Abstract

Explainable machine learning (ML) has gained traction in recent years due to the increasing adoption of ML-based systems in many sectors. Counterfactual explanations (CFEs) provide “what if” feedback of the form “if an input datapoint were \( x' \) instead of \( x \), then an ML-based system’s output would be \( y' \) instead of \( y \).” CFEs are attractive due to their actionable feedback, amenability to existing legal frameworks, and fidelity to the underlying ML model. Yet, current CFE approaches are single shot—that is, they assume \( x \) can change to \( x' \) in a single time period. We propose a novel stochastic-control-based approach that generates sequential CFEs, that is, CFEs that allow \( x \) to move stochastically and sequentially across intermediate states to a final state \( x' \). Our approach is model agnostic and black box. Furthermore, calculation of CFEs is amortized such that once trained, it applies to multiple datapoints without the need for re-optimization. In addition to these primary characteristics, our approach admits optional desiderata such as adherence to the data manifold, respect for causal relations, and sparsity—identified by past research as desirable properties of CFEs. We evaluate our approach using three real-world datasets and show successful generation of sequential CFEs that respect other counterfactual desiderata.

1 Introduction

Machine learning (ML) models are increasingly used to make predictions in systems that directly or indirectly impact humans. This includes critical applications like healthcare [18], finance [56], hiring [54], and parole [58]. To understand ML models better and to promote the equitable impact of their deployment in society, it is necessary to assess stakeholders’—both expert [23] and layperson [50]—comprehension of and needs for general observability into their systems [43, 17]. The nascent Fairness, Accountability, Transparency, and Ethics in machine learning (aka “FATE ML”) community conducts research to develop methods to detect (and counteract) bias in ML models, develop techniques that make complex models explainable, and propose policies to advise and adhere to regulation of algorithmic decision-making. Here, we focus on black box model explainability.

Research in explainable ML is bifurcated. One high-level approach aims to develop inherently interpretable models such as decision trees and linear models [48]. The downside to these models is their inability to achieve high accuracy on complicated tasks in computer vision and natural language processing. Another high-level approach aims to utilize existing complex classification techniques (such as deep neural networks), but to bolster them with surrogate models that can render their predictions and/or internal processes understandable [1]. This is achieved through explaining models holistically (global explanation) or single predictions from the model (local explanation). Global explanation generally requires approximating complex models via interpretable surrogates, while local explanation methods largely approximate a local region around a complex decision boundary.

Counterfactual explanations (CFEs). A technique for providing local explanations, CFEs explain a classification by finding the minimum change in the original datapoint such that the underlying ML model will end up classifying the new datapoint into a desired class. (We provide an in-depth
Operationalizing counterfactual explanations. We propose a novel approach (FastCFE) for generating CFEs for ML models by translating a given counterfactual generation problem into a Markov Decision Process (MDP), which is solved using standard algorithms for solving Reinforcement Learning (RL) problems (see Appendix A) or, given complete access to the underlying model, planning. Since FastCFE aims to learn a policy that can generate CFEs, upon learning that policy once, we can generate CFEs for multiple datapoints from the same distribution without the need to re-optimize (which is required by most previous approaches; see Appendix B). Thus, FastCFE amortizes the cost of repeatedly computing CFEs for different inputs on the same model. FastCFE also allows enforcing desirable properties of CFEs, such as closeness to the training data distribution (data manifold), respect of causal relations between the features, and mutability and actionability of different features. FastCFE only requires access to the predict function of the ML model, and therefore works for black-box models and is model agnostic.

The output of FastCFE is a learned policy, which can be used to generate CFEs for any input datapoint. Via the learned policy, FastCFE outputs CFEs as a sequence of steps that lead an individual to the final counterfactual state. To our knowledge, we are the first to leverage techniques from stochastic control to provide such sequential CFEs [45]. Furthermore, if desired, that sequence can adhere to particular sparsity constraints (e.g., only one feature changing per step). Sequential and “rolled out” CFEs have several advantages, directly addressing gaps identified by recent survey papers [64, 5, 27] and workshops [16]: 1) optional action sparsity allows an individual to focus their effort on changing a small number of features at a time; 2) if an individual is not able to precisely follow prior advice, they can update their features and get new advice to achieve the nearest counterfactual; and 3) presentation of CFEs as a set of discrete and sequential steps which is closer to real-world actions, rather than one step continuous change to attain a counterfactual state, which all previous approaches do.

