Abstract

Many reinforcement learning (RL) environments consist of independent entities that interact sparsely. In such environments, RL agents have only limited influence over other entities in any particular situation. Our idea in this work is that learning can be efficiently guided by knowing when and what the agent can influence with its actions. To achieve this, we introduce a measure of situation-dependent causal influence based on conditional mutual information and show that it can reliably detect states of influence. We then propose several ways to integrate this measure into RL algorithms to improve exploration and off-policy learning. All modified algorithms show strong increases in data efficiency on robotic manipulation tasks.

1 Introduction

Reinforcement learning (RL) is a promising route towards versatile and dexterous artificial agents. Learning from interactions can lead to robust control strategies that can cope with all the intricacies of the real world that are hard to engineer correctly. Still, many relevant tasks such as object manipulation pose significant challenges for RL. Although impressive results have been achieved using simulation-to-real transfer [1] or heavy physical parallelization [2], training requires countless hours of interaction. Improving sample efficiency is thus a key concern in RL. In this paper, we approach this issue from a causal inference perspective.

When is an agent in control of its environment? An agent can only influence the environment by its actions. This seemingly trivial observation has the underappreciated aspect that the causal influence of actions is situation dependent. Consider the simple scenario of a robotic arm in front of an object on a table. Clearly, the object can only be moved when contact between the robot and object is made. Generally, there are situations where immediate causal influence is possible, while in others, none is. In this work, we formalize this situation-dependent nature of control and show how it can be exploited to improve the sample efficiency of RL agents. To this end, we derive a measure that captures the causal influence of actions on the environment and devise a practical method to compute it.

Knowing when the agent has control over an object of interest is important both from a learning and an exploration perspective. The learning algorithm should pay particular attention to these situations because (i) the robot is initially rarely in control of the object of interest, making training inefficient, (ii) physical contacts are hard to model, thus require more effort to learn and (iii) these states are enabling manipulation towards further goals. But for learning to take place, the algorithm first needs data that contains these relevant states. Thus, the agent has to take its causal influence into account already during exploration.

We propose several ways in which our measure of causal influence can be integrated into RL algorithms to address both the exploration, and the learning side. For exploration, agents can be rewarded with a bonus for visiting states of causal influence. We show that such a bonus leads the...
agent to quickly discover useful behavior even in the absence of task-specific rewards. Moreover, our approach allows to explicitly guide the exploration to favor actions with higher predicted causal impact. This works well as an alternative to $\epsilon$-greedy exploration, as we demonstrate. Finally, for learning, we propose an off-policy prioritization scheme and show that it reliably improves the speed of learning. Each of our investigations is backed by empirical evaluations in robotic manipulation environments and demonstrates a clear improvement of the state-of-the-art with the same generic influence measure.

2 Related Work

The idea underlying our work is that an agent can only sometimes influence its surroundings. This rests on two basic assumptions about the causal structure of the world. The first is that the world consists of independent entities, in accordance with the principle of independent causal mechanisms (ICM) [3], stating that the world’s generative process consists of autonomous modules. The second assumption is that the potential influence that entities have over other entities is localized spatially and occurs sparsely in time. We can see this as explaining the sparse mechanism shift hypothesis, which states that naturally occurring distribution shifts will be due to local mechanism changes [4]. This is usually traced back to the ICM principle, i.e. that interventions on one mechanism will not affect other mechanisms [5]. But we argue that it is also due to the limited interventional range of agents (or, more generally, physical processes), which restricts the breadth and frequency of mechanism changes in the real world. Previous work has used sparseness to learn disentangled representations [6, 7], causal models [8], or modular architectures [9]. In the present work, we show that taking the localized and sparse nature of influence into account can also strongly improve RL algorithms.

Detecting causal influence, informally, means deciding whether changing a causal variable would have an impact on another variable. This involves causal discovery, that is, finding the existence of arrows in the causal graph [10]. While the task of causal discovery is unidentifiable in general [11], there are assumptions which permit discovery [12], in particular in the time series setting we are concerned with [13]. Even if the existence of an arrow is established, the problem of quantifying its causal impact remains – various measures such as transfer entropy or information flow have been proposed for this [14–18]. We compare how our work relates to these measures in Sec. 4.1.

The intersection of RL and causality has been the subject of recent research [19–23]. Close to ours is the work of Pitis et al. [24], who also use influence detection, albeit to create counterfactual data that augments the training of RL agents. In Sec. 5, we find that our approach to action influence detection performs better than their heuristic approach. Additionally, we demonstrate that influence detection can also be used to help agents explore better. To this end, we use influence as a type of intrinsic motivation. For exploration, various signals have been proposed, e.g. model surprise [25–27], learning progress [27, 28], empowerment [29, 30], information gain [31–33], or predictive information [34, 35]. Inspired by causality, Sontakke et al. [36] introduce an exploration signal that leads agents to experiment with the environment to discover causal factors of variation. In concurrent work, Zhao et al. [37] propose to use mutual information between the agent and the environment state for exploration. As in our work, the agent is considered a separate entity from the environment. However, their approach does not discriminate between individual situations the agent is in. Causal influence is also related to the concept of contingency awareness from psychology [38], that is, the knowledge that one’s actions can affect the environment. On Atari games, exploring through the lens of contingency awareness has led to state-of-the-art results [39, 40].

3 Background

We are concerned with a Markov decision process $\langle S, A, P, r, \gamma \rangle$ consisting of state and action space, transition distribution, reward function and discount factor. Most real world environments consist of entities that behave mostly independently of each other. We model this by assuming a known state space factorization $S = S_1 \times \ldots \times S_N$, where each $S_i$ corresponds to the state of an entity.

---

1 We use capital letters (e.g. $X$) to denote random variables, small letters to denote samples drawn from particular distributions (e.g. $x \sim P_X$), and caligraphy letters to denote graphs, sets and sample spaces (e.g. $x \in X$). We denote distributions with $P$ and their densities with $p$.  

2
When is an agent’s action \( A = a \) the cause of an outcome \( B = b \)? Answering this question precisely is surprisingly non-trivial and is studied under the name of actual causation \([10, 41]\). Humans would answer by contrasting the actual outcome to some normative world in which \( A = a \) did not happen,
We want this measure to be independent of the particular policy used in the joint distribution.

As Prop. 1 tells us, control (or its absence) is linked to the independence $S | A = a$.

In other words, $A = a$ was a necessary condition for $B = b$ to occur, and under a different value for $A, B$ would have had a different value as well. This matches well with an algorithmic view on causation: $A$ is a cause of $B$ if the value of $A$ is required to determine the value of $B$.

The but-for test yields potentially counterintuitive assessments. Consider a robotic arm close to an object but performing an action that moves it away from the object. Then this action is considered a cause for the position of the object in this step, as an alternative action touching the object would have led to a different outcome. Algorithmically, knowing the action is required to determine what happens to the object – all actions are considered to be a cause in this situation. Importantly, this implies that we cannot differentiate whether individual actions are causes or not, but can only identify whether or not the agent has causal influence on other entities in the current state.

