readout position.  

**e,** A small change is also observed in the sum of the two hyperfine interactions $A_t = A_1 + A_2$.  

**f,** Electrical modulation (Stark shift) of the electron gyromagnetic ratio $\gamma_e$, extracted from the shift of the average of the hyperfine-split electron resonances. The ESR frequencies can be tuned with fast donor gates at the rate of $\Delta \nu_e|\uparrow\uparrow = 0.3$ MHz/V; $\Delta \nu_e|\uparrow\downarrow = 5.2$ MHz/V; $\Delta \nu_e|\downarrow\uparrow = 7.6$ MHz/V; $\Delta \nu_e|\downarrow\downarrow = 2.4$ MHz/V.
Extended Data Fig. 3 | Coherence metrics of the electron spin qubit. The columns correspond to the nuclear configurations |⇓⇓⟩, |⇓⇑⟩, |⇑⇓⟩, |⇑⇑⟩, respectively. All measurements start with the electron spin initialized in the |↓⟩ state. a, Electron Rabi oscillations. The measurements were performed by applying a resonant ESR pulse of increasing duration. The different Rabi frequencies $f_{\text{Rabi}}$ on each resonance are likely due to a frequency-dependent response of the on-chip antenna and the cable connected to it. b, Electron spin-lattice relaxation times $T_{1e}$. Measurements were obtained by first adiabatically inverting the electron spin to |↑⟩, followed by a varying wait time $\tau$ before electron readout. The observed relaxation times are nearly three orders of magnitude shorter than typically observed in single-electron, single-donor devices [70], and even shorter compared to 1e-2P clusters. This strongly suggests that the measured electron is the third one, on top of two more tightly-bound electrons which form a singlet spin state [71]. We also observe a strong dependence of $T_{1e}$ on nuclear spin configuration. c, Electron dephasing times $T_{2e}^*$. The measurements were conducted by performing a Ramsey experiment, i.e. by applying two $\pi/2$ pulses separated by a varying wait time $\tau$, followed by electron readout. The Ramsey fringes are fitted to a function of the form $P_{\uparrow}(\tau) = C_0 + C_1 \cos(\Delta \omega \cdot \tau + \Delta \phi) \exp[-(\tau/T_{2e}^*)^2]$, where $\Delta \omega$ is the frequency detuning and $\Delta \phi$ is a phase offset. The observed $T_{2e}^*$ times are comparable to previous values for electrons coupled to a single $^{31}$P nucleus. d, Electron Hahn-echo coherence times $T_{2e}^{\text{H}}$, obtained by adding a $\pi$ refocusing pulse to the Ramsey sequence. We also varied the phase of the final $\pi/2$ pulse at a rate of one period per $\tau = (5 \text{ kHz})^{-1}$, to introduce oscillations in the spin-up fraction which help improve the fitting. The curves are fitted to the same function used to fit the Ramsey fringes, with fixed $\Delta \omega = 5 \text{ kHz}$. The measured $T_{2e}^{\text{H}}$ times are similar to previous observations for electrons coupled to a single $^{31}$P nucleus.
Extended Data Fig. 4 | Nuclear spin coherence times. Panels in column 1 (2) correspond to nucleus Q1 (Q2). a, Nuclear dephasing times $T_{2n}^*$, obtained from a Ramsey experiment. Results are fitted with a decaying sinusoid with fixed exponent factor 2 (see Extended Data Fig. 3). b, Nuclear Hahn-echo coherence times $T_{2n}^H$. To improve fitting, oscillations are induced by incrementing the phase of the final $\pi/2$ pulse with $\tau$ at a rate of one period per $(3.5 \text{ kHz})^{-1}$. Results are fitted with a decaying sinusoid with fixed exponent factor 2 (see Extended Data Fig. 3). c, Dependence of $T_{2n}^H$ on the amplitude of an off-resonance pulse. We perform this experiment to study whether a qubit, nominally left idle (or, in quantum information terms, subjected to an identity gate) is affected by the application of an RF pulse to the other qubit, at a vastly different frequency. Here, during the idle times between NMR pulses, an RF pulse is applied at a fixed frequency $20 \text{ MHz}$ – far off-resonance from both qubits’ transitions – with varying amplitude $V_{RF}$. The red dashed line indicates the applied RF amplitude for NMR pulses throughout the experiment. We observe a slow decrease of $T_{2n}^H$ with increasing $V_{RF}$. This is qualitatively consistent with the observation of large stochastic errors on the idle qubit, as extracted by the GST analysis in Fig. 3.