Our main contribution is a general-purpose algorithm that translates a standard CFE problem into a Markov decision process (MDP). To the best of our knowledge, our stochastic-control-based approach is the first to simultaneously address roadblocks to using CFEs in practice that have been identified by the community [e.g., 64, 5, 27].

2 Desiderata of Practical Counterfactual Explanations (CFEs)

The overarching goal of a counterfactual explanation (CFE) is to provide practical guidance to an individual seeking to change their treatment (e.g., class label) by a deployed ML model. Apart from the necessary property of a CFE having a desired class label, other desiderata have been identified in the literature, enumerated here:

- **Actionability**: CFEs should only recommend changes to the features that are actionable by an individual [e.g., 61, 26, 25, 39, 7]. Actionable features are dataset dependent. CFEs should also consider personal preferences; it may be easier for someone to change feature A than B, and vice-versa for others.
- **Sparsity**: Ideally, CFEs should make changes to a smaller set of features [e.g., 65, 61, 26, 20, 62]. Miller [37] have argued that smaller explanations are more comprehensible to humans.
- **Adherence to data manifold**: To obey the correlations between features, their input domain, and to be realistic and actionable, CFEs should adhere to the training data manifold [e.g., 11, 25, 7, 62].
- **Respect for causal relations**: Several common facts cannot be learned from data itself, but while recommending changes, they must be respected, e.g., asking someone to decrease their age to get the desired label is not helpful. Structural causal models (SCM) [31] represents such knowledge and captures the effect of change in one feature on others. Causal relations can encode facts like age cannot decrease or age increases if education level increases [e.g., 36].

Discussion of terminology in Appendix D.) For example, if an individual were denied a loan request, a CFE might tell them that if they were to increase their income by $2000, their request would be approved. CFEs do not necessarily approximate the underlying ML model, and hence the changes recommended by them are fidelitous to the model—they indeed get the desired class label. CFEs provide a precise recommendation to an individual and are therefore more directly actionable than other forms of local explainability. Recent research in this area has aimed to ensure CFEs are actionable and useful by incorporating additional constraints and desiderata into the counterfactual generation problem. As described in Section 2, these include notions of sparsity, causality, and realism of CFEs, among others. What is needed [see, e.g., 64, 5, 27] is a generalized approach that can accommodate such varied constraints and can also be computed efficiently.
Table 1: Qualitative comparison of various CFE generating approaches on the counterfactual desiderata. FASTCFE is the first and only one which satisfies all desiderata.

- **Model-agnostic:** For applicability across different classes of ML models, a CFE generating approach may need to be model-agnostic [e.g., 34, 20, 55].
- **Black-box models:** If CFEs are required for a proprietary ML model, the generating approach should work for black-box models, i.e., require access to only the predict function [e.g., 34, 20, 55].
- **Amortized CFEs:** CFEs are often required for several datapoints belonging to the same distribution. It would be effective if an approach can generate CFEs without optimizing separately for each of them. An approach that generates CFEs after single optimization produces amortized CFEs.

FASTCFE satisfies all the above desiderata. As shown in Table 1 and to the best of our knowledge, it is also the first approach to do so. The choice of action space helps produce CFEs that consider actionability among features and are sparse. We only modify the actionable features. Our CFEs are realistic and actionable as they adhere to the training data manifold and respect causal relations among features. FASTCFE works for black-box models and therefore, is model-agnostic. It learns a policy that can produce CFEs for many input datapoints (individuals) without the need to optimize again; and therefore, generates amortized CFEs.

3 Illustrative Examples: Translating CFEs to MDPs

We now give two examples of translating a CFE problem into an MDP. Once modeled as an MDP, we can use various off-the-shelf algorithms (from planning or RL) to learn a policy to generate CFEs.

**Example 1:** Consider inputs consisting of two features \(a, b \in \{0, 1, 2\}\). The combinations of possible values for \(a\) and \(b\) form the state space for the MDP, and is represented by \(S\). Figure 1a shows how we can move between different states by changing feature values. The directed edges show that upon taking a specific action, the agent can move from one state to another, e.g., the agent transits from state \((0,1)\) to \((0,2)\) by taking the action \(b+1\), which increments the value of feature \(b\) by 1. Actions \(a+1\) and \(a-1\) respectively increase and decrease the value of feature \(a\) by 1. This is similar for feature \(b\). These actions constitute the action space for the MDP, and are represented by \(A\).

