In fundamental papers from 1962 [1, 2], Heffener and Haus showed that it is not possible to construct a linear noiseless amplifier. The implies that the amplifier intrinsic noise sources induce random perturbations on the phase of the incoming optical signal which translates into spectral broadening. To achieve the minimum (quantum noise limited) induced phase fluctuation, and the corresponding minimum spectral broadening, an optimum phase measurement method is needed. We demonstrate that a measurement method based on the heterodyne detection and the extended Kalman filtering approaches an optimum phase measurement in the presence of amplifier noise. A penalty of 5 dB (numerical) and 15 dB (experimental) compared to the quantum limited spectral broadening is achieved. For comparison, the conventional phase measurement method’s penalty exceeds 30 dB for the measurements. Our results reveal new scientific insights by demonstrating that the impact of amplifier noise can be significantly reduced by using the proposed phase measurement method. An impact is envisioned for the phase-based optical sensing system, as optical amplification could increase sensing distance with the minimum impact on the phase.

1. INTRODUCTION

High-power narrow-linewidth lasers are essential for optical fibre sensing, gravitational wave detection, optical space communication and high-capacity optical fibre communication [3–9]. Typically, a high-power performance is achieved by amplifying a low-noise seed laser with a single or several stages of fiber-optic amplification.

Apart from increasing the amplitude, an optical amplifier will induce random fluctuations on the phase of the incoming optical signal. The minimum induced phase fluctuation due to the amplifier noise, denoted by $\Delta \phi_{ql}$, is a consequence of Heisenberg’s uncertainty principle [1, 2]. Moreover, to reach the minimum value, the detector must measure photon number and phase with the same relative uncertainties as those introduced by the amplifier, i.e. optimum detector [1, 2]. As the optical amplifier reduces the signal-to-noise-ratio of the incoming signal, the magnitude of $\Delta \phi_{ql}$ is inversely proportional to it. The random fluctuation of the optical phase, $\Delta \phi_{ql}$, will translate into minimum spectral broadening denoted by $\Delta \nu_{ql}$. For the applications of high-power narrow-linewidth laser in optical sensing and communication increasing the laser’s spectral width translates into system performance degradation, and it should therefore be kept at its minimum.

In order to quantify the impact of the amplifier noise, a measurement of the optical phase and the corresponding spectral width, with and without the optical amplification, and the comparison to the quantum limits $\Delta \phi_{ql}$ and $\Delta \nu_{ql}$ is needed. A practical optimum phase measurement method is needed to approach $\Delta \phi_{ql}$ and $\Delta \nu_{ql}$ and thereby minimize the impact of the amplifier noise.

So far, the approach for quantifying the impact of amplifier noise has been based on the measurement of the phase power...
spectrum density (PSD) before and after the amplification [9–15]. However, the reported experimental results do not fully agree, and are even contradictory, in some cases. What makes the measurements challenging is that the impact of the amplifier noise is mostly visible at high frequencies (>10MHz) of the phase PSD and for low input signal power levels. The state-of-the-art optical phase measurement methods, including spectrum analyzers, suffer from the limited sensitivity as well as the limited dynamic and frequency range. This makes it challenging to measure optical phase below the thermal phase noise floor, which typically lies around -150 dB rad²/Hz, and at frequencies exceeding a few MHz. Thus observing and quantifying the impact of amplifier noise requires a highly-sensitive optical phase measurement method. Finally, to fully quantify the impact of the amplifier noise a comparison to the quantum limit $\Delta \phi_{\text{q}}$ is necessary.

In this paper, we investigate the impact of the amplifier noise on the phase fluctuation and the spectral broadening of the incoming optical signal, as a function of the input signal power into the amplifier, and compare it to the quantum limits. For measuring the optical phase, a heterodyne receiver in a combination with the extended Kalman filter is proposed. The phase measurement method is a practical implementation of the theoretically optimal phase measurement in the presence of amplifier noise. We demonstrate a highly accurate phase measurement resulting in a penalty of 5 dB (numerically) and 15 dB (experimentally) compared to the quantum limits. Finally, we show that the commonly employed phase measurement method results in a large penalty compared to the quantum limits for the increasing system bandwidth and decreasing signal power.