Extended Data Fig. 5 | Nuclear spin quantum jumps caused by ionization shock. The electron and nuclear spin readout relies upon spin-dependent charge tunnelling between the donors and the SET island. If the electron tunnels out of the two-donor system, the hyperfine interactions $A_1, A_2$ suddenly drop to zero. If $A_1$ and $A_2$ include an anisotropic component (e.g. due to the non-spherical shape of the electron wavefunction which results in nonzero dipolar fields at the nuclei), the ionisation is accompanied by a sudden change in the nuclear spin quantisation axes (“ionisation shock”), and can result in a flip of the nuclear spin state. We measure the nuclear spin flips caused by ionisation shock by forcibly loading and unloading an electron from the 2P cluster every 0.8 ms. a, For qubit 1 with $A_1 = 95$ MHz, the flip rate is $\Gamma_1 = 2.8 \times 10^{-6}$ $N_{\text{flip}} / N_{\text{ion}}$. b, For qubit 2 with $A_2 = 9$ MHz, the flip rate is $\Gamma_2 = 4.0 \times 10^{-7}$ $N_{\text{flip}} / N_{\text{ion}}$. This means that the nuclear spin readout via the electron ancilla is almost exactly quantum non-demolition. The extremely low values of $\Gamma$ – comparable to those observed in single-donor systems – are the reason why we can reliably operate the two $^{31}$P nuclei as high-fidelity qubits.
Extended Data Fig. 6 | CNOT and zero-CNOT nuclear two-qubit gates. We perform Rabi oscillation on the control qubit followed by the application of a, zCNOT or b, CNOT gates. The two qubits are initialized in the $|\downarrow \downarrow\rangle\equiv|11\rangle$ state. We observe the Rabi oscillations of both qubits in phase for zCNOT and out of phase for CNOT. At every odd multiple of $\pi/2$ rotation of the control qubit the Bell states are created.
Extended Data Fig. 7 | Two-qubit gate set tomography. a, Measurement circuit for the two-qubit gate set tomography. A modified version of this circuit has been used for Bell state tomography. The green box prepares the qubit 2 in the $|\uparrow\rangle$ state, then the orange box prepares the qubit 1 in the $|\uparrow\rangle$ state. The readout step in the blue box determines whether the $|\uparrow\uparrow\rangle$ state initialization was successful. Only then the record will be saved. The electron spin is prepared in $|\downarrow\rangle$ during the nuclear spin readout process. Subsequently, the GST sequence is executed. The red box indicates the Q1,Q2 readout step. b, Measurement results for individual two-qubit gate set tomography circuit. The first 145 circuits estimate the preparation and measurement fiducials, and the subsequent circuits are ordered by increasing circuit depth. At the end of a circuit, there are three situations for the target state populations: 1) the population is entirely in one state, while all others are zero; 2) the population is equally spread over two states, while the other two are zero; 3) the population is equally spread over all four states. The measured state populations for the different circuits therefore congregate around the four bands 0, 0.25, 0.5, and 1, as indicated by black dashed lines.