The third component of our MDP is the transition function which is represented by \(T: S \times A \rightarrow S\). This denotes that if the agent takes an action \(A\) in state \(S\) then it will end up in state \(S'\).

The aforementioned transition function is deterministic because with a probability of 1, taking the action \(A\) in state \(S\), will land the agent in the state \(S' \in S\), and the probability of ending up in any other state \(S'' \in S\) is 0. In probabilistic transition functions, there is a probability distribution over destination states. It is denoted by \(T: S \times A \times S \rightarrow \{0, 1\}\) with an additional constraint of \(\forall S \in S, \forall A \in A \sum_{S' \in S} T(S, A, S') = 1\) (probability laws).

The final component of the MDP is the reward function. Taking an action costs some amount (negative reward), and reaching desirable states gives a positive reward. For example, in this MDP taking any action costs a constant amount of 1. Reaching all states gives 0 reward, except for a terminal state \((\phi)\), which gives a reward of +10. The terminal state \((\phi)\) can only be reached via \((2,2)\) (using any action), the state in green color. All actions in the terminal state lead to itself with 0 cost. This represents the situation in which a ML classifier classifies all individuals as 0, except when their features are \((2,2)\). Therefore \((2,2)\) is the desirable state.
Figure 1: Transition function for the two examples. Circles show all the states, and edges show possible transitions. 1) Left-hand-side shows the transition function for a dataset with two features $a$ and $b$, with no restrictions on the values both of them can take within the input domain. The transition edges are therefore bidirectional. 2) Right-hand-side shows the transition function for a dataset with three features: age ($a$), education-level ($b$), and race ($r$). The transition edges are unidirectional as both age and education cannot decrease. Since race is immutable, there are no actions for $r$. Since increase in education stochastically affects age, the dashed edges represent a 50% probability of transition.

The aim is to learn a policy that reaches a terminal state from any state at lowest cost (e.g., taking the fewest number of steps), if a terminal state is reachable. Cost (or reward) can be discounted in the traditional way using a discount factor $\gamma \in [0, 1)$, or even $\gamma = 1$ when a fixed horizon (e.g., maximum number of steps) is used. Formally, for this example with a discrete state space and discrete action space, our MDP is:

- **States** = \{ $S \in S : \{0, 0\}, \{0, 1\}, \{0, 2\}, \{1, 0\}, \ldots$ \}.
- **Actions** = \{ $A \in A : a+1, a-1, b+1, b-1$ \}.
- **Transition function** $T : S \times A \rightarrow S$.
- **Reward function** $r : S \times A \rightarrow \mathbb{R}$.
- **Discount factor** $\gamma \in [0, 1]$, capturing the tradeoff between current and future reward.

Our goal is then the traditional goal of finding a policy $\pi : S \rightarrow A$ that, given a state $S \in S$ (in our case, an input datapoint), returns an action $A \in A$ that represents the best first step to take to achieve a goal (in our case, a first feasible change to a portion of an input datapoint’s feature vector). In the context of FASTCFE, one would then call this precomputed policy repeatedly to achieve an optimal path to a final goal with a desired class label as output.

**Example 2:** Now consider a realistic dataset with 3 features: age (denoted by $a$), education-level (denoted by $b$), and race (denoted by $r$). Features can be causally related. In this dataset: age cannot decrease, education-level cannot decrease, education-level influences age, and race is immutable. When we increase the education-level $b$ by 1, there is a 50% chance that the age $a$ will remain the same and a 50% chance that it will increase (by 1). These interactions between variables can be captured by a structural causal model (SCM), as we discuss in Section 4. Therefore, the transition function for the MDP representing the CFE problem for this dataset is stochastic.

Defined formally, here are the components for this MDP:

- **States** = \{ $S \in S : \{0, 0, 0\}, \{0, 1, 0\}, \{0, 2, 1\}, \{1, 0, 0\}, \ldots$ \}.
- **Actions** = \{ $A \in A : a+1, a-1, b+1, b-1$ \}.
- **Transition function** $T : S \times A \times S' \rightarrow A$ s.t. $\forall S \in S, \forall A \in A, \sum_{S' \in S} T(S, A, S') = 1$.
- **Reward function** $r : S \times A \rightarrow \mathbb{R}$.
- **Discount factor** $\gamma \in [0, 1]$.

