Abstract

Safely deploying machine learning models to the real world is often a challenging process. Models trained with data obtained from a specific geographic location tend to fail when queried with data obtained elsewhere, agents trained in a simulation can struggle to adapt when deployed in the real world or novel environments, and neural networks that are fit to a subset of the population might carry some selection bias into their decision process. In this work, we describe the problem of data shift from a novel information-theoretic perspective by (i) identifying and describing the different sources of error, (ii) comparing some of the most promising objectives explored in the recent domain generalization and fair classification literature. From our theoretical analysis and empirical evaluation, we conclude that the model selection procedure needs to be guided by careful considerations regarding the observed data, the factors used for correction and the structure of the data-generating process.

1 Introduction

One of the most common assumptions for machine learning models is that the training and test data are independently and identically sampled (IID) from the same distribution. In practice, this assumption does not hold in many practical scenarios (Bengio et al. 2020). A machine learning model trained to recognize land usage from satellite images using pictures from the early 2000s may struggle to recognize the style of modern architectures (Christie et al. 2018), data collected on a limited set of hospitals may not be representative of the variation introduced by the use of different machines or procedures (Zech et al. 2018; Beede et al. 2020). Other kinds of distribution shifts are more subtle and difficult to recognize despite having a noticeable impact on the model’s predictive performance. Examples include under-represented or over-represented population groups (Popejoy & Fullerton 2016; Buolamwini & Gebru 2018) or biased annotations collected from crowd-sourcing services (Zhang et al. 2017; Xia et al. 2020).

Different approaches in literature address these issues by using some external source of knowledge such as domain or environment annotations (Wang & Deng 2018), protected attributes (Mehrabi et al. 2019) or sub-population groups (Santurkar et al. 2020) to reduce bias and minimize the model error outside of the training distribution. Despite the progress in the field of domain generalization literature, Gulrajani & Lopez-Paz (2020) has shown that the effectiveness of some of the most common algorithms heavily relies on the hyper-parameter tuning strategy, revealing limitations of

Preprint. Under review.
examined models when compared to a more traditional empirical risk minimization strategy. One of the major issues behind this observed behavior is a lack of clarity and applicability for the underlying assumptions regarding the problem statement and the data-generating process (Zhao et al., 2019; Rosenfeld et al., 2020; Mahajan et al., 2020).

With this work, we aim to present a new perspective on the problem to analyze and clarify the fundamental differences between some of the most common approaches by:

1. Introducing a novel information-theoretical framework to describe the problem of distribution shift and connecting it to the out-of-distribution error and its components (section 2).
2. Analyzing three main families of objectives and describing some of their guarantees and assumptions (section 3).
3. Showing that the effectiveness of different criteria is determined by the structure of the underlying data-generating process other than the chosen approximations (section 5).

The analysis of the independence, sufficiency, and separation criteria reveals that some of the most popular models can systematically fail to reduce the out-of-distribution error even for simple datasets. No unique objective is simultaneously optimal for every problem, but additional insights and knowledge about the selection procedure can help to mitigate the bias.

2 Framework and Problem Statement

Consider $x$ and $y$ as the features and targets respectively with joint density $p(x, y)$ for the predictive problem of interest. Let $t$ be a binary random variable representing which data is selected for training ($t = 1$) and which is not ($t = 0$). We will refer to $p(x, y | t = 1)$ as the joint Training distribution and $p(x, y | t = 0)$ as the Test distribution that are induced by the selection $t$. Throughout the paper, we will consider selections $t$ that can be expressed as a function of the features $x$, targets $y$, independent noise $\epsilon$ and other variables $e$, which represent other factors that are affecting the data collection procedure (e.g. geographic location, time intervals, population groups).

Let $q(y | x)$ represent a learnable model for the predictive distribution $p(y | x)$. We use the Kullback-Leibler divergence to express the Training and Out-Of-Distribution (OOD) error respectively:

$$D_{KL}(p_{y|x}^{t=1}||q_{y|x}) := D_{KL}(p(y | x, t = 1) || q(y | x)), \quad (1)$$

$$D_{KL}(p_{y|x}^{t=0}||q_{y|x}) := D_{KL}(p(y | x, t = 0) || q(y | x)). \quad (2)$$

2.1 Characterizing Distribution Shift

The effect of the selection can be quantified by considering the mutual information between the features-target pair $xy$ and the selection variable $t$, which can be also expressed as a Kullback-Leibler divergence: $I(xy; t) = D_{KL}(p(x, y | t) || p(x, y))$. This measure of distribution shift intuitively represents how many bits the selection variable carries about the joint distribution of targets and features or, equivalently, how much the joint density $p(x, y)$ has changed as a result of the selection.

Using the chain rule of mutual information, one can express the distribution shift as the sum of two separate components:

$$I(xy; t) = I(x; t) + I(y; t|x), \quad (3)$$

which can be interpreted as the amount of covariate shift (Shimodaira, 2000) and concept shift (Widmer & Kubat, 1996; Moreno-Torres et al., 2012), respectively. These two quantities refer to the changes in the predictive distribution $p(y | x)$ and the marginal features distribution $p(x)$ respectively, which add up to represent the changes in the joint distribution.

Whenever the data selection is perfectly IID, the selection variable can be expressed as a function of some independent noise ($t = f(\epsilon)$) and the corresponding distribution shift $I(xy; t)$ is zero. On the other hand, if the data collection procedure has been influenced by other factors, we do not have such a guarantee, even when the selection does not depend on features and targets directly ($t = f(e, \epsilon)$).

---

1 Further details regarding the convention used for conditional KL-divergence can be found in appendix A.
Train and OOD error relate to the concept shift via the following expression:

**Proposition 1.** For any model \( q(y|x) \) and \( \alpha := \min\{p(t = 0), p(t = 1)\} \):

\[
D_{KL}(p_{y|x}^{t=1}||q_y|x) + D_{KL}(p_{y|x}^{t=0}||q_y|x) \geq \frac{1}{1 - \alpha} I(y; t|x),
\]

As a consequence, whenever the selection induces concept shift \( I(y; t|x) > 0 \), any sufficiently flexible model \( \hat{q}(y|x) \) trained using a maximum likelihood approach must incur in strictly positive OOD error. Intuitively, whenever the selection induces a change in the predictive distribution \( p(y|x) \neq p(y|x, t = 1) \) fitting the model to the training distribution will incorporate the selection bias into the model prediction, necessarily resulting in errors when evaluated on the test distribution, as shown in the example reported in Figure 1.

### 2.2 A Representation-Learning-based Approach

We first introduce a latent representation \( z \) and parametrize the model \( q(y|x) \) with an encoder \( q(z|x) \) and a latent classifier\(^2\) \( \hat{q}(y|z) \).

\[
q(y|x) = \mathbb{E}_{z \sim q(z|x)} [q(y|z = z)].
\]

The effect of the introduction of a latent representation can be observed by expressing the training and OOD error as a function of the encoder and the classifier.

**Proposition 2.** For any encoder \( q(z|x) \) and classifier \( q(y|z) \):

\[
D_{KL}(p_{y|x}^{t=1}||q_y|x) \leq I_{t=1}(x; y|z) + D_{KL}(p_{y|x}^{t=1}||q_y|x),
\]

\[
D_{KL}(p_{y|x}^{t=0}||q_y|x) \leq I_{t=0}(x; y|z) + D_{KL}(p_{y|x}^{t=0}||q_y|x).
\]

The two terms \( I_{t=1}(x; y|z) \) and \( I_{t=0}(x; y|z) \) represent the amount of predictive information that is lost by encoding the features \( x \) into \( z \) on train and test distribution respectively, while \( D_{KL}(p_{y|x}^{t=1}||q_y|x) \)

\(^2\)The name classifier will be used for convenience to express both classification and regression problems.