Extended Data Fig. 8 | Estimated gate set, from process matrices to error rates. Experimental GST data were analyzed using pyGSTi to obtain self-consistent maximum likelihood estimates of 2-qubit process matrices for all 6 elementary gates. These are represented (1st column) in a gauge that minimizes their average total error, as superoperators in the 2-qubit Pauli basis. Green columns indicate positive matrix elements, orange ones are negative. Wireframe sections indicate differences between estimated and ideal (target) process matrices. Those process matrices can be transformed to error generators (2nd column) that isolate those differences, and are zero if the estimated gate equals its target. Each gate’s error generator was decomposed into a sparse sum of Hamiltonian and stochastic elementary error generators. Those rates are depicted (3rd column) as contributions to the gate’s total error. Each non-vanishing elementary error rate (error generators are denoted “H” or “S” followed by a Pauli operator) is listed, and identified with its role in the total error budget (reproduced from Figure 3). Orange bars indicate stochastic errors, dark blue indicate coherent errors that are intrinsic to the gate, and light blue indicate relational coherent errors that were assigned to this gate. Total height of the blue region indicates the total coherent error, but because coherent error amplitudes add in quadrature, individual components’ heights are proportional to their quadrature.
Extended Data Fig. 9 | Simulation of standard and interleaved randomized benchmarking (RB). All simulated RB experiments used 2-qubit Clifford subroutines compiled from the 6 native gates, requiring (on average) 14.58 individual gate operations per 2-qubit Clifford. a, Standard randomized benchmarking, simulated using the GST-estimated gate set, yields a “reference” decay rate of \( r_r = 22.2(2)\% \), suggesting an average per-gate error rate of \( r_r / 14.58 \approx 1.5\% \). b-f, Simulated interleaved randomized benchmarking for the CZ gate, and 1-qubit \( X_{\pi/2} \) and \( Y_{\pi/2} \) gates on each qubit, yielded interleaved decay rates \( r_r + r_i \). For each experiment, 1000 random Clifford sequences were generated, at each of 15 circuit depths \( m \), and simulated using the GST process matrices. Exact probabilities (effectively infinitely many shots of each sequence) were recorded. Inset histograms show the distribution over 1000 random circuits at \( m=4 \). Observed decays are consistent with each gate’s GST-estimated infidelities – e.g. \( 1 - F = 0.79\% \) for the C-Z gate (b). Performing these exact RB experiments in the lab would have required running 90000 circuits to estimate a single parameter \( (r_i) \) for each gate to the given precision of \( \pm 0.25\% \). Using fewer (< 1000) random circuits at each \( m \) would yield lower precision. GST required only 1500 circuits to estimate all error rates to the same precision.
### Extended Data Fig. 10 | Estimated state preparation and measurement (SPAM) error rates.

In the GST analysis, the system’s initial state was represented by a $4 \times 4$ density matrix $\rho$, and the final measurement/readout by a 4-element $4 \times 4$ POVM (positive operator-valued measure) $\{E_{\uparrow\uparrow}, E_{\uparrow\downarrow}, E_{\downarrow\uparrow}, E_{\downarrow\downarrow}\}$ with $E_j \geq 0$ and $\sum_j E_j = I$. We quantified the overall quality of the SPAM operations by using the GST estimate to compute the table of conditional probabilities shown here. Each cell shows the estimated probability of a particular readout (e.g., $\uparrow\uparrow$) given (imperfect) initialization in a particular state (e.g., $\downarrow\downarrow$). The $\uparrow\uparrow$ column can be read out directly from the estimate, since the experiment initialized into $\uparrow\uparrow$. Other states must be prepared by applying $X_{\pi/2}$ or $Y_{\pi/2}$ pulses. These add additional error, which should not be attributed to SPAM operations. To correct for this, we simulated ideal unitary rotation of the real $\uparrow\uparrow$ state into each of the other 3 states by (1) taking the GST-estimated $X_{\pi/2}$ gates on each qubit and removing all intrinsic errors from them, and (2) simulating a circuit comprising initialization in $\rho$, an appropriate sequence of those idealized gates, and readout according to $\{E_j\}$. The resulting analysis shows probabilities of all but one readout error to be below 1%, which is unprecedented in semiconductor spin qubit systems, and competitive with the state of the art in other physical platforms.