The outline of the paper is as follows: In section 2, a theoretically achievable minimum variance of the phase fluctuations, due amplifier noise, is derived for statistically optimum and sub-optimum phase estimation methods. We also implement a numerical simulation model of a coherent heterodyne receiver and make a comparison of the proposed phase estimation methods. In section 3, the impact of amplifier noise on the phase PSD is experimentally investigated. Finally, in section 4, the main findings are summarized and the impact of results is discussed.

2. THEORETICAL AND NUMERICAL INVESTIGATIONS

A. Amplifier induced amplitude and phase fluctuations

We start by considering a linear amplifier followed by an ideal which typically lies around -150 dB rad²/Hz, and at frequencies exceeding a few MHz. Thus observing and quantifying the impact of amplifier noise requires a highly-sensitive optical phase measurement method. Finally, to fully quantify the impact of the amplifier noise a comparison to the quantum limit $\Delta \phi_{\text{q}}$ is necessary.

The uncertainties in the output photon number, $\Delta n_{\text{out}}$, and the phase, $\Delta \phi_{\text{out}}$, are caused by the noise in the amplifier itself and the receiver. Since the aforementioned sources of uncertainties are uncorrelated, the uncertainties in the number of photons and the phase of the output photon stream can be expressed as:

$$\Delta n_{\text{out}}^2 = \Delta n_{\text{in}}^2 + \Delta n_{\text{a}}^2$$
$$\Delta \phi_{\text{out}}^2 = \Delta \phi_{\text{in}}^2 + \Delta \phi_{\text{a}}^2$$

where $\Delta n_{\text{in}}^2$, $\Delta n_{\text{a}}^2$, $\Delta \phi_{\text{in}}^2$ and $\Delta \phi_{\text{a}}^2$ are the photon number and the phase uncertainties associated with the amplifier and the receiver, respectively. The input–output photon number and phase uncertainties are related by [1]:

$$\Delta n_{\text{out}}^2 = G \Delta n_{\text{in}}^2$$
$$\Delta \phi_{\text{out}}^2 = \Delta \phi_{\text{in}}^2$$

We impose the requirement that the receiver photon number–phase uncertainty takes its minimum value: $\Delta n_{\text{in}} \Delta \phi_{\text{in}} = 1/2$. Using Eq. (3), (4), (5) and (6), the following expression for the photon number–phase uncertainty of the input photon stream is obtained:

$$\Delta n_{\text{in}}^2 \Delta \phi_{\text{in}}^2 = \frac{1}{G^2} \left[ \Delta n_{\text{in}}^2 \Delta \phi_{\text{in}}^2 + \frac{1}{4} \frac{\Delta \phi_{\text{a}}^2}{\Delta n_{\text{in}}} \frac{\Delta \phi_{\text{in}}}{\Delta \phi_{\text{a}}} \left( \frac{\Delta n_{\text{a}}^2}{\Delta \phi_{\text{in}}} + 2 \frac{\Delta n_{\text{in}}^2}{\Delta \phi_{\text{a}}} \right) \right]$$

We are interested in minimizing the the product: $\Delta n_{\text{in}}^2 \Delta \phi_{\text{in}}^2$. It is observed from Eq. (7) that $x = \Delta n_{\text{a}} / \Delta \phi_{\text{a}}$ is a degree of freedom over which the minimization can be performed, i.e. finding a value of $\Delta n_{\text{in}} / \Delta \phi_{\text{in}}$ for which $\Delta n_{\text{in}}^2 \Delta \phi_{\text{in}}^2 / dx = 0$. Physically, this corresponds to finding a receiver that would minimize the input photon number–phase uncertainty.

The outcome of the minimization of $\Delta n_{\text{in}}^2 \Delta \phi_{\text{in}}^2$ with respect to $\Delta n_{\text{in}} / \Delta \phi_{\text{in}}$ is that the ratio of uncertainties between the receiver and the amplifier needs to be matched: $\Delta n_{\text{a}} / \Delta \phi_{\text{a}} = \Delta n_{\text{in}} / \Delta \phi_{\text{in}}$ [1].