Figure 1b shows the transition function for this problem input. The action that increases the education-level (represented by $b$), now has a probabilistic transition to two destination states, represented by dashed unidirectional edges. Each transition edge has a 50% probability of occurrence. Unidirectionality comes from the fact that education-level cannot decrease. The edges which denote action on the feature $a$ are also unidirectional as age cannot decrease. The reward function is identical to the previous example; optionally, it can be changed to accommodate desired real-world preference such
ALGORITHM 1: Generate MDP from a Counterfactual Explanation Problem

Input : Training Dataset ($D$), ML model ($f$), Structural Causal Model ($SCM$), Actionable features ($ActF$), Data Manifold distance function ($DistD$), Data Manifold adherence ($\lambda$), Desired Label ($L$), Distance Function ($DistF$), Discount Factor ($\gamma$)

Output : MDP

// States consist of numerical ($Num$) and categorical ($Cat$) features.
1 State space $S \subseteq R^{[Num]} \times Z^{[Cat]}$

// Actions change an actionable feature by some amount.
2 Action space $A \subseteq R^{[ActF]}$: denote actions $A \in A$

Function Reward($f, L, CurrState, A, D, \lambda, DistD, SCM$)
4 $NextState \leftarrow Transition(CurrState, A, SCM)$
5 if $\text{argmax}(f(NextState)) = L$ then
6     $\text{CFReward} \leftarrow \text{Pos}$ // High positive reward
7 else
8     $\text{CFReward} \leftarrow f(NextState)[L]$ // Probability of classification in the desired class
9 return $\text{DistF}(CurrState, A, D)$ // cost of an action
10 + $\lambda \cdot \text{DistD}(NextState, D)$ // Manifold distance cost
11 + $\text{CFReward}$ // Counterfactual label reward

Function Transition($CurrState, A, SCM$)
12 // Action does not violate feature domain and unary constraints
13 if $\text{Allowed}(A) \& \text{InDomain}(A)$ then
14     $NextState \leftarrow CurrState + A$ // Modify features
15 else
16     return $CurrState$ // Modify the endogenous features

for $V \in SCM$ do
19     if $A \in \text{Parent}(V)$ then
20         $NextState[V] \leftarrow F(U)$ // Stochastic or deterministic update of endogenous features
21 return $NextState$

$MDP \leftarrow \{S, A, Transition, Reward, \gamma\}$

as adherence to the data manifold (Section 2) or having different costs for changing different features, which we describe in Section 4. Additional examples can be found in Appendix C.

4 An Algorithmic Approach to Generating MDPs from CFE Problems

We now present a general approach for translating a CFE problem setup into an MDP. Algorithm 1 generates each component of an MDP: state space, action space, transition function, reward function, and additional inputs such as discount factor. We detail each component’s generation below.

State space. We focus first on the features of a particular dataset. Broadly, features can be categorized into numerical ($Num$) and categorical ($Cat$). For each categorical variable, we map each value of that variable to a unique integer. Consequently, the state space $S$ of our MDP (line 1) consists of the product of the continuous domains for numerical features (a subset of $R^{[Num]}$) and product of the integer domains for categorical features (a subset of $Z^{[Cat]}$).

Action space. To facilitate capturing actionability [61] and causal relationships between variables [28, 29, 36, 41], we further categorize features as follows.

- **Actionable** features can be directly changed by an agent, e.g., income, education level, age.
- **Mutable but not actionable** features are mutable but cannot be modified directly. They change as an effect of change in other features, e.g., credit score cannot be directly set by a person, it changes due to change in other features like income and loan amount. These dynamics are determined by a structural causal model (SCM) [41], described in detail below.
- **Immutable** features cannot change, e.g., race, birthplace.

The agent is permitted to change only the actionable features (denoted by $ActF$). Consequently, the action space $A$ is a subset of $R^{[ActF]}$ (line 2). Categorical features can be changed within their discrete domain, while numerical features can be changed within their continuous domain. Line 13 further enforces the infeasibility of out-of-domain actions.
Transition function. The third component is the transition function (line 12), which finds the modified state when an action is taken. This function is constructed using the structural causal model (SCM), which is an input to Algorithm 1. An SCM consists of a triplet $M = (U, V, F)$. $U$ is the set of exogenous features and $V$ is the set of endogenous features. In terms of a causal graph, the exogenous features $U$ consist of features that have no parents, i.e., they can change independently. The endogenous features $V$ consist of features that have parents in $U$ and/or other features in $V$. They change as an effect of change in their parents. $F$ is the set of functions that determine the relationship between exogenous and endogenous features. Since knowing the exact SCM is mostly infeasible, Algorithm 1 also accepts causal relations in form of unary ($\text{Un}$) and binary ($\text{Bin}$) constraints. Unary constraints are derived from the property of one feature, e.g., age and education level cannot decrease. Binary constraints are derived from the relation between two features, e.g., if education level increases, age increases. If an action does not violate the domain of the feature it is changing, nor the constraints in the SCM, then the feature is modified in NextState (line 14). If the modified feature is a parent node to endogenous features in the SCM, we update its children by using the $F$ functions (line 17-19).