\(^3\)The expressions in equations 6 and 7 hold with equality for deterministic encoders as shown in appendix B.
and $D_{KL}(p_t=1 || q_{y|x})$ refer to the train and OOD error when using $z$ instead of the original observations as the predictive features, which will be referred to as latent training error and latent out of distribution error respectively. Latent OOD error and the test information loss capture two intrinsically different kinds of error. The former indicates the discrepancy between the model $q(y|z)$ and the test predictive distribution $p(y|z, t = 0)$, while the latter represents the increase in the prediction uncertainty as a result of the encoding procedure.

2.3 Latent OOD error

Guaranteeing that $q(y|z)$ is not confident about the wrong prediction requires minimizing the latent OOD error, which represents how far the classifier model is from the test latent predictive distribution. We can show that the Jensen-Shannon divergence between the two distributions is upper-bounded by a monotonic function of the latent training error and the amount of concept shift in the latent space (latent concept-shift $I(y; t|x)$):

**Proposition 3.** For any $q(y|x)$, $q(y|z)$ and any representation $z$ that satisfies $p(z = z|t = 0) > 0$ and $p(z = z|t = 1) > 0$:

$$
\left( \sqrt{\frac{1}{2\alpha} I(y; t|z = z)} + \sqrt{\frac{1}{2} D_{KL}(p_t=1 || q_{y|x})} \right)^2 \geq D_{JSD}(p_t=0 || q_{y|x}).
$$

(8)

Whenever the Jensen-Shannon divergence between the test predictive distribution $p(y|z, t = 0)$ and the classifier $q(y|z)$ is small, the Latent OOD error (measured in terms of KL-divergence) must also be small at least for the regions that have positive probability according to both train $p(x|t = 1)$ and test $p(x|t = 0)$ data distributions (Figure 1a). Since the train predictive distribution $p(y|x, t = 1)$ is not defined for $x$ that have zero probability on the train distribution, we have no guarantees regarding the model predictions in those regions unless other inductive biases are considered.

The left hand side of the expression in proposition 3 can be minimized by addressing $I(y; t|z)$ and $D_{KL}(p_t=1 || q_{y|x})$ with respect to the encoder and classifier respectively. In other words, we can minimize the distance between the classifier and the latent test predictive distribution by simultaneously fitting $q(y|z)$ to the train predictive distribution $p(y|z, t = 1)$ and minimizing the latent concept shift induced by the encoder $q(z|x)$. When the latent concept shift and latent OOD error approach zero, the latent train predictive distribution $p(y|z, t = 1)$ approaches the true (unselected) predictive distribution $p(y|z)$, and so does the modeled classifier $q(y|z)$. In this scenario, the only source of OOD error is the information that has been lost in the encoding procedure.

2.4 Minimizing the information loss

Combining the results from propositions 1 and 2 we can infer that reducing the latent OOD error necessarily requires the representation to discard some train predictive information ($I_{t=1}(z; y|x)>0$).

This is because a lossless encoder $q(z|x)$ together with the optimal latent classifier $q(y|z)$ would result in an overall model $q(y|x)$ that achieves zero training error, and, therefore, positive latent OOD error (proposition 1). However, discarding information without any specific criteria can even increase the latent concept shift, as shown by the example in figure 1b.

As the amount of information that is lost in the encoding procedure is one of the two components of the OOD error (equation 7), we will consider objectives that discard the minimal amount of information required to reduce the latent concept shift. Since only the selected training distribution is available at training time, we will consider objectives that maximize the amount of predictive training information $I_{t=1}(y; z)$ or, equivalently, minimize the KL-divergence between the training predictive distribution $p(y|x, t = 1)$ and the latent classifier model $q(y|z)$:

$$
\min_{q(x|z)} I_{t=1}(y; x) = I_{t=1}(y; x) - \max_{q(x|z)} I_{t=1}(y; z) \leq \min_{q(x|z)} D_{KL}(p_t=1 || q_{y|x})
$$

(9)

2.5 A General Loss function

To summarize, the overall objective is finding the maximally informative representation that minimizes latent concept shift while fitting the latent classifier to the data. This is achieved by (i) matching
the classifier \( q(y|z) \) and the training latent predictive distribution \( p(y|z, t = 1) \), (ii) maximizing the amount of predictive information in the representation, and (iii) minimizing the amount of latent concept shift induced by the representation. The three requirements can be enforced by considering the following loss function:

\[
\mathcal{L}(q_{z|x}, q_{y|z}; \lambda) = D_{KL}(q_{y|z}^{t=1}||q_{y|z}) + \lambda R(q_{z|x}),
\]

(10)
in which, the first term addresses (i) and (ii), while the second term represent a regularization term that acts on the encoder \( q(z|x) \) to minimize latent concept shift \( I(y; t|z) \), following (iii). The hyper-parameter \( \lambda \) defines the trade-off requirements (ii) and (iii).

3 Regularization Criteria

Since only selected data \( (t = 1) \) is accessible at training time, the latent concept shift cannot be computed or minimized directly. The different approaches considered in this analysis make use of a regularization \( R(q_{z|x}) \) that is based on the observation of an additional variable \( e \) which relates to the selection criteria. This variable is usually referred to as domain or environment\(^4\) in the domain adaptation and generalization literature, while the name protected attribute is used in the context of fair classification. We will refer to this variable \( e \) as environmental factors in the following sections.

We analyze three families of criteria proposed in the domain generalization (Koyama & Yamaguchi 2020) and fair classification (Barocas et al. 2018) literature focusing on their underlying assumptions and theoretical guarantees. The different regularization strategies and models can be seen as specific instance of the loss function in equation 10. An empirical comparison between instances of the different criteria can be found in section 5, proofs are reported in appendix B, while the relation between the reported criteria is further discussed in appendix B.8.

3.1 Independence Criterion

Whenever the data selection \( t \) depends exclusively on some variable \( e \) \((t = f(e; \epsilon))\), the most intuitive approach to reduce the latent OOD error is to make the representation \( z \) independent of the environmental factors \( e \). This can be done by minimizing mutual information between \( e \) and \( z \):

\( R(q_{z|x}) := I_{t=1}(e; z) \).

This criterion, known as statistical parity in the fair classification literature (Dwork et al. 2011; Corbett-Davies et al. 2017), aims to remove any environmental information from \( z \) resulting in a representation that satisfies \( p(z|t = 1) = p(z|e, t = 1) \).

Despite the usefulness of this criterion in the fairness and differential privacy literature, enforcing independence does not necessarily reduce the OOD error (Zhao et al. 2019; Johansson et al. 2019). This is because a consistent marginal across different environments does not imply a consistent predictive distribution \( p(y|z, e, t = 1) \neq p(y|z, t = 1) \), and enforcing independence may even increase the latent concept shift and the OOD error (as shown in section 5.3).

3.2 Sufficiency Criterion

Instead of enforcing a property on the marginal feature distribution, one can consider stable properties of the joint distribution of features \( z \) and labels \( y \). The requirement of creating a representation that yields a stable classifier for different values of the environmental factor \( e \) can be captured by the following regularization:

\( R(q_{z|x}) := I_{t=1}(e; y|z) \).

Intuitively minimizing \( I_{t=1}(e; y|z) \) corresponds to minimizing the distance between the predictive distribution \( p(y|e, z, t = 1) \) for each one of the observed environmental conditions. As a result:

**Proposition 4.** Whenever the selection \( t \) is a function of \( e \) and some independent noise \( \epsilon \), the latent concept shift induced by a representation \( z \) of \( x \) must be upper-bounded by \( I(y; e|z) \):

\[
\exists f : t = f(e, \epsilon) \implies I(y; t|z) \leq I(y; e|z).
\]

(11)

In other words, for a given selection \( t \), it is possible to remove the effect of concept shift by enforcing the sufficiency constraint using the variable (or variables) \( e \) that are responsible for that selection.