Inserting, this condition in Eq. (7) and requiring that the input photon stream photon number–phase uncertainty is minimal: $\Delta n_{\text{in}} \Delta \phi_{\text{in}} = 1/2$, the minimum photon number – phase uncertainty, due to the amplifier noise, becomes:

$$\Delta n_{\text{a}} \Delta \phi_{\text{a}} = \frac{G - 1}{2}$$

Next, we determine the uncertainty in photon number, $\Delta n_{\text{a}}$, and the phase, $\Delta \phi_{\text{a}}$. The output of the amplifier is expressed as a coherent superposition of the amplified signal and the amplifier noise:

$$E_{\text{out}}(t) = \sqrt{P_{\text{in}}} \cos(\omega_0 t + \phi_0) + n_{\text{a}}(t)$$

where $P_{\text{in}} = GP_{\text{in}}, \phi_0$ is a constant phase shift (can be set to zero for the convenience), $t$ denotes time, $P_{\text{in}}$ and $\omega_0$ are the inputs signal power and angular frequency, respectively. $n_{\text{a}}(t)$ is a noise term, added by the amplifier, with a zero mean Gaussian distribution and variance (noise power) $P_{\text{a}}$. Applying a receiver, that acts as a narrow-band filter tightly centered around $\omega_0$, on $E_{\text{out}}(t)$, the receiver output can be expressed as [16]:

$$E_{\text{out}}(t) = \sqrt{P_{\text{in}}} \cos(\omega_0 t + \phi_0) + n_{\text{a}}(t)$$

where $P_{\text{in}} = GP_{\text{in}}, \phi_0$ is a constant phase shift (can be set to zero for the convenience), $t$ denotes time, $P_{\text{in}}$ and $\omega_0$ are the inputs signal power and angular frequency, respectively. $n_{\text{a}}(t)$ is a noise term, added by the amplifier, with a zero mean Gaussian distribution and variance (noise power) $P_{\text{a}}$. Applying a receiver, that acts as a narrow-band filter tightly centered around $\omega_0$, on $E_{\text{out}}(t)$, the receiver output can be expressed as [16]:
The fluctuation in the number of photons is then expressed as:

\[ \Delta_P^2 = \frac{P_0}{2P_N} \]  

where \( \frac{P_0}{2P_N} \) and \( \phi_0(t) \) are slowly-varying (random) functions of time [16], i.e. fluctuations in the amplitude and phase. Determining the variance of \( P_0(t) \) and \( \phi_0(t) \) requires a method for estimating the amplitude and the phase from \( E_r(t) \). Narrow-band filtering ensures high SNR and an accurate phase estimation is then obtained using [16]:

\[ \phi_a^{est} = \tan^{-1} \left[ \frac{I_r(t)}{\sqrt{P_0^2 + I_r(t)}} \right] \]  

where \( I_r(t) \) and \( I_r(t) \) are in the quadrature and in-phase components of \( E_r(t) \). A more practical and thereby implementable approach, as well as equal in performance to Eq. (11), is obtained using [17]:

\[ \phi_{tan}^{est} = \arg \left[ (E_{out}(t) + jH\{E_{out}(t)\})e^{-j\omega_0 t} \right] = \arg \left[ (1 + jQ)e^{-j\omega_0 t} \right] = \tan^{-1} \left( \frac{Q}{I} \right) \]  

where \( H\{ \cdot \} \) denotes Hilbert transform. Using Eq. (11) or (12), the resulting minimum phase fluctuation (standard deviation) due to the amplifier noise can then be computed to as [16]:

\[ \Delta \phi_a = \sqrt{\frac{P_0N}{2P_N}} \]  

Similarly, the signal power of \( E_r(t) \) can be estimated using [16]:

\[ P_s^{est} = \left( \sqrt{I_r} + I_c(t) \right)^2 + I_s^2(t) = \]  

or by applying:

\[ P_{est} = E[|E_{out}(t) + jH\{E_{out}(t)\}|^2] \]  

where \( E[\cdot] \) is an expectation operator. Using Eq. (14) or (15), the resulting minimum power fluctuation of due to the amplifier noise becomes [1]:

\[ \Delta P_s = \sqrt{2P_0P_N} \]  