4 Causal Influence Detection

As the previous discussion showed, having causal influence is dependent on the situation the agent is in, rather than the chosen actions. We characterize this as the agent being in control, analogous to similar notions in control theory.

We define the agent to be in control of $S_j$ in state $S = s$ if there is an edge $A \rightarrow S_j'$ in the local causal graph $G_{S=s}$. The following proposition characterizes when this is the case (proofs in Suppl. A.1).

**Proposition 1.** Let $G_{S=s}$ be the graph of the local CGM induced by $S = s$. There is an edge $A \rightarrow S_j'$ in $G_{S=s}$ if and only if $S_j' \not\perp \! \! \! \perp A \mid S = s$ for some $j \in \{1, \ldots, n\}$. Further, this holds under all possible interventions $do(A := \pi(a|s))$ with $\pi$ having full support.

To detect when the agent is in control, we can intervene with a policy. The following proposition gives conditions under which conclusions drawn from one policy generalize to many policies.

**Proposition 2.** If there is an intervention $do(A := \pi(a|s))$ with $\pi$ having full support for which it holds that $S_j' \not\perp \! \! \! \perp A \mid S = s$, this independence holds under all possible interventions and the agent is not in control in $s$. If there is an intervention $do(A := \pi(a|s))$ for which it holds that $S_j' \not\perp \! \! \! \perp A \mid S = s$, this dependence holds under all interventions with full support, and the agent is in control in $s$.

4.1 Measuring Causal Action Influence

Our goal is to find a state-dependent quantity that measures whether the agent is in control of $S_j'$. As Prop. 1 tells us, control (or its absence) is linked to the independence $S_j' \not\perp \! \! \! \perp A \mid S = s$. A well-known measure of dependence is the conditional mutual information (CMI) [44] which is zero for independence. We thus propose to use (pointwise) CMI as a measure of causal action influence (CAI) that can be thresholded to get a classification of control (see Suppl. A.2 for a derivation):

$$C^j(s) := I(S_j'; A \mid S = s) = \mathbb{E}_{a \sim \pi} \left[ \text{KL} \left( P_{S_j'|s,a} \bigg\| P_{S_j'|s} \right) \right].$$  \hspace{1cm} (2)

We want this measure to be independent of the particular policy used in the joint distribution $P(S, A, S_j')$. This is because we might not be able to sample from or evaluate this policy (e.g. in off-policy RL, the data stems from a mixture of different policies). Fortunately, Prop. 2 shows that to detect control, it is sufficient to demonstrate (in-)dependence for a single policy with full support. Thus, we can choose a uniform distribution over the action space as the policy: $\pi(A) = \mathcal{U}(A)$.

Let us discuss how CAI relates to previously suggested measures of (causal) influence. Transfer entropy [17] is a non-linear extension of Granger causality [45] quantifying causal influence in time series under certain conditions. CAI is similar to a one-step, local transfer entropy [17] with the difference that CAI conditions on the full state $S$. Janzing et al. [18] put forward a measure of causal strength fulfilling several natural criteria that other measures, including transfer entropy, fail to satisfy. In Suppl. A.3, we show that CAI is a pointwise version of Janzing et al.’s causal strength, for policies not conditional on the state $S$ (adding further justification for the choice of a uniform random
policy. Furthermore, we can relate CAI to notions of controllability [43]. Decomposing $C^j(s)$ as $H(S'_j \mid s) - H(S'_j \mid A, s)$, where $H$ denotes the conditional entropy [44], we can interpret CAI as quantifying the degree to which $S'_j$ can be controlled in $s$, accounting for the system’s intrinsic uncertainty that cannot be reduced by the action.

In the context of RL, empowerment [29, 30, 46] is a well-known quantity used for intrinsically-motivated exploration that leads agents to states of maximal influence over the environment. Empowerment, for a state $s$, is defined as the channel capacity between action and a future state, which coincides with $\max_\pi C(s)$ for one-step empowerment. CAI can thus be seen as a non-trivial lower bound of empowerment that is easier to compute. However, CAI differs from empowerment in that it does not treat the state space as monolithic and is specific to an entity. In Sec. 6.1, we demonstrate that an RL agent maximizing CAI quickly achieves control over its environment.

4.2 Learning to Detect Control

Estimating CMI is a hard problem on many levels: it involves computing high dimensional integrals, representing complicated distributions and having access to limited data; strictly speaking, each conditioning point $s$ is seen only once in continuous spaces. In practice, one thus has to resort to an approximation. Non-parametric estimators based on nearest neighbors [47, 48] or kernels methods [49] are known to not scale well to higher dimensions [50]. Instead, we approach the problem by learning neural network models with suitable simplifying assumptions.

Expanding the KL divergence in Eq. 2, we can write CAI as

$$C^j(s) = I(S'_j; A \mid S = s) = E_A E_{S'_j|s,a} \left[ \log \frac{p(s'_j \mid s, a)}{\int p(s'_j \mid s, a, \pi(s)\mid a)\, da} \right]$$

To compute this term, we estimate the transition distribution $p(s'_j \mid s, a)$ from data. We then approximate the outer expectation and the transition marginal $p(s'_j \mid s)$ by sampling $K$ actions from the policy $\pi$. This gives us the estimator

$$\hat{C}^j(s) = \frac{1}{K} \sum_{i=1}^{K} \left[ \text{KL} \left( p(s'_j \mid s, a^{(i)}) \mid \frac{1}{K} \sum_{k=1}^{K} p(s'_j \mid s, a^{(k)}) \right) \right],$$

with $\{a^{(1)}, \ldots, a^{(K)}\} \stackrel{iid}{\sim} \pi$. Here, we replaced the infinite mixture $p(s'_j \mid s)$ with a finite mixture, $p(s'_j \mid s) \approx \frac{1}{K} \sum_{i=1}^{K} p(s'_j \mid s, a^{(i)})$, and used Monte-Carlo to approximate the expectation. Poole et al. [51] show that this estimator is a lower bound converging to the true mutual information $I(S'_j; A \mid S = s)$ as $K$ increases (assuming, however, the true density $p(s'_j \mid s, a)$).

To compute the KL divergence itself, we make the simplifying assumption that the transition distribution $p(s'_j \mid s, a)$ is normally distributed given the action, which is reasonable in the robotics environment we are targeting. This allows us to estimate the KL without expensive MC sampling by using an approximation for mixtures of Gaussians from Durrieu et al. [52]. We detail the exact formula we use in Suppl. A.4.