\(^4\)In contrast with the domain adaptation and generalization literature, we will consider the more general case in which \( e \) is represented by a vector.
The result from proposition 4 is applicable only if the two following conditions are met: (i) a sufficient representation must exist (Koyama & Yamaguchi, 2020); (ii) enforcing sufficiency on the selected train distribution results in sufficiency for the overall joint distribution \( I_{t=1}(y; e|z) = 0 \) (Rosenfeld et al., 2020). Even if assumptions (i) and (ii) are often acceptable in practice, lack of environment variety at training time or direct dependencies between environmental factors and targets (such as in the y-CMNIST dataset in section 5.3) can compromise the effectiveness of the sufficiency criterion. An in depth discussion with a simple example is reported in appendix F.

### 3.3 Separation Criterion

The last family of objectives includes approaches that aim to capture the stability in the latent feature distribution when the target is observed across different environmental conditions \( p(z|y) = p(z|y, e) \). This requirement can be enforced by minimizing the dependency between environmental factors and the representation when the label is observed: \( R(q_{e|x}) := I_{t=1}(e; z|y) \). The resulting separation criterion can be used to identify stable properties of the joint distributions even when the selection \( t \) depends on both targets \( y \) and environmental factors \( e \):

**Proposition 5.** If the selection \( t \) is a function of \( e, y \) and some independent noise \( \epsilon \), the latent concept shift of a representation \( z \) of \( x \) is upper-bounded by the sum of prior-shift \( I(y; t) \) and \( I(e; z|y) \):

\[
\exists f : t = f(e, y, \epsilon) \implies I(y; t|z) \leq I(y; t) + I(e; z|y).
\]

When selection \( t \) and targets \( y \) are marginally independent, proposition 5 guarantees that the latent concept shift of a representation that enforces separation is zero. Furthermore, whenever the marginal distribution \( p(y|t = 0) \) is known, it is possible to adjust the prediction of the latent classifier on the test distribution.

Similarly to the sufficiency criterion, one needs to assume that enforcing separation on the train suffices to guarantee \( I(e; z|y) = 0 \). Although a representation that enforces separation always exists, the effectiveness of the separation criteria depends on the data-generating process, since the requirement could be exclusively satisfied by a constant representation.

### 4 Related work

The problem of distribution (or dataset) shift (Quionero-Candela et al., 2009; Koh et al., 2020) has been explored in different areas in the machine learning literature ranging domain adaptation and generalization (Wang & Deng, 2018) to sub-population shift and fair classification (Mehrabi et al., 2019; Santurkar et al., 2020). Although goals, availability of test features and environments at training time, and data selection criteria (Koh et al., 2020) may differ, most recent approaches focus on extracting features with some desired properties through three different families of objectives.

The independence criterion has been used to find the transformation which minimizes the distance between the distribution of the encoded features across different environments by using adversarial training (Ganin et al., 2016; Xie et al., 2017; Li et al., 2018a), features adjustment (Lum & Johndrow, 2016), kernel methods (Muandet et al., 2013), or variational approaches (Louizos et al., 2016; Moyer et al., 2018; Ilse et al., 2020). Despite the success of the independence criterion, Zhao et al. (2019); Johansson et al. (2019) have shown that enforcing stability of the marginal feature distribution is not sufficient to guarantee generalization.

Li et al. (2018b) extends the independence criterion using adversarial training to create representations that are independent of the environment when the label is observed. The corresponding separation criterion has been explored in the context of fair classification as equalized odds (Hardt et al., 2016) and some tractable relaxations (Darlington, 1971; Woodworth et al., 2017; Chouldechova, 2017).

The idea of considering features that lead to a consistent predictive distribution has been explored in the causality literature (Peters et al., 2016; Magliacane et al., 2018) for linear models as a feature selection criteria. Other work approached the problem in the non-linear case by considering gradients of the classifier (Arjovsky et al., 2019; Koyama & Yamaguchi, 2020; Parascandolo et al., 2020) or penalizing the variance of error (Krueger et al., 2020; Xie et al., 2020) across different environments.

---

*Further details on the re-weighting procedure can be found in appendix B.7.*
Figure 2: Graphical models (a) and error components (b) for the CMNIST, d-CMNIST and y-CMNIST data distributions. (a) Dashed lines are used to underline marginal independence between color c and environment e, while red arrows denote dependencies added to the original CMNIST distribution. (b) Models trained with strong regularization ($\lambda \approx 10^7$) for the three different criteria are compared against the classifiers trained using only color ($p(y|c, t = 1)$), digit ($p(y|d, t = 1)$), picture ($p(y|x, t = 1)$), or prior information ($p(y|t = 1)$). The colors show the proportion of the OOD error (in nats) due to the predictive information loss ($I_{t=0}(x; y|z)$, in orange) and the latent OOD error ($D_{KL}(p_{y|z}||q_{y|z})$, in blue) according to the decomposition in equation 7.

Other relaxations of the sufficiency criterion such as as predictive parity (Chouldechova, 2017) have been considered in the fairness literature.

Despite the promising directions of research, Gulrajani & Lopez-Paz (2020) have shown that the performance of the most popular approaches in the literature strongly depends on the hyper-parameter tuning strategy, underlying the problem of the lack of (i) standardized benchmark procedures and (ii) clarity regarding guarantees and hidden assumptions for the different algorithms. Although the problem of distribution shift has been widely studied in the classic domain generalization literature (Mansour et al., 2009; Schölkopf et al., 2012; Gong et al., 2016), this work aims to characterize the problem from a representation learning and information theoretical perspective, providing different insights and identifying potential issues and benefits of several popular models.

5 Experiments

We evaluate the effectiveness of different criteria presented in section 3 and some of their most popular implementations on multiple versions of the CMNIST dataset (Arjovsky et al., 2019) produced by altering the data-generating process (figure 2a) to underline the shortcomings of different criteria.

The main advantage of using a synthetic dataset is the possibility to estimate the training and out-of-distribution error for the different criteria while directly optimizing their objective. This is possible only when the variables in the data-generating process are discrete and low-dimensional, since direct optimization requires mutual information terms to be computed. As a result, the effect of the different criteria can be observed in isolation, without the influence introduced by the approximations. Further details regarding the direct optimization of the analyzed criteria are reported in appendix D.

5.1 Models and Criteria

The theoretical performance for each criterion is compared against the results obtained by training different models in the literature using neural network architectures to parametrize the encoder $q(z|x)$ and classifier $q(y|z)$. For the comparison, we selected one representative model for each criterion defined in section 3 together with a baseline trained using the Information Bottleneck criterion (Tishby & Zaslavsky, 2015), which does not use any environmental information and blindly discards data-features depending on the regularization strength $\lambda$. The overall comparison includes the following models:
• Variational Information Bottleneck (VIB) (Alemi et al., 2017): a variational approximation of the Information Bottleneck criterion;
• Domain Adversarial Neural Network (DANN) (Ganin et al., 2016): an adversarial model based on a min-max game with discriminator \( d(e|z) \) that is optimized to predict environment information from the representation \( z \) to enforce the Independence criterion;
• Variance-based Risk Extrapolation (VREx) (Krueger et al., 2020): a relaxation of the Sufficiency criterion based on the minimization of the training error variance across the different environments;
• Conditional Domain Adversarial Neural Network (CDANN) (Li et al., 2018b): an adversarial approximation of the Separation criterion in which, analogously to DANN, a discriminator tries to predict the environment when the representation \( z \) and the true label \( y \) are given.

For a better comparison, all the models use the same encoder and classifier neural network architectures. Each model has been trained by slowly increasing the regularization strength after an initial pre-training with \( \lambda = 0 \). Further details regarding the neural network architectures, objectives, optimization, and specific hyper-parameters can be found in appendix E.