The fluctuation in the power, \( \Delta P \), needs to be related to the fluctuations in the photon number \( \Delta n_a \). Converting the fluctuations in the output photon stream energy \( \Delta E = h\nu \Delta n_a \) to the fluctuations in the power is obtained by multiplying \( \Delta E \) with the receiver bandwidth (2B): \( \Delta P = \Delta E = h\nu \Delta n_a 2B = \sqrt{2P_0P_N} \). The fluctuation in the number of photons is then expressed as:

\[ \Delta n_a = \frac{\sqrt{P_0P_N}}{h\nu 2B} \]  

where the signal-to-noise-ratio (SNR) is defined as: \( P_s/\nu(G - 1)B \) and \( N_p \) denotes the mean number of photons.

We would like to stress that the limit for the minimum phase fluctuation in Eq.(19) assumes that: 1) input signal to the amplifier contains a single frequency and a constant phase and 2) the power spectrum density of the amplified signal is confined to a relatively narrow band in the neighborhood the signal frequency. The second condition can be assured by having a receiver that performs an ultra narrow-band filtering or by having a sufficiently high input signal power to the amplifier which translates into high signal-to-noise (SNR) ratio. However, for many practical applications within optical metrology and transmission, a relatively large receiver bandwidth is needed (up to a few GHz) and the input signal power to the amplifier may be low. Finally, the first condition is hard to satisfy in practice as the input to the amplifier is provided by a laser source that has a time-varying phase (phase noise) which translates into spectral broadening characterized by a spectral width. Under those aforementioned practical conditions, we now need to determine the minimum phase fluctuation due to amplifier noise.

As the input to the optical amplifier is provided by a laser source, \( \phi_0 \) in Eq. (9) is not a constant but a time-varying function, i.e. \( \phi_0(t) \). The minimum fluctuation of \( \phi_0(t) \) is governed by the amplified spontaneous emission within the laser cavity (quantum noise) and can be approximated by a Wiener process [18]:

\[ \frac{d\phi_0}{dt} = \sqrt{\kappa} \Gamma(t) \]  

where \( \kappa \) is the rate of phase diffusion and is related to laser coherence time \( \tau_c \). \( \Gamma(t) \) is a Langevin noise source with Gaussian distribution. It has a zero mean and a delta correlation function. The PSD of a laser signal with a time-varying phase described by Wiener process has a Lorentzian shape and is centered around \( \omega_0 \). The spectral width, \( \Delta \nu_c \), is inversely proportional to coherence time, \( \tau_c \) and can be computed using:

\[ \Delta \nu_c = \left( \frac{\tau_c}{f_0^\infty S(v)dv} \right)^2 \]  

\[ \tau_c = \left[ \frac{\int_0^\infty |U^*(t)(t)U(t)(t+\tau)|^2 dt}{\int_0^\infty (U^*(t)U(t))^2 dt} \right]^{-\frac{1}{2}} \]  

where \( S(v) \) is the PSD of the laser output, \( \tau_c \) is the corresponding coherence time and \( U(t) = \sqrt{P_0(t)}e^{j(\omega_0 t + \phi_0(t))} \). The output of the amplifier is expressed:

\[ E_{out}(t) = \sqrt{P_0(t)}e^{j(\omega_0 t + \phi_0(t))} + n_a(t) \]  

where the minimum noise power (variance) of \( n_a(t) \) is expressed by Eq. (18). Given the output signal from the amplifier, \( E_{out}(t) \), in Eq. (22), the phase estimation method in Eq. (11) and (12) are no longer optimum for \( B > \Delta \nu_c \). However, if we apply the phase estimation given by Eq. (11) and (12), the corresponding limit is still governed by Eq. (19), but it does not represent the lower limit. Therefore, in order to obtain a minimum variance on the phase fluctuation, an optimum phase estimation method that would result in a minimum phase fluctuation needs to be found.
The statistically optimum phase estimate is found as a solution to the following Maximum a Posteriori (MAP) phase estimation problem [19–21]:

$$\phi_{MAP}(t) = \arg\max_{\phi} p(\phi(t)|E_{out}(t))$$

where $\phi(t)$ represents various phase evolutions (different trail phases). $p(\cdot)$ and $p(\cdot|\cdot)$ denote the marginal and the conditional probability densities, respectively.