With the normality assumption, the density itself can be learned using a probabilistic neural network and simple maximum likelihood estimation. That is, we parametrize $p(s'_j \mid s, a)$ as $\mathcal{N}(\mu_\theta(s, a), \sigma_\theta^2(s, a))$, where $\mu_\theta, \sigma_\theta^2$ are the outputs of a neural network $f_\theta(s, a)$. We find the parameters $\theta$ by minimizing the negative log-likelihood over samples $D = \{(s^{(i)}, a^{(i)}, s'^{(i)})\}_{i=1}^{N}$ collected by some policy:

$$\theta^* = \arg \min_\theta \frac{1}{N} \sum_{i=1}^{N} \left[ \frac{1}{2} \frac{\|f_\theta(s^{(i)}, a^{(i)}) - \mu_\theta(s^{(i)}, a^{(i)})\|_2^2}{2\sigma_\theta^2(s^{(i)}, a^{(i)})} \right] + \log \sigma_\theta(s^{(i)}, a^{(i)}).$$

There are some intricacies regarding the policy that collects the data for model training and the sampling policy $\pi$ that is used to compute CAI. First of all, the two policies need to have overlapping support to avoid evaluating the model under actions never seen during training. Furthermore, if the data policy is different from the sampling policy $\pi$, the model is biased to some degree. This suggests to use $\pi$ for collecting the data; however, as we use a random policy, this will not result in interesting data in most environments. The bias can be reduced by sampling actions from $\pi$ during data collection with some probability and only train on those. In practice, however, we find to obtain better performing models by training on all data despite potentially being biased.

5 Empirical Evaluation of Causal Influence Detection

In this section, we evaluate the quality of our proposed causal influence detection approach in relevant environments. As a simple test case, we designed an environment (IDSslide) in which the agent must slide an object to a goal location by colliding with it. Furthermore, we test on the FETCHPickAndPlace environment from OpenAI Gym [53], in its original setting and when adding Gaussian noise to the observations to simulate more real-world conditions. In both environments, the target variables of interest are the coordinates of the object. Note that we need the true causal graph at each time step for the evaluation. For IDSslide, we derive this information from the simulation. For the pick and place environment with its non-trivial dynamics, we resort to a heuristic of the possible movement range of the robotic arm in one step. Detailed information about the setup is provided in Suppls. B and E.

For our method, we use CAI estimated according to Eq. 4 (with $K = 64$) as a classification score that is thresholded to gain a binary decision. We compare with a recently proposed method [24] that uses the attention weights of a Transformer model [54] to model influence. Moreover, we compare with an Entropy baseline that uses $H(S'_{t} \mid s)$ as a score and a Contact baseline based on binary contact information from the simulator. We show the test results over 5 random seeds in Table 1 and Fig. 2. We observe that CAI is able to reliably detect causal influence and no other baseline is able to do so. When increasing the observation noise, the performance drops gracefully for CAI as shown in Fig. 2c. Suppl. C contains more experimental results, including a visualization of CAI’s behavior.

6 Improving Efficiency in Reinforcement Learning

Having established the efficacy of our causal action influence (CAI) measure, we now develop several approaches to use it to improve RL algorithms. We will empirically verify the following claims in robotic manipulation environments: CAI improves sample efficiency and performance by (i) better state exploration through an exploration bonus, (ii) causal action exploration, and (iii) prioritizing experiences with causal influence during training.

We consider the environments FETCHPush, FETCHPickAndPlace from OpenAI Gym [55], and FETCHROT TABLE which is our modification containing a rotating table (explained in Suppl. B.3).

Figure 2: Causal influence detection performance. (a, b) ROC curves on IDSslide and FETCHPickAndPlace environments. (c) Average precision for FETCHPickAndPlace depending on added state noise. Noise level is given as percentage of one standard deviation over the dataset.
These environments are goal-conditioned RL tasks with sparse rewards, meaning that each episode, a new goal is provided and the agent only receives a distinct reward upon reaching it. We use DDPG [56] with hindsight experience replay (HER) [57] as the base RL algorithm, a combination that achieves state-of-the-art results in these environment. The influence detection model is trained online on the data collected from an RL agent learning to solve its task. Since our measure $C^j$ requires an entity of interest, we choose the coordinates of the object (as $S_j$). In all experiments, we report the mean success rate with standard deviation over 10 random seeds. More information about the experimental settings can be found in Suppl. F.

6.1 Intrinsic Motivation to Seek Influence

Causal Action Influence as Reward Bonus. We hypothesize that it is useful for an agent to be intrinsically motivated to gain control over its environment. We test this hypothesis by letting the agent maximize the causal influence it has over entities of interest. This can be achieved by using our influence measure as a reward signal. The reward signal can be used on its own, as an intrinsic motivation-type objective, or in conjunction with a task-specific reward as an exploration bonus. In the former case, we expect the agent to discover useful behaviors that can help it master task-oriented skills afterwards; in the latter case, we expect learning efficiency to improve, especially in sparse extrinsic reward scenarios. Concretely, for a state $s$, we define the bonus as $r_{CAI}(s) = C^j(s)$, and the total reward as $r(s) = r_{task}(s) + \lambda_{bonus} r_{CAI}(s)$, where $r_{task}(s)$ is the task reward, and $\lambda_{bonus}$ is a hyperparameter.

Experiment on Intrinsically Motivated Learning. We first test the behavior of the agent in the absence of any task-specific reward on the FETCHPICKANDPLACE environment. Interestingly, the agent learned to grasp, lift, and hold the object in the air already after 2000 episodes, as shown in Fig. 3. The results demonstrate that encouraging causal control over the environment is well suited to prepare the agent for further tasks it might have to solve.

Impact of CAI Reward Bonus. Second, we are interested in the impact of adding an exploration bonus. In Fig. 4, we present results on the FETCHPICKANDPLACE environment when varying the reward scale $\lambda_{bonus}$. Naturally, the exploration bonus needs to be selected in the appropriate scale as a value too high will make it dominate the task reward. If selected correctly, the sample efficiency is improved drastically; for example, we find that the agent reaches a success rate of 60% four-times faster than the baseline (DDPG+HER) without any bonus ($\lambda_{bonus} = 0$).

6.2 Actively Exploring Actions with Causal Influence

Following Actions with the Most Causal Influence. Exploration via bonus rewards favors the re-visitation of already seen states. An alternative approach to exploration uses pro-active planning to choose exploratory actions. In our case, we can make use of our learned influence estimator to pick actions which we expect will have the largest causal effect on the agent’s surroundings. From a causal viewpoint, the resulting agent can be seen as an experimenter that performs planned interventions in the environment to verify its beliefs. Should the actual outcome differ from the expected outcome, subsequent model updates can integrate the new data to self-correct the causal influence estimator.
Figure 5: Performance of active exploration in FetchPickAndPlace depending on the fraction of exploratory actions chosen actively (Eq. 6) from a total of 30% exploratory actions.

Figure 6: Experiment comparing exploration strategies on FetchPickAndPlace. The combination of active exploration and reward bonus yields the largest sample efficiency.

Concretely, given the agent being in state $s$, we choose the action that has the largest contribution to the empirical mean in Eq. 4:

$$a^* = \arg\max_{a \in \{a^{(1)}, \ldots, a^{(K)}\}} D_{KL} \left( p(s'_j | s, a) \parallel \frac{1}{K} \sum_{i=1}^{K} p(s'_j | s, a^{(i)}) \right), \quad (6)$$

with $\{a^{(1)}, \ldots, a^{(K)}\} \sim \pi$. Intuitively, the selected action will be the one which results in maximal deviation from the expected outcome under all actions. For states $s$ where the agent is not in control, i.e. $C^\pi(s) \approx 0$, the action selection is uniform at random.