5.2 Evaluation metric

The measure of OOD error, information Loss and latent OOD error reported in figure 2b have been computed directly by considering a discrete version of the analyzed datasets. For neural network models, on the other hand, the training and OOD error defined in section 2 can be estimated up to a constant entropy by considering the expected negative log-likelihood (empirical cross-entropy):

\[
D_{KL}(p_{y|x\mid t=1} || q_{y|x}) \approx - \frac{1}{N} \sum_{i=1}^{N} \log q(y = y_i | x = x_i) - H_{t=1}(y|x) \tag{13}
\]

The samples \( x_i, y_i \) are obtained from \( p(x, y|t=1) \) and \( p(x, y|t=0) \) for train and test cross-entropy respectively. By computing the training and OOD cross-entropy values for different regularization strength \( \lambda \), each model defines a trajectory from a maximum likelihood solution (\( \lambda = 0 \)) to the results obtained when the corresponding independence constraint is enforced (large \( \lambda \)), as shown in figure 3. Contrarily to accuracy measurements, the use of cross-entropy allows us to detect under-confident or over-confident predictive distributions.

5.3 Datasets

The two variants of the CMNIST dataset considered in this work have been designed by minimally changing the original distribution to underline the strengths and weaknesses of the different criteria. Across different experiments, each MNIST picture \( x \) with digit label \( d \) is associated with a color \( c \) which depends on a binary target \( y \) and an environment \( e \). The \( d \)-CMNIST and \( y \)-CMNIST datasets are created by adding a dependency from the environment to digit \( d \) (\( d \)-CMNIST) and label \( y \) (\( y \)-CMNIST), which results in a correlation between targets and environment (\( I(e; y) > 0 \)). Further details regarding the conditional distributions used to produce the different datasets can be found in appendix C.

The strong correlation between color and label across the different CMNIST versions can be seen as an artifact introduced by the selection \( t = f(e) \), and models that consider only digit information (green crosses in figure 5) outperform the ones that capture color information (red crosses) or both (orange crosses) in terms of OOD cross-entropy.

CMNIST The CMNIST dataset was originally designed to underline the weaknesses of maximum-likelihood and Empirical Risk Minimization strategies (Arjovsky et al., 2019). The results displayed in the first column of figure 5 confirm that both the sufficiency and separation criteria manage to effectively reduce the OOD cross entropy error for sufficiently strong regularization \( \lambda \) by minimizing the latent OOD error while retaining more predictive information than a constant representation.

\[\text{\footnotesize\textsuperscript{6}Results obtained using the Invariant Risk Minimization model (Arjovsky et al., 2019) as an alternative to enforce sufficiency are also reported in appendix E.2.}\]
which some labels are more frequent in some environments. The arrow between d and y flips when 
(2019), models based on the sufficiency criterion manage to reduce the latent OOD error (second 
column of figure 2b). On the CMNIST dataset, both the DANN and CDANN models closely 
structure of the underlying graphical model.

Figure 2b confirms that the separation criterion is the only one that manages to decrease the latent 
OOD error to zero without discarding the entirety of the information contained in z. Despite the 
effectiveness of the sufficiency criterion, the model trained with the VREx objective is 
unable to recover the optimal solution. Note that enforcing separation or independence does not 
improve upon the result that can be obtained by blindly discarding information using VIB.

d-CMNIST The d-CMNIST dataset adds a dependency between environment e and digit d, increasing 
the frequency of specific digits for some environments. Digit information makes environment and 
label conditionally independent (y and e are d-separated in figure 2b). As claimed in Arjovsky et al. 
(2019), models based on the sufficiency criterion manage to reduce the latent OOD error (second 
column of figure 2b), while the separation criterion fails because of the direct dependency between 
environment and digits. The independence criterion does not improve the OOD performance since 
both color and digit correlate with the environment.

Both DANN and CDANN architectures exhibit the expected behavior across different runs while, 
despite the effectiveness of the sufficiency criterion, the model trained with the VREx objective is 
unable to recover the optimal solution. Note that enforcing separation or independence does not 
improve upon the result that can be obtained by blindly discarding information using VIB.

y-CMNIST Adding a dependency between environment e and label y simulates the scenario in which some labels are more frequent in some environments. The arrow between d and y flips when 
compared to the d-CMNIST dataset to represent stable p(d|y) across different environments. The corresponding y-CMNIST dataset includes a path from e to y that can not be blocked since no representation z can achieve sufficiency (I(e; y|z) = 0). Despite the optimality of the separation 
criterion (dashed light blue line, third column of figure 3), the model trained with the DANN objective 
fails to minimize the OOD error due to instabilities of the adversarial training procedure. Once 
again, the trajectory described by the VREx objective interpolates between the maximum likelihood 
solution and a prior classifier p(y|t = 0).

Figure 2b confirms that the separation criterion is the only one that manages to decrease the latent 
OOD error to zero without discarding the entirety of the information contained in x on the y-CMNIST 
dataset. This confirms that the effectiveness of both sufficiency and separation criteria depends on the 
structure of the underlying graphical model.

Further details on the observes instabilities are discussed in appendix E.

---
6 Discussion and Conclusion

In this work, we characterize an information-theoretic framework to analyze the distribution shift problem by relating it to the train and out of distribution error. We identify two sources of errors for models based on latent representations, and we show that different criteria explored in literature can be seen as different strategies to minimize concept shift in the latent space using extra information about the data selection procedure. We demonstrate both theoretically and empirically that their effectiveness depends on the structure of the underlying graphical model with respect to the observed variables, training data, and data selection criteria other than the chosen approximation and relaxations for optimization.

Although test information loss and latent out of distribution error are challenging to estimate for real-world datasets, we argue that the presented analysis can be useful to better understand and mitigate the effect of selection bias and distribution shift in machine learning models. An accurate estimation of the error decomposition could be further used to guide processes of causal discovery.

### A Notation

For a given joint distribution $p(x, y, e)$ on $x$, $y$ and $e$, a binary selection $t = f(x, y, e, c)$, and a conditional distribution $q(y|x)$ we use the following notation

#### A.1 Conditional Kullback-Leibler divergence

$$D_{KL}(p(y|x)||q(y|x)) := E_{x,y \sim p(x,y)} \left[ \log \frac{p(y = y | x = x)}{q(y = y | x = x)} \right]. \quad (14)$$

Note that the expectation is always considered with respect to the joint distribution for the first argument of the KL-divergence. The notation $D_{KL}(p_y|x||q_y|x)$ will be used to abbreviate the same quantity.

#### A.2 Jensen-Shannon divergence

$$D_{JSD}(p(x)||q(x)) := \frac{1}{2} D_{KL}(p(x)||m(x)) + \frac{1}{2} D_{KL}(q(x)||m(x)), \quad (15)$$

with $m(x) = 1/2 \ p(x) + 1/2 \ q(x)$. 

13
A.3 Mutual Information

\[ I(x; y) := D_{KL}(p(x, y) || p(x)p(y)) \]  \hspace{1cm} (16)

\[ = D_{KL}(p(y|x) || p(y)) \]  \hspace{1cm} (17)

\[ = D_{KL}(p(x|y) || p(x)). \]  \hspace{1cm} (18)

The subscript \( t = 1 \) is used to indicate that both joint and marginal distribution are conditioned on \( t = 1 \):

\[ I_{t=1}(x; y) := D_{KL}(p(x, y|t = 1) || p(x|t = 1)p(y|t = 1)) \]  \hspace{1cm} (19)

Conditional mutual information is defined as:

\[ I(x; y|e) := D_{KL}(p(x, y|e) || p(x|e)p(y|e)) \]  \hspace{1cm} (20)

\[ := D_{KL}(p(y|x, e) || p(y|e)) \]  \hspace{1cm} (21)

\[ := D_{KL}(p(x|y, e) || p(x|e)). \]  \hspace{1cm} (22)

Note that all the mutual information terms in this work are implicitly expressed in terms of the distribution \( p \).

B Proofs and Additional details

The proofs for the statement in the main text are reported in this section.