The solution to Eq. (23) results in the minimization of the mean square error between the "true" and the estimated phase $\phi_0(t)$ and $\phi_{MAP}(t)$, respectively, i.e., $E[(\phi_0(t) - \phi(t))^2]$ is minimized when $\phi(t) = \phi_{MAP}(t)$. The minimum phase fluctuation due to the amplifier noise, when employing the MAP phase estimator, is then expressed as:

$$\Delta \phi_{MAP} = \sqrt{E[(\phi_0(t) - \phi_{MAP}(t))^2]}$$

B. Proposed close-to-optimal receiver architecture

In this section, we consider a practically implementable receiver architecture that can enable minimum phase fluctuation due to the amplifier noise and approach Eq. (25). The proposed receiver architecture, described below, employs heterodyne coherent detection in combination with digital signal processing for phase estimation.

We assume that the output of the laser source is passed through an optical amplifier and combined with an ideal Local Oscillator (LO) laser ($\kappa = 0$) in a 3-dB coupler. The amplifier has a noise power $P_N$ specified by Eq. (18). The beat signal is then detected by the shot-noise limited balanced receiver and sampled by an analogue–to–digital converter. The sampled beat signal is expressed as:

$$y[k] = 2R \sqrt{P_s P_{LO}} \cos(\Delta\omega n \tau_s + \phi_0[k] + n_b[k] + n_r[k]}$$

where $k = 1, ..., K$ is an integer representing the discrete-time, $P_s = GP_0$ and $P_{LO}$ are the power of the signal, after the amplifier, and the LO laser, respectively. $R$ is the responsivity of photodetector assumed to be 1. $\Delta\omega$ is the difference angular frequency between the signal and the LO laser, $\tau_s$ is the sampling time, $\phi_0[k]$ is the laser source time–varying phase modelled as a Wiener process with a phase diffusion constant $\kappa^2 = 2\pi\Delta\nu_{FWHM}\tau_s$. The shot and the beat noise terms $n_b[k]$ and $n_r[k]$ are modelled as Gaussian noise sources with zero mean and variances: $\sigma_{shot}^2 = 2qR(P_{LO})B$ and $\sigma_{b}^2 = 4P_sG(G-1)B$, respectively [22], $q$ is the elementary charge and $B$ is the 3-dB bandwidth of the balanced receiver.

Given the samples $y[k]$, the theoretically optimum phase estimation is obtained by solving the MAP problem in Eq. (23). For the specific case of $y[k]$ described by Eq. (28), the exact solution to Eq. (23) does not exist. The reason is the nonlinear relationship between $y[k]$ and the time–varying phase $\phi_0[k]$. However, the Bayesian filtering techniques such as the Unscented and Extended Kalman Filter can provide a good approximation to the MAP phase estimation problem [23].

In this paper, we employ the proposed EKF based state-space framework for the estimation of the phase from the sampled beat signal $y[k]$ [17]. Within the framework, we explore correlation properties of $\phi_0[k]$ for tracking and estimation purposes, while ignoring the contribution from the amplifier noise since there is no correlation between $\phi_0[k]$ and $n_b[k]$. The estimated phase will be denoted as $\phi_{EKF}(k)$. For a comparison reasons, we also apply the phase estimation method expressed by Eq. (12) and denote the estimated phase by $\phi_{tan^{-1}}[k]$. Using the aforementioned phase estimators, the phase fluctuation due to the amplifier noise is then computed as a sample standard deviation:

$$\Delta\sigma_{EKF/tan^{-1}} = \sqrt{\frac{1}{K} \sum_{k=1}^{K} (\phi_0[k] - \phi_{EKF/tan^{-1}}[k])^2}$$