**Active Exploration in Practice.** Can active exploration replace $\epsilon$-greedy exploration? To gain insights, we study the impact of the fraction of actively chosen exploration actions. For every exploratory action ($\epsilon$ is 30% in our experiments), we choose an action according to Eq. 6 the specified fraction of the time, and otherwise a random action. Figure 5 shows that any amount of active exploration improves over simple random exploration. Active causal action exploration can improve the sample efficiency roughly by a factor of two.

**Combined CAI Exploration.** We also present the combination of reward bonus and active exploration and compare our method with VIME, another exploration scheme based on information-theoretic measures [33]. In contrast to our method, VIME maximizes the information gain about the state transition dynamics (we compare different VIME variants in Suppl. D). Figure 6 quantifies the superiority of all CAI variants and shows that combining the two exploration strategies compounds to increase sample efficiency even further. In the figure, CAI uses 100% active exploration and $\lambda_{\text{bonus}} = 0.2$ as the bonus reward scale.

### 6.3 Causal Influence-based Experience Replay

**Prioritizing According to Causal Influence.** We will now propose another method using CAI, namely to inform the choice of samples replayed to the agent during off-policy training. Typically, past states are sampled uniformly for learning. Intuitively, focusing on those states where the agent has control over the object of interest (as measured by CAI) should improve the sample efficiency. We can implement this idea using a prioritization scheme that samples past episodes more frequently in which the agent had more influence. Concretely, we define the probability $P^{(i)}$ of sampling any state $s$ in episode $i$ (of $M$ episodes) in the replay buffer as

$$P^{(i)} = \frac{p^{(i)} / \sum_{i=1}^{M} p^{(i)}}{T}, \quad \text{with} \quad p^{(i)} = \left( M + 1 - \text{rank} \sum_{i=1}^{T} C^\pi(s^{(i)}) \right)^{-1}. \quad (7, 8)$$

where $p^{(i)}$ is the priority of episode $i$ and $T$ is the episode length. The priority of an episode is based on the (inverse) rank of the episode when sorting all $M$ episodes according to their total influence. We call this causal action influence prioritization (CAI-P).

This scheme is similar to Prioritized Experience Replay [58], with two differences: instead of using the TD error for prioritization, we use the causal influence measure. Furthermore, instead of
prioritizing individual states, we prioritize episodes and sample states uniformly within episodes. This is because the information about the return that can be achieved from an influence state still needs to be propagated back to non-influenced states by TD updates, which requires sampling them.

**Influence-Based Prioritization in Manipulation Tasks.** We compare our influence-based prioritization (CAI-P) against no prioritization in hindsight experience replay (HER) (a strong baseline for multi-goal RL), and two other prioritization schemes: prioritized experience replay (PER) [58] and energy-based prioritization (EBP) [59]. Especially EBP is a strong method for the environments we are considering as it uses privileged knowledge of the underlying physics to replay episodes based on the amount of energy that is transferred from agent to the object to manipulate. All prioritization variants are equipped with HER as well.

The FETCHROTTable environment, as shown in Fig. 8, is an interesting test bed, as the objects can move by the rotating table without the control of the agent. The results, as shown in Fig. 7, show that causal influence prioritization can speed up learning drastically. Our method is on par or better than the energy-based (oracle) method EBP and improves over PER by a factor of 1.5–2.5 in learning speed (at 60% success rate). Finally, in Suppl. D, we combine all our proposed improvements and show that FETCHPICKANDPLACE can be solved up to 95% success rate in just 3000 episodes.

### 7 Discussion

In this work, we show how situation-dependent causal influence detection can help improve reinforcement learning agents. To this end, we derive a measure of local causal action influence (CAI) and introduce a data-driven approach based on neural network models to estimate it. We showcase using CAI as an exploration bonus, as a way to perform active action exploration, and to prioritize in experience replay. Each of our applications yields strong improvements in sample efficiency. We expect that there are further ways to use our causal measure in RL, e.g. for credit assignment.

Our work has several limitations. First, we assume full observability of the state, which simplifies the causal inference problem as there is no confounding between an agent’s action and its effect. Under partial observability, our approach could still be applicable using latent variable models [60]. Second, we require an available factorization of the state into causal variables. The problem of automatically learning causal variables from high-dimensional data is open [4] and our method would likely benefit from advances in this field. Third, the accurate estimation of our measure relies on a correct model. We found that deep networks can struggle at times to pick up the causal relationship between actions and entities. How to design models with appropriate inductive biases for cause-effect inference is an open question [3, 4, 61].

An intriguing future direction is to extend our work to influence detection between entities, a prerequisite for identifying multi-step influences of the agent on the environment. Being able to model such indirect interventions would bring us closer to "artificial scientists" – agents that can perform planned experiments to reveal the latent causal structure of the world.

A Proofs and Derivations

A.1 Proof of Propositions

Proof of Prop. 1. “if”: If there is an edge $A \rightarrow S_j'$ in $G_{S=s}$, then causal minimality says that $S_j'$ must be dependent on each parent given its other parents, meaning $S_j' \not\perp A \mid S = s$. “only if”: If it holds that $S_j' \not\perp A \mid S = s$, then by the Markov property \cite[Def. 6.21]{pearl2000causality}, there must be an unblocked path from $A$ to $S_j'$ in $G_{S=s}$. Because the path over $S$ is blocked by observing $S = s$, and we assume no instantaneous effects, the only possible such path is the direct edge $A \rightarrow S_j'$.

To see why this holds for all interventions, note that intervening with $\text{do}(A := \pi(a \mid s))$ means replacing $A$’s conditional in the joint with $\pi(a \mid s)$. An independence between $S_j'$ and $A$ is not affected by this operation as long as it is not a “spurious” independence created by some policy that hides the dependence in $s$ (e.g. a deterministic policy); this spurious case is ruled out by assuming causal minimality of the pre-interventional joint distribution. A dependence is not affected as long as the intervention $\text{do}(A := \pi(a \mid s))$ does not introduce a new independence, which is the case as only interventions with full support on $A$ are covered by Prop. 1. To see this, note that a dependence implies that there exists some $s_j'$ and $a_1, a_2$ with $p(a_1 \mid s) > 0, p(a_2 \mid s) > 0$, and

$$p(s_j' \mid s, a_1) \neq p(s_j' \mid s, a_2),$$

where we let $p(a \mid s)$ denote the pre-interventional policy. Any interventional policy $\pi$ with full support would also have $\pi(a_1 \mid s) > 0, \pi(a_2 \mid s) > 0$, and so

$$p^{\text{do}(A := \pi)}(s_j' \mid s, a_1) = p(s_j' \mid s, a_1) \neq p(s_j' \mid s, a_2) = p^{\text{do}(A := \pi)}(s_j' \mid s, a_2),$$

implying the dependence for $\text{do}(A := \pi)$.

The following simple proposition shows us that whenever the agent is not in control, there is no possible intervening action it could perform to affect $S_j'$:

**Proposition 3.** If the agent is not in control of $S_j'$ in state $S = s$, there is no possible intervention $\text{do}(A := a)$ with $a \in A$ such that $p^{\text{do}(A := a)}(S_j' \mid S = s, A) \neq p^{\text{do}(A := a)}(S_j' \mid S = s)$. Further, this also holds for any stochastic intervention $\text{do}(A := \pi(a \mid s))$.