B.1 Proof for Proposition[1]

Proof. Consider \( D_{KL}(p(y|x)||q(y|x)) \). By multiplying and dividing by \( p(y|x, t) \), we obtain:

\[
D_{KL}(p(y|x)||q(y|x)) = \mathbb{E}_{x,y \sim p(x,y)} \left[ \log \frac{p(y = y|x = x)}{q(y = y|x = x)} \right] \\
= \mathbb{E}_{x,y \sim p(x,y)} \left[ \log \frac{p(y = y|x = x, t = t)}{q(y = y|x = x)} \frac{p(y = y|x = x)}{p(y = y|x = x, t = t)} \right] \\
= D_{KL}(p(y|x, t)||q(y|x)) - I(y; t|x). \tag{23}
\]

Splitting the expectation on \( t \), we express the first term as:

\[
D_{KL}(p(y|x, t)||q(y|x)) = p(t = 1) \mathbb{E}_{x,y \sim p(x,y|t = 1)} \left[ \log \frac{p(y = y|x = x, t = 1)}{q(y = y|x = x)} \right] \\
+ p(t = 0) \mathbb{E}_{x,y \sim p(x,y|t = 0)} \left[ \log \frac{p(y = y|x = x, t = 0)}{q(y = y|x = x)} \right] \\
= p(t = 1) D_{KL}(p(y|x, t = 1)||q(y|x)) + p(t = 0) D_{KL}(p(y|x, t = 0)||q(y|x)) \\
= p(t = 1) D_{KL}(p_{y|x}^{t=1}||q_{y|x}) + p(t = 0) D_{KL}(p_{y|x}^{t=0}||q_{y|x}). \tag{24}
\]

Since the KL-divergence between two distributions is always positive, using the result from equations 23 and 24 we have:

\[
I(y; t|x) \leq D_{KL}(p(y|x, t)||q(y|x)) \\
= p(t = 1) D_{KL}(p_{y|x}^{t=1}||q_{y|x}) + p(t = 0) D_{KL}(p_{y|x}^{t=0}||q_{y|x}) \\
\leq (1 - \alpha) \left( D_{KL}(p_{y|x}^{t=1}||q_{y|x}) + D_{KL}(p_{y|x}^{t=0}||q_{y|x}) \right), \tag{25}
\]

with \( \alpha := \min\{p(t = 0), p(t = 1)\} \).

Whenever \( \alpha = 1 \), the inequality in equation 25 holds since \( I(y; t|x) = 0 \) and KL-divergence is always positive. For \( \alpha < 1 \) we can divide both sides by \( 1 - \alpha \), obtaining:

\[
D_{KL}(p_{y|x}^{t=1}||q_{y|x}) + D_{KL}(p_{y|x}^{t=0}||q_{y|x}) \geq \frac{1}{1 - \alpha} I(y; t|x) \]

\[
\square
\]

14
B.2 Proof for Proposition 2

Proof. Using Jensen’s inequality we have:

\[
D_{KL}\left(p_{y|x}^t \mid \mid q_{y|x}\right) = \mathbb{E}_{x,y \sim (x,y)^{t=1}} \left[ \log \frac{p(y = y \mid x = x, t = 1)}{q(y = y \mid x = z)} \right] \\
\leq * \mathbb{E}_{x,y \sim (x,y)^{t=1}} \left[ \log \frac{p(y = y \mid x = x, t = 1)}{q(y = y \mid x = z)} \right] \\
= D_{KL}\left(p_{y|x}^t \mid \mid q_{y|x}\right),
\]

in which * holds with equality when \(q(z|x)\) is a delta peak.

Secondly, by multiplying and dividing by \(p(y = y \mid z = z, t = 1)\):

\[
D_{KL}\left(p_{y|x}^t \mid \mid q_{y|x}\right) = \mathbb{E}_{x,y \sim (x,y)^{t=1}} \mathbb{E}_{y \sim q(z|x=1)} \left[ \log \frac{p(y = y \mid x = x, t = 1) p(y = y \mid z = z, t = 1)}{p(y = y \mid z = z, t = 1) q(y = y \mid z = z)} \right] \\
= I(y; x|z) + D_{KL}\left(p_{y|x}^t \mid \mid q_{y|x}\right).
\]

The bound for \(D_{KL}(p_{y|x}^0 \mid \mid q(y|x))\) is obtained analogously. □

B.3 Proof for Proposition 3

Proof. We first define the average latent predictive distribution \(\bar{p}(y|z) := \frac{1}{2}p(y|z, t = 0) + \frac{1}{2}p(y|z, t = 1)\), then

\[
I(y; t|z) = D_{KL}(p(y|z, t) \mid \mid p(y|z)) \\
\geq 2 \alpha \left( \frac{1}{2}D_{KL}(p_{y|x}^t \mid \mid p_{y|x}) + \frac{1}{2}D_{KL}(p_{y|x}^1 \mid \mid p_{y|x}) \right) \\
= 2 \alpha \mathbb{E}_{t \sim Ber(1/2)} \mathbb{E}_{z,y \sim p(z,y)^{t=1}} \left[ \log \frac{p(y = y \mid z = z, t = 1) p(y = y \mid z = z)}{p(y = y \mid z = z)} \right] \\
= 2 \alpha D_{JSD}(p_{y|x}^0 \mid \mid p_{y|x}^1) + D_{KL}(p(y|z) \mid \mid p(y|z)) \\
\geq 2 \alpha D_{JSD}(p_{y|x}^0 \mid \mid p_{y|x}^1),
\]

(28)

where \(Ber(1/2)\) refers to a Bernoulli distribution with parameter \(p = 1/2\).

Secondly, since the square root of the Jensen-Shannon divergence is a metric [Endres & Schindelin 2003], using triangle inequality we have:

\[
\sqrt{D_{JSD}(p_{y|x|z = z}^0 \mid \mid q_{y|x|z = z})} + \sqrt{D_{JSD}(p_{y|x|z = z}^1 \mid \mid p_{y|x|z = z}^0)} \geq \sqrt{D_{JSD}(p_{y|x|z = z}^0 \mid \mid q_{y|x|z = z})}.
\]

(29)

Note that the conditional distributions \(p_{y|x|z = z}^0\) and \(p_{y|x|z = z}^1\) are defined only for latent vectors \(z\) that have positive probability according to \(p(z|t = 0)\) and \(p(z|t = 1)\) respectively. Therefore inequality is defined only for \(z\) that have simultaneously strictly positive probability on both train and test distributions.

Lastly, The Jensen-Shannon divergence can be upper-bounded by a function of the corresponding Kullback-Leibler divergence:

\[
D_{JSD}(p_{y|x}^t \mid \mid q_{y|x}) = \frac{1}{2}D_{KL}(p_{y|x}^t \mid \mid q_{y|x}) - D_{KL}(m_{y|z} \mid \mid q_{y|x}) \leq \frac{1}{2}D_{KL}(p_{y|x}^1 \mid \mid q_{y|x}),
\]

(30)

with \(m_{y|z} := \frac{1}{2}p(y|z, t = 1) + \frac{1}{2}q(y|z)\).
Using the results from \[28\], \[29\] and \[30\] we have
\[
D_{\text{JSD}}(p_{y|x=z}^{t=0} || q_{y|x=z}) \leq \left( \sqrt{D_{\text{JSD}}(p_{y|x=z}^{t=1} || q_{y|x=z})} + \sqrt{D_{\text{JSD}}(p_{y|x=z}^{t=0} || p_{y|x=z}^{t=1})} \right)^2
\]
\[28\]
\[
\leq \left( \frac{1}{2e^x} I(y; t | z = z) + \sqrt{D_{\text{JSD}}(p_{y|x=z}^{t=0} || p_{y|x=z}^{t=1})} \right)^2
\]
\[29\]
\[
\leq \left( \frac{1}{2e^x} I(y; t | z = z) + \sqrt{D_{\text{KL}}(p_{y|x=z}^{t=1} || q_{y|x=z})} \right)^2
\]
\[30\]
\[
(31)
\]