C. Numerical results

In Fig. 1, phase fluctuation is plotted as a function of input signal power using Eq. (19) ($\Delta\phi_0$), (25) ($\Delta\phi_{MAP}$) and (29) for $\phi_{EKF}[k]$ ($\Delta\sigma_{EKF}$) and $\phi_{tan^{-1}}[k]$ ($\Delta\sigma_{tan^{-1}}$), respectively. We consider receiver bandwidth $B$ of 1 GHz and 5 GHz. The laser linewidth $\Delta\nu_{FWHM}$ is chosen to be 10 Hz. The reason for choosing a low, yet realistic, linewidth is to minimize the penalty induced by the extended Kalman filter and see how close we can operate to the limit expressed by Eq. (25).
It should be noticed from Fig. 1 is that the minimum phase fluctuation $\Delta \phi_{\text{MAP}}$ is significantly lower compared to $\Delta \phi_a$ for $B = 5 \text{ Hz}$. As the bandwidth is reduced to $B = 1 \text{ GHz}$, $\Delta \phi_{\text{MAP}}$ still provides a lower phase fluctuation for the input signal power levels up to 20 dBm.

The phase fluctuation $\Delta \phi_{\text{EKF}}$ exhibits only 5 dB of penalty compared to the theoretically achievable limit given by $\Delta \phi_{\text{MAP}}$ and does not increase as the bandwidth is increased from 1 GHz to 5 GHz. The major part of the penalty is due to the variance of the beat term, $n_b[k]$, being 4 times larger than the variance of $n_a[k]$. In general, the results for $\Delta \phi_{\text{EKF}}$ illustrate the robustness of the EKF method for estimating the phase in the presence of the amplifier noise. Finally, the phase fluctuation $\Delta \phi_{\text{tan}^{-1}}$ is within 1 dB of the theoretical limit given by $\Delta \phi_a$. The penalty is due to the enhanced variance of the beat term. Also, it should be noted that both $\Delta \phi_a$ and $\Delta \phi_{\text{tan}^{-1}}$ increase for increasing bandwidth as expected.

From the practical point of view, quantifying the impact of the amplifier noise in terms of phase fluctuation is very challenging. Moreover, expressing the impact of the amplifier noise in terms of the spectral broadening is more informative. Next, we therefore consider the impact of amplifier noise on the phase PSD.

In Fig. 2, the PSD of the estimated phase, using the EKF and Eq. (12) ($\tan^{-1}$), is plotted as a function of frequency. We also plot a reference PSD computed using $\phi_k[k]$ directly. The input signal power $P_s$ is varied from -20 dBm to -5 dBm. Using the phase estimation based on Eq. (12), the impact of the amplifier noise is clearly observable. The amplifier noise results in a horizontal noise floor which increases as $P_s$ is decreased.

The shape of the PSD computed using the EKF–based phase estimation method resembles, to a high degree, the reference spectra. The impact of the amplifier noise is visible as the deviation from the reference spectrum is observed. However, the deviation is not as nearly as large as when Eq. (12) is employed for phase estimation. This illustrates the efficiency of the phase estimation method based on the EKF to filter out the amplifier’s contribution to the phase fluctuation.

Next, we compute the spectral broadening, as a function of the input signal power $P_s$. The theoretical values are obtained by inserting Eq. (19) and (25) in (27) and are denoted by $\Delta \nu_a$ and $\Delta \nu_{a,\text{MAP}}$, respectively. Given the estimated phase $\phi_{\text{EKF}}[k]$ and $\phi_{\text{EKF},\text{int.}}[k]$, we first compute the corresponding spectral width using the numerical integration of the autocorrelation function in Eq. (21). The obtained values are then subtracted from the reference spectral width, $\Delta \nu_0$, computed for the phase $\phi_0[k]$. The corresponding spectral widths are denoted by $\Delta \nu_{a,\text{EKF},\text{int.}}$ and $\Delta \nu_{a,\text{tan}^{-1},\text{int.}}$, respectively.