**Proof.** When the agent is not in control in state $S = s$, it follows from Prop. 1 that $S_j' \not\perp A \mid S = s$. Then, for any $a \in A$:

$$p^{\text{do}(A := a)}(S_j' \mid S = s, A = a) = p(S_j' \mid S = s, A = a)$$

$$= p(S_j' \mid S = s) = p^{\text{do}(A := a)}(S_j' \mid S = s)$$

by the autonomy property of causal mechanisms \cite[Eq. 6.7]{pearl2000causality}. For stochastic interventions $\text{do}(A := \pi(a \mid s))$, the same reasoning can be applied.

We can make use of Prop. 3 to prove Prop. 2.

**Proof of Prop. 2.** From Prop. 1, if $S_j' \not\perp A \mid S = s$ for any intervention $\text{do}(A := \pi(a \mid s))$ with $\pi$ having full support, the agent is not in control in $S = s$ as there is no edge $A \rightarrow S_j'$ in $G_{S=s}$. From Prop. 3 it then follows that under any intervention, $p^{\text{do}(A := \pi(a \mid s))}(S_j' \mid S = s, A) = p^{\text{do}(A := \pi(a \mid s))}(S_j' \mid S = s)$. To show that the agent is in control if $S_j' \not\perp A \mid S = s$ for any intervention $\text{do}(A := \pi(a \mid s))$, there needs to be an an edge $A \rightarrow S_j'$ in $G_{S=s}$. This is the case because assuming there would be no edge, $S_j' \perp A \mid S = s$ by the Markov condition (as there would be no unblocked path from $A$ to $S_j'$). To show that the dependence then holds for all interventions $\text{do}(A := \pi'(a \mid s))$ with $\pi'$ having full support, we employ a similar argument as in the proof of Prop. 1. That is, note that the dependence implies that there exists some $s_j'$ and $a_1, a_2$ with $\pi(a_1 \mid s) > 0, \pi(a_2 \mid s) > 0$ for which

$$p^{\text{do}(A := \pi)}(s_j' \mid s, a_1) = p(s_j' \mid s, a_1) \neq p(s_j' \mid s, a_2) = p^{\text{do}(A := \pi)}(s_j' \mid s, a_2).$$
We rewrite this further:

\[ p^{\text{do}(A:=\pi')}(s_j' \mid s, a_1) = p(s_j' \mid s, a_1) \neq p(s_j' \mid s, a_2) = p^{\text{do}(A:=\pi')}(s_j' \mid s, a_2), \]  

implying the dependence for \( \text{do}(A := \pi') \).

### A.2 CMI Formula

\[
C^j(s) = I(S_j' ; A \mid S = s) = D_{KL} \left( P_{S_j', A \mid s} \parallel P_{S_j' \mid s} \otimes P_A | s \right)
\]

\[
= \mathbb{E}_{S_j', A \mid s} \left[ \log \frac{p(s_j', a \mid s)}{p(s_j' \mid s)p(a \mid s)} \right]
\]

\[
= \mathbb{E}_{S_j', A \mid s} \left[ \log \frac{p(s_j' \mid s, a)}{p(s_j' \mid s)} \right]
\]

\[
= \mathbb{E}_{A \mid s} \left[ D_{KL} \left( P_{S_j' \mid s, a} \parallel P_{S_j' \mid s} \right) \right]
\]

### A.3 Proof that CAI is a Pointwise Version of Janzing et al.’s Causal Strength

Janzing et al.’s measure of causal strength quantifies the impact that removing a set of arrows in the causal graph would have. As it is the relevant case for us, we concentrate here on the single arrow version, for instance, between random variables \( X \) and \( Y \). The idea is to consider the arrow as a “communication channel” and evaluate the corruption that could be done to the signal that flows between \( X \) and \( Y \) by cutting the channel. To do so, the distribution that feeds the channel is replaced with \( P(X) \), i.e., the marginal distribution of \( X \). The measure of causal strength then is equal to the difference between the pre- and post-cutting joint distribution as given by the KL divergence.

Formally, let \( V \) denote the set of variables in the causal graph, let \( X \to Y \) be the arrow of interest with \( X, Y \in V \), and let \( \text{Pa}_Y \) be the set of parents of \( Y \) without \( X \). Then, the post-cutting distribution on \( Y \) is defined as

\[
p_{X \to Y}(y \mid \text{Pa}_Y) = \int p(y \mid x, \text{Pa}_Y) p(x) dx.
\]

The new joint distribution after such an intervention is defined as

\[
p_{X \to Y}(v_1, \ldots, v_{|V|}) = p_{X \to Y}(y \mid \text{Pa}_Y) \prod_{v_j \neq y} p(v_j \mid \text{Pa}(v_j)).
\]

Finally, the causal strength of the arrow \( X \to Y \) is defined as

\[
\mathcal{C}_{X \to Y} = D_{KL}(P(V) \parallel P_{X \to Y}(V)).
\]

To show the correspondence to our measure, we first restate Lemma 3 of [18]. For a single arrow \( X \to Y \), causal strength can also be written as the KL between the conditionals on \( Y \):

\[
\mathcal{C}_{X \to Y} = D_{KL}(P(Y \mid \text{Pa}_Y) \parallel P_{X \to Y}(Y \mid \text{Pa}_Y))
\]

\[
= \int D_{KL}(P(Y \mid \text{Pa}_Y) \parallel P_{X \to Y}(Y \mid \text{Pa}_Y)) p(\text{Pa}_Y) d\text{Pa}_Y
\]

We rewrite this further:

\[
= \int P(\text{Pa}_Y) P(X \mid \text{Pa}_Y) D_{KL}(P(Y \mid \text{Pa}_Y) \parallel P_{X \to Y}(Y \mid \text{Pa}_Y)) dx d\text{Pa}_Y
\]

\[
= \mathbb{E}_{\text{Pa}_Y} \left[ \int P(X \mid \text{Pa}_Y) D_{KL}(P(Y \mid \text{Pa}_Y) \parallel P_{X \to Y}(Y \mid \text{Pa}_Y)) dx \right]
\]

\[
= \mathbb{E}_{\text{Pa}_Y} \left[ \mathbb{E}_{x | \text{Pa}_Y} \left[ D_{KL}(P(Y \mid \text{Pa}_Y) \parallel P_{X \to Y}(Y \mid \text{Pa}_Y)) \right] \right]
\]

And we see that the inner part corresponds to our measure \( C^j(s) \) (cmp. Eq. 2) for the choices of variables \( X \equiv A, Y \equiv S_j', \) and \( \text{Pa}_Y \equiv S \), provided that \( P(X) \equiv \pi(A) \) is not dependent on \( S \). Thus, CAI is a pointwise version of causal strength for policies independent of the state:

\[
\mathcal{C}_{A \to S_j'} = \mathbb{E}_s[C^j(s)]
\]
A.4 Approximating the KL Divergence Between a Gaussian and a Mixture of Gaussians

In this section, we give the approximation we use for the KL divergence in Eq. 4. We first state the approximation for the general case of the KL between two mixtures of Gaussians, and then specialize to our case when the first distribution is Gaussian distributed. Here, we use the notation of Durrieu et al. [52].