**B.4 Bound in expression \[9\]**

**Proof.** Consider the amount of predictive information lost by encoding \(x\) into \(z\):
\[
I_{t=1}(x; y | z) = I_{t=1}(z; y) - I_{t=1}(z; y | x) = I_{t=1}(z; y) + I_{t=1}(z; y | x) - I_{t=1}(z; y | x) = I_{t=1}(z; y) - I_{t=1}(z; y),
\]
in which \(I_{t=1}(z; y | x) = 0\) since \(z\) depends only on \(x\).
Since \(I(x; y)\) is constant in \(q(z|x)\):
\[
\min_{q(z|x)} I_{t=1}(x; y | z) = I(x; y) - \max_{q(z|x)} I_{t=1}(y; z).
\]
(33)
The upper-bound is derived considering \(q(z|x)\) as a variational distribution. For any \(q(z|x)\):
\[
I_{t=1}(x; y | z) = D_{\text{KL}}(p_{y|x}^{t=1} || p_{y|z})
\]
\[
= D_{\text{KL}}(p_{y|x}^{t=1} || q_{y|x}) - D_{\text{KL}}(p_{y|x}^{t=1} || q_{y|z})
\]
\[
\leq D_{\text{KL}}(p_{y|x}^{t=1} || q_{y|z}),
\]
(34)
and in particular
\[
I_{t=1}(x; y | z) \leq \min_{q(z|x)} D_{\text{KL}}(p_{y|x}^{t=1} || q_{y|z}),
\]
(35)
in which equality holds for \(q(y|z) = p(y|z, t = 1)\).

**B.5 Proof for Proposition \[4\]**

**Proof.** Consider the latent concept shift \(I(y; t | z)\). Using the chain rule of mutual information, we obtain:
\[
I(y; t | z) = I(y; e | z) - I(y; e | z t)
\]
\[
\leq I(y; e | z)
\]
\[
= I(y; e | z) + I(y; t | z e).
\]
(36)
Whenever \(t\) can be expressed as a function of \(e\) and some independent noise \(\epsilon\), we have:
\[
t = f(e, \epsilon)
\]
\[
\implies p(t | e) = p(t | e, z) = p(t | e, z, y)
\]
\[
\implies D_{\text{KL}}(p(t | e, z) || p(t | e, z, y)) = 0
\]
\[
\iff I(y; t | z e) = 0.
\]
(37)
Therefore, we conclude:
\[
I(y; t | z) \leq I(y; e | z)
\]
(38)
B.6 Proof for Proposition 5

Proof. Consider the latent concept shift \( I(y; t|z) \). Using the chain rule of mutual information, we obtain:

\[
I(y; t|z) = I(yz; t) - I(t; z)
\]

\[
\leq I(yz; t)
\]

\[
= I(y; t) + I(t; z|y)
\]  

(39)

Then, we express \( I(t; z|y) \) as a function of \( I(e; z|y) \):

\[
I(t; z|y) = I(et; z|y) - I(e; z|yt)
\]

\[
\leq I(et; z|y)
\]

\[
= I(e; z|y) + I(t; z|ye).
\]  

(40)

Whenever \( t \) can be expressed as a function of \( e, y \) and some independent noise \( \epsilon \), we have:

\[
\exists f : t = f(e, y, \epsilon)
\]

\[
\implies p(t|e, y) = p(t|e, y, z)
\]

\[
\implies D_{KL}(p(t|e, y, z)||p(t|e, y)) = 0
\]

\[
\iff I(t; z|ye) = 0.
\]  

(41)

Using the results from equations (39) and (41),

\[
I(y; t|z) \leq I(y; t) + I(t; z|y)
\]

\[
\leq I(y; t) + I(e; z|y).
\]  

(42)

\[ \square \]

B.7 Correcting Separation for prior shift

When the separation constraint \( I(e; z|y) = 0 \) is enforced the reverse concept shift \( I(t; z|y) \), which represents how much the distribution \( p(z|y) \) changes as a result of the selection, is zero (equations 40 and 41). Considering the stability of \( p(z|y) \), we can express the test predictive distribution \( p(y|z, t = 0) \) as a function of the train one using Bayes rule:

\[
p(y|z, t = 0) = \frac{p(z|y, t = 0)p(y|t = 0)}{p(z|t = 0)}
\]

\[
= \frac{p(y|z, t = 1)p(y|t = 0)}{p(z|t = 0)}
\]

\[
= \frac{p(y|z, t = 1)p(y|t = 1)}{p(z|t = 0)}
\]

\[
= p(y|z, t = 1) \frac{p(y|t = 0)}{1/Z} \frac{p(z|t = 1)}{p(z|t = 1)}.
\]  

(43)

where \( * \) uses \( p(z|y, t = 0) = p(z|y, t = 1) \). The ratio \( r(y) \) represents the fraction of the marginal probabilities of \( y \), while \( Z \) is a normalization constant.

We define the corrected model \( q'(y|z) \) following the result from equation 43:

\[
q'(y|z) := \frac{1}{Z} q(y|z) r(y).
\]  

(44)
Across the three datasets:

- The different criteria mentioned in section 3 are related by the following expression, which follows from the chain rule of mutual information:

\[
D_{KL}(p_{y|z}^{t=0} || q_{y|z}^{t=0}) = \mathbb{E}_{y \sim p(y|z=z, t=0)} \left[ \log \frac{p(y = y|z = z, t = 0)}{q(y = y|z = z)} \right]
\]

\[
= \mathbb{E}_{y \sim p(y|z=z, t=0)} \left[ \log \frac{p(y = y|z = z, t = 0)}{q(y = y|z = z)} \right] \frac{p(y = y|z = z, t = 0)}{p(y = y|z = z, t = 0)}
\]

\[
= \mathbb{E}_{y \sim p(y|z=z, t=0)} \left[ \log \frac{p(y = y|z = z, t = 0)}{p(y = y|z = z, t = 0)} \right] + D_{KL}(p_{y|z}^{t=1} || q_{y|z})
\]

\[
= \ast D_{KL}(p_{y|z}^{t=1} || q_{y|z}), \tag{45}
\]

where \( * \) uses \( p(z|y, t = 0) = p(z|y, t = 1) \).

### B.8 Relation between the different criteria

The different criteria mentioned in section 3 are related by the following expression, which follows from the chain rule of mutual information:

\[
I(e; z|y) + I(e; y) = I(e; y'z) + I(e; z)
\]

From which we can derive the following:

1. if \( y \) and \( e \) are independent \( (I(y; e) = 0) \) enforcing separation is equivalent to enforcing both sufficiency and independence:

\[
I(e; z|y) + I(e; y) = 0
\]

\[
\iff I(y; e|z) + I(e; z) = 0 \tag{46}
\]

2. if \( y \) and \( e \) are dependent \( (I(e; y) > 0) \), sufficiency and independence are mutually exclusive conditions \cite{Barocas2018}:

\[
I(e; y'z) + I(e; z) \geq I(e; y) \tag{47}
\]

### C Datasets

Here we report the conditional probability distributions used to produce the d-CMNIST and y-CMNIST datasets, underlining the commonalities and differences from the original CMNIST distribution.

Across the three datasets:

- The first two environments are selected for training.

<table>
<thead>
<tr>
<th>( t )</th>
<th>( e = 0 )</th>
<th>( e = 1 )</th>
<th>( e = 2 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>0</td>
<td></td>
</tr>
<tr>
<td>0</td>
<td>0</td>
<td>0</td>
<td>1</td>
</tr>
</tbody>
</table>

- The correlation between color \( c \) and label \( y \) is positive in the first two environments and negative on the last.
- For a given color \( c \) and digit \( d \), the corresponding picture is a MNIST digit with label \( d \) and red \( (c = 1) \) or green \( (c = 0) \) color. In the discrete settings we assume that pictures contain only color and digit information (ignoring the style) and we construct \( x \) as a concatenation of the color \( c \) and digit \( d \): \( x := [c, d] \).
\[
p(c = 1|y = y, e = e)
\]
\[
\begin{array}{c|ccc}
  y = 0 & 9/10 & 4/5 & 1/10 \\
  y = 1 & 1/10 & 1/5 & 9/10 \\
\end{array}
\]

C.1 CMNIST

- All 10 digits \(d\) the same probability:
  \[
  \forall d \in 0, \ldots, 9 : p(d = d) = 1/10
  \]

- The 3 environments have the same probability to occur:
  \[
  \forall e \in 0, 1, 2 : p(e = e) = 1/3
  \]

Note that the first two environments will have probability 0.5 on the selected training set, while the last one will be drawn with probability 1 from the test distribution.