Reward function. Line 3 defines a reward function that, given a state and an action, returns a reward based on three components derived from the initial CFE problem:

- Given the current state ($\text{CurrState}$), action ($A$), training dataset ($D$), and distance function $\text{DistF}$, the first part returns the appropriate cost to take that action (line 9). The distance function can either be $\ell_p$ norm of the change produced by the action or a more complex function that takes into account the cumulative distribution function (CDF) of the specific feature that the action is modifying. The latter function can account for cases where, e.g., changing a feature from its 90th to 95th percentile value costs more than changing it from its 50th to 55th percentile value [61].
- The second part adds a cost if a datapoint is away from the training data manifold (line 10). The $\text{DistD}$ function finds the distance of the datapoint from the data manifold and returns a real number. That is multiplied by a factor $\lambda$ to control the strictness of data manifold adherence.
- The third part rewards the agent with a large positive value if the trained model $f$ produces the desired label for NextState ($\text{CFReward}$ in line 11). To avoid sparse rewards, we partially reward the agent with a small positive value otherwise. This reward is equal to the probability of NextState being classified in the desired class (line 8). This can only be used if the underlying classifier provides the class label probabilities instead of only the class label. In conjunction with the discount factor $\gamma$, this encourages the agent to learn the policy that quickly gets the desired label for any datapoint.

Other parameters. MDPs require additional parameters such as the discount factor $\gamma \in [0, 1]$, which is an input to Algorithm 1. At a high level, setting $\gamma < 1$ penalizes longer (in terms of the number of steps) paths; for additional intuition, see Sutton and Barto [57]. We note that $\lambda$, $\text{DistD}$, and $\text{DistF}$ are user-specified and domain-specific parameters that directly impact the reward function for the MDP.

5 Evaluation

We next provide experimental validation of FASTCFE using several real-world datasets. We also explore the impact of varying domain-specific parameters on the policies, and thus sequential CFEs, produced by FASTCFE. Our experiments answer the following research questions:

RQ1 Does FASTCFE successfully generate CFEs for various input datapoints (validity)?
RQ2 How much change is required to reach a counterfactual state (proximity)?
RQ3 How many features are changed to reach a counterfactual state (sparsity)?
RQ4 Do the generated CFEs adhere to the data manifold (realisticness)?
RQ5 Do the generated CFEs respect causal relations (feasibility)?
RQ6 How much time does FASTCFE take to generate CFEs (amortizability)?

Datasets. We use 3 datasets in our experiments: German Credit, Adult Income, and Credit Default [13]. These datasets have 20, 14, and 23 features respectively. We omitted the feature education-num in the Adult dataset as it has one to one mapping with another feature education, resulting in 13 features. We split the datasets into 80%-10%-10% for training, validation, and testing, respectively. Each dataset has two labels, ‘1’ and ‘0’, where ‘1’ is the desired label. Using the training dataset, we trained a simple classifier: a neural network with two hidden layers (5 and 3 neurons) with ReLU activations. The test accuracy of the classifier was above 80% for all the datasets; specifically, 83.0% for German Credit, 83.7% for Adult Income, and 83.2% for Credit Default. These rates are comparable to other simple classification models; still, we note that the competitive performance of the trained classifier $f$ is relatively less important for FASTCFE’s validation.
Table 2: Causal relations and immutable features we identified for the datasets used in experiments.

Implementation Algorithm. Any appropriate method for computing an optimal policy $\pi^*: S \rightarrow A$, or any approximately optimal policy, to the MDP output of Algorithm 1 can be used. The datasets used in our experiments yield an MDP with a continuous state and action space, so we train the agent using a policy gradient algorithm. Specifically, we use proximal policy optimization (PPO) [51] with generalized advantage estimate (GAE) [52] to train the agent. The features in the dataset are scaled between $-1$ and $1$ before training both the classifier and the agent.