Let $f$ be the PDFs of a multivariate Gaussians mixture with $A$ components, mixture weights $\omega_a^f \in (0, 1]$, means $\mu_a^f \in \mathbb{R}^d$ and covariances $\Sigma_a^f \in \mathbb{R}^{d \times d}$, where $a \in \{1, \ldots, A\}$ is the index of the $a$’th component. Then,

$$f(x) = \sum_{a=1}^{A} \omega_a^f f_a(x) = \sum_{a=1}^{A} \omega_a^f N(x; \mu_a^f, \Sigma_a^f),$$  \hspace{1cm} (27)

where $f_a(x) = N(x; \mu_a^f, \Sigma_a^f)$ is the PDF of a multivariate Gaussian with mean $\mu_a^f$ and covariance $\Sigma_a^f$. Analogously, let $g$ be the PDF of a multivariate Gaussians mixture with $B$ components. We are interested in the KL divergence $D_{\text{KL}}(f \parallel g) = \int_{\mathbb{R}^d} f(x) \log \frac{f(x)}{g(x)} \, dx$, which is intractable.

There are several ways to approximate the KL based on the decomposition $D_{\text{KL}} = H(f, g) - H(f)$, where $H(f, g)$ is the cross-entropy between $f$ and $g$ and $H(f)$ is the entropy of $f$. We will state the so-called product approximation $D_{\text{prod}}$ and the variational approximation $D_{\text{var}}$ [62]. Starting with $D_{\text{prod}}$:

$$H(f, g) \geq - \sum_a \omega_a^f \log \left( \sum_b \omega_b^g t_{ab} \right)$$  \hspace{1cm} (28)

$$H(f) \geq - \sum_a \omega_a^f \log \left( \sum_{a'} \omega_{a'}^f z_{aa'} \right)$$  \hspace{1cm} (29)

$$D_{\text{prod}} := \sum_a \omega_a^f \log \left( \sum_{a'} \omega_{a'}^f z_{aa'} \right)$$  \hspace{1cm} (30)

where $t_{ab} = \int f_a(x) g_b(x) \, dx$, $z_{aa'} = \int f_a(x) f_a(x) \, dx$ are normalization constants of product of Gaussians, and the inequalities in (28), (29) are based on Jensen’s inequality. For the variational approximation:

$$H(f, g) \leq \sum_a \omega_a^f H(f_a) - \sum_a \omega_a^f \log \left( \sum_b \omega_b^g e^{-D_{\text{KL}}(f_a \parallel g_b)} \right)$$  \hspace{1cm} (31)

$$H(f) \leq \sum_a \omega_a^f H(f_a) - \sum_a \omega_a^f \log \left( \sum_{a'} \omega_{a'}^f e^{-D_{\text{KL}}(f_a \parallel f_{a'})} \right)$$  \hspace{1cm} (32)

$$D_{\text{var}} := \sum_a \omega_a^f \log \left( \sum_{a'} \omega_{a'}^f e^{-D_{\text{KL}}(f_a \parallel f_{a'})} \right)$$  \hspace{1cm} (33)

where (31), (32) are based on solving variational problems. It can be shown that the mean between $D_{\text{prod}}$ and $D_{\text{var}}$ is the mean of a lower and upper bound to $D_{\text{KL}}$, with better approximation qualities [52]. Consequently, we use $D_{\text{mean}} := \frac{D_{\text{prod}} + D_{\text{var}}}{2}$ as the basis of our approximation. We can simplify $D_{\text{mean}}$ as in our case, we know that $f$ has only one component. This means that we can compute $H(f)$ in closed form, and do not need to use the inequalities (29), (32). Approximating $H(f, g)$ with the mean of the lower bound (28) and upper bound (31),

$$H_{\text{mean}}(f, g) := \frac{1}{2} \left( \log \left( \sum_b \omega_b^g t_{ab} \right) + H(f) - \log \left( \sum_b \omega_b^g e^{-D_{\text{KL}}(f_a \parallel g_b)} \right) \right),$$  \hspace{1cm} (34)

we get the final formula we use

$$D_{\text{mean}} := H_{\text{mean}}(f, g) - H(f)$$  \hspace{1cm} (35) 

$$= - \frac{1}{2} \log \left( \sum_b \omega_b^g t_{ab} \right) - \frac{1}{2} \log \left( \sum_b \omega_b^g e^{-D_{\text{KL}}(f_a \parallel g_b)} \right) - \frac{1}{2} H(f).$$  \hspace{1cm} (36)
Note that this term can become negative, whereas the KL is non-negative. In practice, we thus threshold $D_{\text{mean}}$ at zero. For completeness, we also state the entropy of a Gaussian

$$H(f) = \frac{1}{2} \log((2\pi e)^d |\Sigma|),$$  \hfill (37)

the log normalization constant for a product of Gaussians

$$\log t_{ab} = -\frac{d}{2} \log 2\pi - \frac{1}{2} \log|\Sigma_a| + \frac{1}{2} \left( (\mu^g_a - \mu^f_a)^T \Sigma_a^{-1} (\mu^g_a - \mu^f_a) + 1 \right) \log|\Sigma_b| + \frac{1}{2} \left( (\mu^g_b - \mu^f_b)^T \Sigma_b^{-1} (\mu^g_b - \mu^f_b) + 1 \right),$$  \hfill (38)

and the KL between two Gaussians

$$D_{KL}(f_a \parallel g_b) = -\frac{d}{2} + \frac{1}{2} \log \frac{|\Sigma_a|}{|\Sigma_b|} + \frac{1}{2} \text{Tr}((\Sigma_b^{-1} \Sigma_a) - 1) + \frac{1}{2} (\mu^g_b - \mu^f_b)^T (\Sigma_b^{-1} - 1) (\mu^g_b - \mu^f_b).$$  \hfill (39)

In our experiments, we assume independent dimensions, that is, we parametrize the covariance $\Sigma$ as a diagonal matrix. With this, the above formulas can be further simplified.

## B Environments

### B.1 1D-Slide

1DSLIDE is a simple environment that we designed to test influence detection, as we can easily derive when the agent has influence or not. It consists of an agent and an object positioned on a line, with both agent and object only being able to move left and right. See Fig. S1 for a visualization. The goal of the agent is to move the object to a goal zone. As the agent can not cross past the center of the environment, it has to hit the object at the appropriate speed. The state space $S \subset \mathbb{R}^4$ consists of position and velocity of the agent and object. The agent’s action $a \in A \subseteq [-1, 1]$ applies acceleration to the agent. On contact with the object, the full impulse of the agent is transferred to the object. We can derive if the agent has causal influence in a state by simulating applying the maximum acceleration in both directions and checking whether a contact has occurred, and the object state has changed.