- The label \(y = 1\) is assigned with probability 0.75 for digits 5-9 and 0.25 for digits 0-4 across all environments.

\[
\begin{array}{c|cc}
  y = 0 & 3/4 & 1/4 \\
  y = 1 & 1/4 & 3/4 \\
\end{array}
\]

C.2 d-CMNIST

- Digits from 0-4 are more likely to occur on the first environment, less likely on the second, while the probability is uniform on the third environment.

\[
p(d \in D|e = e)
\]
\[
\begin{array}{c|ccc}
  D = [0, 4] & 3/5 & 1/5 & 1/2 \\
  D = [5, 9] & 2/5 & 4/5 & 1/2 \\
\end{array}
\]

Digits from 0 to 4 (and from 5 to 9) have the same probability:

\[
\forall d \in [0, 4] : p(d = d) = \frac{\sum_{d' \in [0, 4]} p(d = d')}{5}
\]
\[
\forall d \in [5, 9] : p(d = d) = \frac{\sum_{d' \in [5, 9]} p(d = d')}{5}
\]

- The first environment is more likely than the second:
  \[
  p(e = 0) = 1/2 \\
  p(e = 1) = 1/6 \\
  p(e = 2) = 1/3
  \]

Note that this assignments is designed to ensure that marginally the digits \(d\) have uniform distribution on both train and test.

- Labels \(y\) are assigned in the same way as the original CMNIST distribution, based on the digits \(d\).

C.3 y-CMNIST

- Digits 0-4 are more likely to occur for \(y = 0\) and less likely for \(y = 1\):
Similarly to d-CMNIST, digits in the same group ([0,4], [5,9]) have equal likelihood:

\[
\forall d \in [0,4]: \ p(d = d) = \frac{\sum_{d' \in [0,4]} p(d = d')}{5}
\]

\[
\forall d \in [5,9]: \ p(d = d) = \frac{\sum_{d' \in [5,9]} p(d = d')}{5}
\]

Note that the conditional distribution \( p(d|y) \) is the same as the one of the original CMNIST distribution.

- The label \( y = 0 \) is more likely in the first environment and less on the second. The two labels have the same probability on the third environment:

\[
\begin{array}{c|c|c|c}
\text{y} & \text{e} & \text{p(y|e = e)} \\
\hline
0 & 0 & 3/5 \\
0 & 1 & 1/5 \\
0 & 2 & 1/2 \\
1 & 0 & 2/5 \\
1 & 1 & 4/5 \\
1 & 2 & 1/2 \\
\end{array}
\]

- The marginal environment distribution is the same as the one described in the d-CMNIST dataset. This assignment ensures that both labels \( y \) and digits \( d \) have marginal uniform distribution on train \( t = 1 \) and test \( t = 0 \) splits.

### C.4 Dataset properties

Table 1 reports some of the mutual information measurements for the three CMNIST, d-CMNIST, and y-CMNIST datasets. Note that only representations that contain digit or no information result in zero concept shift.

<table>
<thead>
<tr>
<th>Concept shift</th>
<th>Independence</th>
<th>Sufficiency</th>
<th>Separation</th>
</tr>
</thead>
<tbody>
<tr>
<td>dataset</td>
<td>I_{y</td>
<td>x(t)}</td>
<td>I_{y</td>
</tr>
<tr>
<td>CMNIST</td>
<td>0.219</td>
<td>0.283</td>
<td>0.0</td>
</tr>
<tr>
<td>d-CMNIST</td>
<td>0.238</td>
<td>0.306</td>
<td>0.00</td>
</tr>
<tr>
<td>y-CMNIST</td>
<td>0.238</td>
<td>0.306</td>
<td>0.00</td>
</tr>
</tbody>
</table>

Table 1: Mutual information quantities for the three CMNIST datasets. Note that only a representation containing digit or no information results in zero concept shift. Both color and digit satisfy the independence criterion on CMNIST, while digit information is not satisfying sufficiency or separation for the y-CMNIST and d-CMNIST datasets.

### C.5 Sampling

Since all the three dataset have uniform digit distribution on both train and test splits \( p(d = d|t = 1) = p(d = d|t = 0) = 1/10 \), the training dataset are produced using the following sampling procedure:

1. Determine \( p(c, e, y|d, t = 1) \) using Bayes rule:

\[
p(c, e, y|d, t = 1) = \frac{p(c, e, y|d, t = 1)}{p(d|t = 1)}.
\]

2. Sample a MNIST picture \( \tilde{x} \) with label \( d \) from the MNIST dataset.
3. Sample from \( p(c, e, y|d = d, t = 1) \) to determine color \( c \), environment \( e \) and label \( y \).
4. Color the picture \( \tilde{x} \) in green or red depending on the value of \( c \) to obtain \( x \).

5. Return the triple \((x, y, e)\)

Note that in the reported experiments, step 3) is performed at run-time. Therefore, the same picture \( \tilde{x} \) can appear in different environments with different colors if sampled multiple times.

Digits used for the train \( t = 1 \) and test \( t = 0 \) splits are disjoint, following the traditional train-test MNIST splits. The code used to generate the three datasets can be found at [https://github.com/mfederici/dsit](https://github.com/mfederici/dsit).

## D Direct Optimization

The dashed trajectories in figure [5] are computed by directly optimizing the objectives reported in section [3]. While both label and environment are already categorical variables, the pictures \( x \) are represented as a concatenation of color \( c \) and digit \( d \). This is because both color and digit are accessible from the picture, and the style is irrelevant for the predictive task.

Once \( x, e \) and \( y \) have been converted into categorical variables, we use a \([10 \times 2 \times 64]\) normalized matrix \( W \) to parametrize the encoder \( q(z|x) \). Each column of \( W \) sums to 1 to represent a valid conditional probability distribution. This matrix maps each combination of digit (10) and color (2) into a representation \( z \) consisting of 64 different options using a dot product:

\[
z = W^T x.
\]  \( (48) \)

Since \( x \) has been converted to a categorical variable, this encoder can represent any possible function from \( 10 \times 2 \) to the latent space of size 64. We expect the family of encoders parametrized by \( W \) to be sufficiently flexible since the dimensionality of the representation is bigger when compared to the number of possible inputs.

All mutual information terms in the objective can be computed and differentiated directly, and we can progressively update \( W \) using stochastic gradient descent until convergence. The matrix \( W \) is initialized randomly and updated using the ADAM optimizer [Kingma & Ba, 2015] with a learning rate of \( 10^{-3} \). The optimization stops when the total variation of train and test error is less than \( 10^{-4} \) for at least 1000 iterations.

The results for different values of the hyper-parameter \( \lambda \) are obtained by training a new matrix \( W \) from scratch for each considered value. The parameters \( \lambda \) vary from 0 to \( 10^6 \) for models trained using the independence, sufficiency and separation criteria, while a maximum value of 10 is used for the information bottleneck experiments since \( \lambda = 2 \) is usually sufficient to obtain a constant representation. Further details on the procedure can be found at [https://github.com/mfederici/dsit](https://github.com/mfederici/dsit).

## E Training details

Each model in section [5] is composed of the same encoder \( q(z|x) \) and decoder \( q(y|z) \) neural network consisting of multi-layer perceptrons:

- **Encoder:** \( 784 \rightarrow 128 \rightarrow 128 \rightarrow 64 \) with 0.25 dropout probability and ReLU activation in-between each layer. Note that a final size of \( 128 = 64 + 64 \) is used for the VIB experiments to separately parametrize mean and variance of the encoder \( q(z|x) \).
- **Classifier:** \( 64 \rightarrow 128 \rightarrow 2 \) with ReLU activation and softmax output normalization.