5.1 Baselines

Since, to our knowledge, FASTCFE is the first approach to generate amortized CFEs for black-box models, there exist no previous approaches against which we can directly compare. Nevertheless, we compare FASTCFE to several previous popular CFE generating approaches and two other baselines that we developed.

Baselines we developed. To compare FASTCFE to approaches that generated CFEs in an amortized manner for black-box models, we developed two baselines:

- **Random**: This approach tries to generate CFEs by executing random actions from the action space.
- **Greedy**: This approach tries to generate CFEs by changing features greedily. At each step, it executes all the actions in the action space, and moves forward with the one which gives the highest reward. Naturally, this is expensive.

Note that, in order to have a finite number of actions to evaluate and greedily choose the best action, the greedy approach requires the action space to be discretized. Therefore we compare FASTCFE, random, and the greedy approaches using discrete action space.

Previous CFE generating approaches. Based on the level of required model access, previous CFE generating approaches can be categorized as: 1) access to complete model internals, i.e. weights of neurons or nodes of decision trees, 2) access to model gradients (restricted to differentiable models like neural networks), and 3) access to only the prediction function (black-box). We choose popular approaches from all three categories.

- **Complete model internal access**: We chose MACE [26] from this category.
- **Gradients access**: We chose DiCE [39] from this category.
- **Black-box**: We chose three approaches in this category, which were available in the open-source repository of DiCE [38]. These are black-box and model-agnostic versions of the original DICE approach (which required gradients). They are DiCE-Genetic, DiCE-KD-Tree, and DiCE-Random.

5.2 Experimental Methodology

Here we describe the details of running FASTCFE and other baselines.

FASTCFE specifics. Since FASTCFE requires the set of immutable features and causal constraints as input, we infer them for each dataset. They are shown in Table 2. As described in Algorithm 1, this directly impacts the transition function in the MDP. We use a particular instantiation of Algorithm 1, available in our open source codebase, in the experiments:

- **Action space**: To produce sequential CFEs, actions primarily modify only one feature at a time. However, endogenous features may change due to changes in their parents.
- **Cost of action**: For the experiments, we do not penalize the agent for taking any action, thus $\text{DistF}$ always returns 0. We describe the rationale for this later.
- **Data manifold distance**: Following previous work [e.g., 7, 25], we train a $k$-Nearest Neighbor (KNN) algorithm on the training dataset and use it to find the $\ell_1$ distance of a given datapoint from its nearest neighbor ($k = 1$) in the dataset ($\text{DistD}$). We use several values of the data manifold adherence factor $\lambda$ in the experiments.

</table>

Table 3: Comparison of FASTCFE to all baselines for various CFE evaluation metrics. For validity and causality, a higher value is better, and for all other columns, a lower value is better. MACE could not be run for larger datasets owing to its expensiveness. For the same reason, DiCE-Gradient could not be run for all datapoints.

- **Counterfactual state reward (CFReward)**: As mentioned earlier, when the agent reaches a state, it receives a reward equal to the probability of that state to belong to the desired class. Whenever a counterfactual state is reached, the agent is rewarded with 100 points.
- **Discount Factor**: We use a discount factor $\gamma = 0.99$. This value encourages the agent to learn the policy which takes a datapoint to its counterfactual state in small number of steps, thus removing the requirement of DistF.

**MACE specifics.** MACE requires the user to specify the type of ML model to be used for classification. We choose logistic regression (LR) and random forest (RF) as the underlying models. We could not use neural networks because of the long runtime of MACE (see Section 5.3).

All approaches are requested to generate CFEs for all test datapoints that are predicted as ‘0’ by the underlying classifier. Due to the small size of the German Credit dataset, we generate CFEs for datapoints that are predicted as ‘0’ both in the training and test sets. Thus we generate CFEs for 257 datapoints in the German credit, 7229 datapoints in the Adult Income, and 5363 datapoints in the Credit Default datasets, respectively. Since MACE uses a different classifier, the number of datapoints predicted as ‘0’ were slightly different. More details are provided in section section 5.3. FASTCFE, random, and greedy approaches stop when they reach a counterfactual state (predicted as ‘1’) or exhaust 200 actions. Other baselines have no timeout.

### 5.3 Results

Table 3 shows the performance of FASTCFE and all the baselines on the CFE desiderata. We report the average validity, average proximity (separately for the numerical and categorical features), average sparsity, average data manifold distance, average adherence to causal constraints of the generated CFEs, and the average time to generate the CFEs.