### B.2 FetchPickAndPlace

The FETCH environments in OpenAI Gym [53] are built on top of the MuJoCo simulator [63], and consist of a position-controlled 7 DoF robotic arm [55]. In FETCHPICKANDPLACE, the state space $S \subset \mathbb{R}^{25}$ consists of position and velocity of the robot’s end effector, the position and velocity of the gripper, and the object’s position and rotation, linear and angular velocities, and position relative to the end effector. The action space $A \subseteq [-1, 1]^4$ controls the gripper movement and opening/closing of the gripper. For the experiments involving Transformer models, we split the state space into agent and object state components, where we do not include the relative positions between gripper and object into either component.

For our experiment in Sec. 5 evaluating the causal influence detection, we need to determine whether the agent can potentially influence the object, i.e. whether the agent is “in control”. This is difficult to determine analytically, which is why we designed a heuristic. The idea is to find an ellipsoid around the end effector that captures its maximal movement range, and intersect this ellipsoid with the object to decide whether influence is possible. As the range of movement of the robotic arm is different depending on its position, we first build a lookup table (offline) that contains, for different start positions, end positions after applying different actions. To do so, we grid-sample the 3D-space over the table (50 grid points per dimension), plus a sparser sampling of the outer regions (20 grid points per dimension), resulting in 133 000 starting locations for the lookup table. Then, the following procedure is repeated for each starting location and action: after resetting the simulator, the end effector is manually moved to one of the starting locations, one of the maximal actions in each dimension (i.e., $-1$ and $1$, for a total of 6 actions) is applied, and the end position after one environment step is recorded in the lookup table.

![Figure S1: Schematic of 1DSLIDE environment. The agent (black square) has to slide the object (green square) to the target location (red zone), but can not pass the dotted line.](image)
Now, while the environment runs, for each step, we find the sampling point closest to the position of the robotic arm in the lookup table using a KD-tree, and find the corresponding end positions. From the end positions, we build the ellipsoid by taking the maximum absolute deviation in each dimension to be the length of the ellipsoid axis in this dimension. The ellipsoid so far does not take into account the spatial extents of object and gripper. Thus, we extend the ellipsoid by the sizes of the object and gripper fingers in each dimension. Furthermore, we take into account that the gripper fingers can be slid in y-direction by the agent’s action by extending the ellipsoid’s y-axis correspondingly. The label of “agent in control” is then obtained by checking whether the object location lies within the ellipsoid. Last, we also label a state as “agent in control” when there is an actual contact between gripper and object in the following step. We note that the exact procedure described above is included in the code release.

B.3 FetchRotTable

FetchRotTable is an environment designed by us to test CAI prioritization in a more challenging setting. In FetchRotTable, the table rotates periodically, moving the object around. This creates a confounding effect for influence detection, as there is another source of object movements besides the agent’s own actions. This means that CAI needs to differentiate between different causes for movements.

FetchRotTable is based on FetchPickAndPlace, but the rectangular table is replaced with a circular one (see Fig. 8). The table rotates with inertia by 45 degrees over the course of 25 environment steps, and then pauses for 5 steps. To make the resulting environment Markovian, the state space of FetchPickAndPlace is extended to \( S \subset \mathbb{R}^{29} \), additionally including sine and cosine of the table angle, the rotational velocity of the table, and the amount the table will rotate in the current state in radians. The task of the agent is the same as in FetchPickAndPlace, i.e. to move the object to a target position. If the target position is on the table, the agent thus has to learn to hold the object in position while the table rotates. In contrast to FetchPickAndPlace, the goal distribution is different, with 90% of goals in the air and only 10% on the table. This makes the task more challenging, as the agent has to master grasping and lifting before 90% of the possible positive rewards can be accessed.

C Additional Results for Influence Evaluation

In this section, we include additional results for the empirical evaluation of influence detection in Sec. 5. Figure S2a and Fig. S3b show precision-recall (PR) curves for the experiment in Sec. 5, while Fig. S2c shows how area-under-ROC curve varies while increasing the observation noise level.

For FetchPickAndPlace, we also evaluated on a test dataset obtained from a random policy. On this dataset, the detection task is considerably harder: it contains only 3.3% transitions where the agent has influence (i.e. labeled as positive), and it does not contain samples where the agent moves
the object in the air, which are easier to detect as influence. We show ROC and PR curves for this dataset in Fig. S3a and Fig. S3b. As expected, the detection performance drops compared to the other test dataset, which can in particular be seen in the PR curve. But overall, the performance is still quite good when taking into account the low amount of positive samples. In Fig. S3c, we also plot the impact of varying the number of sampled actions $K$ on this dataset. As one can see, the method is relatively robust to this parameter, giving decent performance even under a small number of sampled actions. However, we think that a higher number of sampled actions is important in edge-case situations, which are overshadowed in such a quantitative analysis.

Finally, in Fig. S4, we give a qualitative analysis of CAI. Here, we plot the trajectory in three different situations: no contact of agent and object, briefly touching the object, and successfully manipulating the object. As desired, CAI is low and high in the “no contact” and “successful manipulation” trajectories. In the “brief touch” trajectory, CAI spikes around the contact. However, in steps 8-11, when the agent hovers near the object, the heuristical labeling (see Sec. B.2) still detects that influence of agent on object is possible, which CAI does not register. These are difficult cases which show that our method still has room for improvement; we think that these failure cases could be resolved by employing a better model. However, we also note that the “ground truth” label is only based on a heuristic, which will make mispredictions at times as well.

D Additional Results for Reinforcement Learning

In this section, we include additional results to the RL experiments in Sec. 6. First of, in Fig. S5, we analyse CAI’s behavior using one the runs from the intrinsic motivation experiment in Sec. 6.1. To this end, we plot a heatmap visualising the score distribution in the replay buffer after 5 000 episodes, a corresponding heatmap with ground truth labels, and the fraction of steps where the object was moved or held in the air by the agent. It can be seen that CAI’s distribution approximates the ground truth label’s distribution well. It also becomes visible that CAI measures the strength of causal influence, as the score is highest after the agent learns to lift the object in the air (episode 3 000 onwards). In comparison, the binary ground truth distribution assigns high scores more uniformly.

In Fig. S6, we analyse the impact of combining our different proposed improvements, namely prioritization, exploration bonus, and active action selection. On its own, prioritization brings the largest benefit. Combining either exploration bonus or active action selection with prioritization leads to similar further improvements. Both are complementary however; combining all three variants together results in the best performing version. Compared to not using CAI, combining two or all three improvements leads to a 4–10× increase in sample efficiency.

Finally, in Fig. S5, we plot different versions of the VIME baseline. For VIME, there is the choice of for which parts of the state space the information gain should be computed. We compared the variants of full state, only the position of the agent and the object, and only the position of the object
Figure S4: Visualizing CAI score $C_j(s)$ over first 20 steps of an episode on FETCHPICKANDPLACE. The red dots mark states where the agent has causal influence on the object (according to the ground truth label as described in Sec. B.2). Yellow stars mark that the agent makes contact with the object between this state and the next state (as derived from the simulator), which also includes that the agent has causal influence. Plotted are episodes with no contact (first row), briefly touching the object (second row), and successful manipulation of the object (third row).

Figure S5: Analyzing the behavior of CAI. Plotted is one run of the intrinsic motivation experiment from Sec. 6.1. Left: heatmap showing score $C_j(s)$ per step, as stored in replay buffer after 5 000 episodes. Score is averaged in groups of 100 episodes and normalized by 95th percentile. Center: heatmap showing ground truth label derived for causal influence, as described in Sec. B.2. CAI approximates the ground truth well. Right: behavior of the agent in this run.