Each model is trained for a total of 35000 iterations with batches of size 256 using the ADAM optimizer [Kingma & Ba, 2015] with a learning rate of \( 10^{-4} \). The neural networks are trained for a total of 5000 iterations without any regularization, then \( \lambda \) is linearly scaled by a constant value after each iteration (\( 10^{-3} \) for VREx, \( 10^{-2} \) for DANN and CDANN, \( 3 \times 10^{-5} \) for VIB). The increment policy has been chosen to maintain stability while exploring the full range of latent representation for each one of the models. The train and OOD cross-entropy error are measures and reported every 10 full iterations of the whole training set across 3 different seeded runs.

The DANN and CDANN models also require an auxiliary discriminator architecture. In both cases we use multi-layer perceptrons \( 64(+2) \rightarrow 128 \rightarrow 2 \) with ReLU activations, softmax output and
spectral norm for additional stability. The +2 in parenthesis accounts for the extra dimensions that are required for the label concatenation in the CDANN model. In between each update of the encoder and classifier neural network, the discriminator model is trained for a total of 9 iterations with a learning rate of $10^{-4}$. This procedure is required to ensure stability of the adversarial training. The entirety of the experiments reported in this work required approximately a total of 250 compute hours on Nvidia 1080 GPUs.

### E.1 Issues with the adversarial training

Figure 4 shows the training cross-entropy and discriminator cross-entropy for a model trained with the CDANN adversarial objective. We observe that instabilities occur when the uncertainty of the discriminator $q(e|z, y)$ approaches the maximum achievable uncertainty $H_{t=1}(e|y)$, which corresponds to a model that predicts the environment using exclusively label information. In this region (yellow area on the figure), the training cross-entropy sharply increases, exceeding $H_{t=1}(y)$, which corresponds to the error of a model that predicts $y$ using only prior information ($p(y|t = 1)$).

Since the label uncertainty when the representation $z$ is given is upper-bounded by the prior uncertainty ($H_{t=1}(y|z) \leq H_{t=1}(y)$), we conclude that the observed error must be due to a mismatch between $p(y|z, t = 1)$ and $\hat{q}(y|z)$ (the learned label classifier $\hat{q}(y|z)$ is not matching the true predictive distribution on the training set). We hypothesize this behaviour happens whenever the representation $z$ changes too quickly for the classifier to adjust. This instability of the latent representation is likely to be caused by the adversarial procedure. Lowering the learning rates, changing the regularization strength increase rate and varying the number of step of the discriminator model might help to alleviate these issues.

### E.2 Invariant Risk Minimization Results

Figure 5 reports the results obtained by running the Invariant Risk Minimization (IRM-v2) model (Arjovsky et al., 2019) on the CMNIST, d-CMNIST and y-CMNIST dataset using the same neural network architectures and training pipeline as the models reported in Figure 2a. The regularization strength $\lambda$ is ranging from 0 to a maximum of $10^3$.

The results on the original CMNIST dataset are consistent with the ones obtained considering the Sufficiency criterion (on the left), while we observed that the IRM model is unable to minimize the OOD error on the d-CMNIST dataset. We identify two main reasons that can explain this issue:

1. The Invariant Risk Minimization introduces a relaxation of the sufficiency criterion:

   Sufficiency $\iff$ IRM-optimality, \hspace{1cm} IRM-optimality $\not\iff$ Sufficiency.
Figure 5: Results for the IRM model on the CMNIST, d-CMNIST and y-CMNIST datasets. Despite the effectiveness of the Sufficiency criterion, IRM is unable to achieve optimality on the d-CMNIST dataset.

As a consequence, the model can converge to an IRM-optimal solution which is not enforcing sufficiency.

2. The gradient penalized by the regularization term \( E_{e} \| \nabla \ell_{e}(y_{y|x} \circ q_{e|x}) \|^{2} \) becomes too small to produce meaningful encoder updates.

Figure 6 shows that the gradient quickly goes to zero as the regularization strength \( \lambda \) is increased. Increasing the batch size by a factor \( x \times 4 \) when compared to the other models results in a decrease in the variance of the gradient estimate, but it does not increase its magnitude. This suggests that either the model already achieved IRM-optimality, or that the gradient is so small that the variance of the regularization term has to decreased by orders of magnitudes to result in meaningful updates. Although possible, the latter option would imply that drastically bigger batch size are needed, reducing the applicability of the IRM model to larger settings.

Other recent work in the literature is either based on the same relaxations of the sufficiency criterion as the IRM or VREx models (Parascandolo et al., 2020; Xie et al., 2020) or does not provide an implementation (Koyama & Yamaguchi, 2020).

F Generalizing constraints from the train distribution

In section 3 we mention that different criteria implicitly rely on the assumption that enforcing a constraint (or maximizing predictive information) on the training distribution is sufficient to ensure that the constraint holds for the whole distribution, even outside of the selection. Here we report a simple example in which these assumption is clearly violated to underline the importance of environment variety at training time and pinpoint the limitations of approaches explored in this work.

Consider the problem of constructing a classifier to distinguish pictures of cows from camels. To simplify our reasoning, we will assume that each picture contains both animal features \( a \in \{ \text{patches, horns, humps, ..} \} \) and background features \( b \in \{ \text{sand, grass} \} \). The data is collected from
different locations e, which represent the environmental factors. If the training distribution does not contain any example of cows on sandy terrains or camels on pastures, we can not expect any of the described criteria to successfully classify pictures that have been taken in locations in which these two characteristics occur together. This happens for two main reasons:

1. On the training distribution animal and background feature are equally predictive of the label:

\[ I_{t=1}(y; a) = I_{t=1}(y; b) = I_{t=1}(y; ab). \]

As a consequence, we can not expect the encoder \( q(z|x) \) to preferentially extract animal features \( a \), especially when the background \( b \) is much easier to identify.

Note that the amount of predictive information for the background \( b \) on the distribution that has not been selected (camels on pastures, cows on sand for \( t = 0 \)) is strictly less than the amount of information carried by \( a \):

\[ I_{t=0}(y; b) < I_{t=0}(y; a) = I_{t=0}(y; ab). \]

This is because not all camels are necessarily in sandy locations, but all of them have humps \( (H_{t=0}(y|b) > H(y|a) = 0) \). In other words, the lack of diversity in the selection makes the background information \( b \) as predictive as the animal features \( a \) on the training distribution, although background is not more predictive than the animal features in general.

2. Background information is stable across all the training locations \( e \):

\[ p(y, b|e, t = 1) = p(y, b|t = 1). \]

This happens since, within the training locations, all cows are on green patches and all camels are on sandy terrains. Since the joint distribution of background and label is the same across different training locations, the constraint imposed by both sufficiency and separation criteria cannot remove the background information \( b \) from the representation \( z \). Since both \( p(y|b, t = 1) \) and \( p(b|y, t = 1) \) appear stable we have:

\[ I_{t=1}(y; e|b) = 0, I_{t=1}(e; b|y) = 0. \]

In other words, no regularization strength \( \lambda \) can force a model trained using the sufficiency or separation (or independence) criterion to remove background information from the representation.

Note that even if background appears to be a stable feature on the selection, it is not stable in general and we have:

\[ I(y; e|b) > 0, I(e; b|y) > 0, \]

since both \( p(y|b) \) and \( p(b|y) \) can change for some environmental conditions that have not been selected. This is because in some (unobserved) locations it is possible to find cows on sandy beaches or camels on grasslands.

To summarize, lack of diversity in the training environment may compromise the effectiveness of the criteria mentioned in this analysis. This is because models can rely on features that appear to be stable on the training distribution to make predictions. Whenever the stability is due to lack of diversity in the data selection, we cannot expect optimal out-of-distribution performance.