**Answer to RQ1:** As shown in Table 3, FASTCFE has very high validity for all datasets. For Adult Income, FASTCFE gets the highest validity at 100%, while for Credit Default and German Credit is achieves the second and third highest validity, respectively. Random and greedy approaches have a low validity in general. DiCE-Genetic has a validity in the high range in general, but this comes at the cost of proximity, sparsity, and data manifold distance. DiCE-KDTree is unable to generate CFE even for a single datapoint in all the three datasets. Unsurprisingly, Dice-KDTree is able to generate some CFEs when all features are deemed mutable. DiCE-Random achieves 100% validity for all datasets, and just like DiCE-Genetic this comes at the cost of proximity, sparsity, and data manifold distance. The conclusion is similar for DiCE-Gradient’s validity. MACE also achieves 100% validity, but it is very expensive to run. Due to this, it was impractical to run MACE for the larger datasets.
datasets, Adult Income and Credit Default (we show MACE run only for the German Credit dataset). MACE was even more expensive when the underlying classifier was a neural network, and we had to abandon that experiment. For the two underlying classifiers, MACE predicted ‘0’ for 210 datapoints for logistic regression (LR) and 287 datapoints for the random forest (RF). MACE was supposed to generate CFEs for these datapoints.

Answer to RQ2: We measure proximity for numerical and categorical features separately (Prox-Num and Prox-Cat respectively). For numerical features, the distance is sum of the $\ell_1$ norm respectively divided by the median average deviation for each numerical feature. For categorical features, the distance is the number of categorical features changed divided by the total number of categorical features. These metrics were proposed and used in previous works [36, 39]. FASTCFE’s CFEs are most proximal for Adult Income and Credit Default datasets, and come second for German Credit. The random approach and the four variants of DiCE have high proximity value. The greedy approach performs well on this metric, but its validity is very low. MACE’s performance is about average.

Answer to RQ3: FASTCFE achieves the lowest sparsity for all the datasets. Note that, for FASTCFE we measure sparsity at the start and end point of a CFE, and not at every step. This is in accordance with previous works [39]. Random, DiCE-Genetic, and DiCE-Gradient’s performance is abysmal. This is surprising because DiCE-Gradient has a post-hoc step specifically for reducing sparsity. Greedy, MACE, and DiCE-Random’s performance is about average.

Answer to RQ4: FASTCFE achieves low average manifold distance. It performs second best for Adult Income and Credit Default and is in the middle for German Credit. The greedy approach and MACE also performs well on this metric. The random approach and all variants of DiCE perform poorly on this metric. In Appendix E, we explore the impacts of hyperparameters related to data manifold distance.

Answer to RQ5: By virtue of construction, FASTCFE always respects causal relations, it has a 100% adherence in all datasets. The DiCE based approaches and MACE take as input the immutable features, but not the other causal constraints and hence do not perform well. The greedy approach performs well on this metric, even though it does not have a knowledge of the causal constraints. The random approach performs abysmally on this metric.

Answer to RQ6: The final column in Table 3 reports the average computation time per CFE. By virtue of amortization, FASTCFE can generate CFEs very quickly. Therefore, on average it takes the lowest time in all datasets. The next best performers are DiCE-Random and the random approach. Even then, FASTCFE is $11\times$ faster than the random approach on average (up to $15\times$ faster), and FASTCFE is $8\times$ faster than DiCE-random on average (up to $15\times$ faster). The difference even more staggering for DiCE-Genetic and greedy approach. MACE and Dice-Gradient were the slowest. FASTCFE is about $1000\times$ faster than MACE on average (up to $1447\times$ faster) and $4500\times$ faster than DiCE-Gradient on average (up to $9400\times$ faster). While amortization allows for rapid generation of new CFEs, the one-time cost of training the agent(s) tended to range from 2 to 12 hours, depending on the dataset.

6 Conclusions & Future Research

CFEs are an effective and actionable way to provide explanations for an ML system. Among the several desirable properties of a CFE generation approach, it is desirable if the approach works for a black-box model and needs to be optimized once and can be used to generate CFEs rapidly thereupon, i.e., amortized CFEs. We propose a novel algorithm that generates amortized and sequential CFEs for black-box models. To the best of our knowledge, we are the first to propose such an approach. Our approach also incorporates other desirable properties like changing only the actionable features, respecting causal constraints, and adhering to the data manifold. We evaluated our approach using several datasets. Our approach successfully generates CFEs for most datapoints, and the CFEs generated by our approach possess desirable properties and perform better than the ones generated by our baselines.