We also convert the sample standard deviation $\sigma_{\text{EKF}}$ and $\sigma_{\text{tan}^{-1}}$ into spectral broadening using Eq. (27). The corresponding spectral broadening are denoted by $\Delta \nu_a^{\text{EKF}}$ and $\Delta \nu_{a,\text{tan}^{-1}}$, respectively. The agreement between $\Delta \nu_a^{\text{EKF},\text{int.}}$ and $\Delta \nu_a^{\text{EKF}}$ indicates that the error induced by the numerical integration is small. A penalty of approximately 3 dB is observed between $\Delta \nu_a^{\text{tan}^{-1},\text{int.}}$ and $\Delta \nu_a^{\text{tan}^{-1}}$. A possible reason is that the $\phi_{\text{tan}^{-1}}[k]$ contains a higher degree of noise compared to $\phi_{\text{EKF}}$, which makes the numerical differentiation becomes less accurate.

It should be emphasized that the spectral broadening $\Delta \nu_a^{\text{EKF},\text{int.}}$ is significantly below $\Delta \nu_a$ and $\Delta \nu_{a,\text{tan}^{-1}}$. Finally, a penalty of only 5 dB is observed between $\Delta \nu_a^{\text{EKF},\text{int.}}$ and a minimum spectral broadening $\Delta \nu_{a,\text{MAP}}$.

### 3. Experimental Results

An experimental set–up for investigating the impact of the amplifier noise on the phase fluctuation and the corresponding spectral broadening is shown in Fig. 4. We employ two similar fiber lasers, one as a signal, and the other as the LO source. Both lasers have matching phase noise performances. The lasers use a fiber Bragg grating cavity to produce an output beam operating in a single mode. The maximum output power measured di-
Fig. 4. Experimental set-up for investigating the impact of amplifier noise on the phase fluctuation of the incoming signal.

Fig. 5. Experiments: Phase power spectral density as a function of frequency using different phase estimation methods and input power to the EDFA.

rectly from the cavity is -2 dBm. The laser cavity is then followed by a master oscillator fiber amplifier (MOPA) to boost the signal power level up to 15 dBm. The signal and LO lasers are set at 1550.08 nm, with a frequency offset of approx. 200 MHz, in order to minimize the impact of the DC response of the electronics at the receiver.

The lasers modules can output the signal directly after the cavity and the MOPA, see Fig. 4. The output signals right after the cavity give us the opportunity to measure a reference phase PSD and its corresponding spectral width. Finally, after the signal and the LO laser modules (cavity plus MOPA), we add an additional Erbium Doped fiber amplifier (EDFA). The ED-FAFs are commercial dual-stage low-noise pre-amplifiers (noise figure approx. 5 dB) operated at maximum pump currents, corresponding to a target output power of approx. 15 dBm. Variable optical attenuators placed before the EDFAs allow to tune the input power \( P_{in} \) and thereby to vary the SNR to the receiver.

The two optical carrier are then combined in a 50:50 coupler and injected into the two inputs of a 43-GHz balanced photodetector used for coherent signal detection. A second set of VOAs at each photodetector inputs allow to keep the input power into each photodetector arm constant to \( P_{PD} = 0.64 \) mW.

The photodetector is followed by a digital storage oscilloscope (DSO) performing the analog-to-digital (A/D) conversion. The DSO has a bandwidth of 13 GHZ and operates at a sampling rate of \( F_s = 40 \) GHz. The sampled signal is then stored for offline signal processing. The memory of the sampling scope allows us to store \( K = 256 \times 10^6 \) samples. This results in the minimum PSD frequency of \( f_{min} = F_s/K = 156 \) Hz, and a maximum PSD frequency of \( f_{max} = F_s/2 = 20 \) GHz. Similarly to the numerical results, we use the EKF and Eq. (12)(\( \tan^{-1} \))-based phase estimation methods.

In Fig. 5, the phase PSD is shown as a function of frequency. To obtain the reference phase PSD, the laser outputs (signal and LO) right after the cavities are measured. We use the EKF method for the phase measurement due to its higher accuracy. Assuming equal contributions from the signal and the LO laser, the obtained phase PSD is divided by a factor of 2. The reference
We have shown that a heterodyne signal detection in combination with the extended Kalman filter is a realization of a practical optimum phase measurement method in the presence of amplifier noise. The proposed method achieves a relatively small penalty compared to the quantum limit. Most importantly, a significant reduction of the impact of the amplifier noise has been demonstrated, both numerically and experimentally, compared to when using a widely deployed (sub-optimal) phase estimation method.