(which would be similar to CAI). The variant of using agent and object position performed best, and thus we use it for comparison in Fig. 6 in the main part.

E  Settings of Influence Detection Evaluation

Datasets  For the experiment in Sec. 5, we use separate training, validation and test datasets. For IDS-LIDE, training and validation set consist of 1 000 episodes (30 000 samples) collected from two separate training runs of a DDPG+HER agent. The test set consists of 4 000 episodes (120 000 samples), where 2 000 episodes were collected by a random policy, and 2 000 by a DDPG+HER
agent. For FetchPickAndPlace, training and validation set consist of 5 000 episodes (250 000 samples) collected from two separate training runs of a DDPG+HER agent. The test set consists of 7 500 episodes (375 000 samples) collected from training a DDPG+HER agent for 30 000 epochs. The test set was subsampled by selecting 250 random episodes from every 1 000 collected episodes (subsampling was performed to ease the computational load of evaluation). The test set has 45.3% samples that are labeled positive, i.e. the agent has influence. We note that it is not strictly necessary to train on data collected from a training RL agent, as we also trained on data from random policies and obtained similar results. In Sec. 5, we also analyse the behavior when adding observation noise, which is given as a percentage level. To determine an appropriate level of noise, we recorded the standard deviations over the different state dimensions on a dataset with 10 000 episodes collected from a random policy. It only has 3.3% samples that are labeled positive, i.e. there is considerably less interaction with the object than on the other test set.

Methods The classification scores for the different methods were obtained as follows. For CAI, we use $C_j(s)$ as given in Eq. 4, with $K = 64$ actions for sampling. For entropy, we use the same model as trained for CAI, and estimate conditional entropy as $H(S_j' | S = s) \approx \frac{1}{K} \sum_{a=1}^{K} H[p(s_j' | s, a^{(i)})]$ with $\{a^{(1)}, \ldots, a^{(K)}\} \overset{iid}{\sim} \pi$, using the formula given in Eq. 37 for the entropy of a Gaussian. For attention, we use the attention weights of a Transformer, where the score is computed as follows. As the Transformer requires a set as input, we split the input vector into components for the agent state, the object state, and the action. The Transformer is trained to predict the position of the object, that is, we discard the Transformer’s output for the other components. Then, letting $A_i$ denote the attention matrix of the $i$’th of $N$ layers, the total attention matrix is computed as $\prod_{i=1}^{N} A_i$. The score is the entry of the total attention matrix corresponding to the input position of the action component, and the output position of the object component. We refer to Pitis et al. [24] for more details.

We list the model hyperparameters for CAI in Table S1 and for the Transformer in Table S2. Training was performed for a maximum of 3 000 epochs on 1DSLIDE and 2 000 epochs on FetchPickAndPlace. The training was stopped early when the mean-squared-error (MSE) did not improve for 10 evaluations on the validation set, where evaluations were conducted every 20 training epochs. We trained all models using the Adam optimizer [64], with $\beta_1 = 0.9, \beta_2 = 0.999$ if not noted otherwise. All models were trained to predict the relative difference to the next state instead of the absolute next state.
state, i.e. the target was $S_j' - S_j$. For FETCHPICKANDPLACE, we rescaled the targets by a factor of 50, as it resulted in better performance.

We used a simple multi-layer perceptron (MLP) for the model in CAI, with two separate output layers for mean and variance. To constrain the variance to positive range, the variance output of the MLP was processed by a softplus function (given by $\log(1 + \exp(x))$), and a small positive constant of $10^{-8}$ was added to prevent instabilities near zero. We also clip the variance to a maximum value of 200. For weight initialization, orthogonal initialization [65] was used. We observed that training with the Gaussian likelihood loss (Eq. 5) can be unstable. Applying spectral normalization [66] to some of the layers decreased the instability considerably. Note that we did not apply spectral normalization to the mean output layer, as doing so resulted in worse predictive performance. For FETCHPICKANDPLACE, the inputs were normalized by applying batch normalization (with no learnable parameters) before the first layer.

F Settings of Reinforcement Learning Experiments

Our RL experiments are run in the goal-conditioned setting, that is, each episode, a goal is created from the environment that the agent has to reach. An episode counts as success when the goal is reached upon the last step of the episode. On the FETCH environments we use, the goal are coordinates where the object has to be moved to. For goal sampling, we use the settings as given by the environments in OpenAI Gym (described in more detail by Plappert et al. [55]). We use the sparse reward setting, that is, the agent receives a reward of 0 when the goal is reached, and $-1$ otherwise. Practically, goal-conditioned RL is implemented by adding the current goal to the input for policy and value function. For evaluating the RL experiments, we run the current RL agent 100-times every 200 episodes, and average the outcomes to obtain the success rate.

For the RL experiments, we use the same base settings for all algorithms, listed in Table S3. These settings (for DDPG+HER) were borrowed from Ren et al. [67], as they already provide excellent performance compared to Plappert et al. [55] (e.g. on FETCHPICKANDPLACE, $4 \times$ faster to reach 90% success rate). Before starting to train the agent, the memory buffer is seeded with 200 episodes collected from a random policy. The input for policy and value function is normalized by tracking mean and standard deviation of inputs seen over the course of training.
All experiments can be run on a standard multi-core CPU machine. Training a CAI model with prioritization for 20 000 epochs on FETCHPICKANDPLACE takes roughly 8 hours using 3 cores on an Intel Xeon Gold 6154 CPU with 3 GHz. Training a DDPG+HER agent takes roughly 4 hours.

**CAI Implementation** For CAI, we list the settings in Table S4. After an episode is collected by the agent, the CAI score \( C_j \) is computed for the episode and stored in the replay buffer. The model for CAI was trained every 100 episodes by sampling batches from the replay buffer. For online training, we designed a training schedule where the number of training batches used is varied over the course of training. We note that the specific schedule used appeared to be not that important as long as the model is sufficiently trained initially. We mostly chose our training schedule to make training computationally cheaper. After every round of model training, the CAI score \( C_j \) is recomputed on the states stored in the replay buffer. With larger buffer sizes, this can become time consuming. We observed that it is also possible to fully recompute scores only every 1 000 epochs, and otherwise recompute scores only on the newest 1 000 epochs, at only a small loss of performance.

**Exploration Bonus** For the exploration bonus experiments, we clip the scores at specific values (listed in the settings tables under “Maximum Bonus”) to restrict the influence of outliers before multiplying with \( \lambda_{\text{bonus}} \) and adding to the task reward. Moreover, the total reward is clipped to a maximum value of 0 to prevent making states more attractive than reached-goal states.

**Baselines** We list specific hyperparameters for the baselines VIME [33] and PER [58] in Table S5. For VIME [33], we adapted a Pytorch port\(^2\) of the official implementation\(^3\). For PER, we used the hyperparameters as proposed in Schaul et al. [58] and implemented it ourselves. For EBP [59], we adapted the official implementation\(^4\).