We see many avenues for future research. We enable sequential explanations by way of a generic MDP; in our setting, it may be the case that any path requires to cross the decision boundary of the ML model f is too costly, thus resulting in the optimal action being not to act at all. MDPs can also model stochastic shortest path problems, or SSPs [15]; here, the goal would be to find the path with the lowest cost that necessarily cross the decision boundary, effectively removing the “do not act” option in the event that the optimal path comes with a negative expected reward. We note that our
general approach can model SSPs, and we believe a specific SSP-based approach could be valuable for particular domains.

A Background

This section provides background about the social implications of ML models and techniques to address concerns, along with a brief introduction to Reinforcement Learning.

A.1 Fairness, Accountability, and Transparency of AI and ML

Fairness and explainability of an ML model are two major themes in the broad area of equitable ML learning research.

Fairness research mostly proposes algorithms that learn a model that does not discriminate against individuals belonging to disadvantaged demographic groups. Other possibilities of intervention lie in modifying the training data itself. Demographic groups are determined by values of sensitive attributes prescribed by law, e.g., race, sex, religion, or the nation of origin. ML models can get biased against certain demographic groups because of the bias in their training data, specifically label bias and selection bias. Label bias occurs due to manual biased labeling of datapoints belonging to a demographic group, e.g., if individuals from the black community were denied loans in the past irrespective of their ability to pay back, this gets captured in the data from which the model can learn. Selection bias occurs when specific subsets of a demographic group are selected, which captures potentially correlations between the prediction target and a specific demographic group, e.g., selecting only defaulters from a demographic group in the training data. More than 20 definitions of fairness of an ML model have been proposed in literature [63]. Dunkelau and Leuschel [14] summarize some of the significant research advances that have been made in fairness research, and is a comprehensive introductory text for understanding the categorization and direction of research.

Explainability research can be broadly divided into model explanation and outcome explanation research problems [21]. The model explanation problem seeks to search for an inherently interpretable and transparent model with high fidelity to the original complex model. Linear models, decision trees, and rule sets are examples of inherently interpretable models. There exists techniques to explain complex models like neural networks and tree ensembles using interpretable surrogate like decision tree [6, 31, 4, 12] and rule sets [8, 2]. There also exist approaches that can be applied to black-box models [22, 32, 68].

The outcome explanation problem seeks to find, for a single datapoint and prediction from a model, an explanation of why the model made its prediction. The explanation is either provided in the form of the importance of each feature in the datapoint, or the form of example datapoints. The first class of methods are called feature attribution methods and are grouped into model-specific [67, 53] and model-agnostic [42, 47, 60] kinds. Example-based approaches return a few datapoints that either have the same class label as the original datapoint or a different class label. The motivation for the first is to provide a set of datapoints that must be similar in the input space. The motivation for the second is to provide a set of datapoints that serves as a target to achieve in case the individual wants to receive the alternative label. The second set of datapoints can be referred to as counterfactual explanations.

Counterfactual explanations are applicable to supervised machine learning where the desired label has not been obtained for a datapoint. Most research in counterfactual explanations assumes a classification setting. Supervised ML setup consists of several labeled datapoints, which are inputs to the algorithm, and the aim is to learn a function mapping from the input datapoints (with say m features) to labels. In classification, the labels are discrete values. The input space is denoted by $X^m$ and the output space is denoted by $Y$. The learned function is the mapping $f : X^m \rightarrow Y$ is used to make predictions. We expound on counterfactual explanations and their desirable properties in Section 2.

Major beneficiaries of explainable machine learning include the healthcare and finance sectors, which have a huge social impact [59]. We point the readers to surveys in the area of explainable machine learning [1, 3, 21].

A.2 Reinforcement Learning

Reinforcement Learning (RL) is one of the three broad classes of machine learning, along with supervised and unsupervised learning. In RL, the goal is to explore a given environment and to learn a policy over time that dictates what action should be taken at a given state. The exploration happens with the help of an agent. Therefore, a policy is a mapping from a state to an action. When an action is taken at a state, the environment returns with the new state and a reward. A good policy aims to maximize the reward over time. The calculation of the new state is facilitated through the transition
function, whereas the calculation of the reward is done using the reward function. Naturally, the agent can either learn policies that are greedy and only focus on immediate reward or learn policies that focus on reward in the long-term. This trade-off is controlled by a discount factor called $\gamma$, whose value lies between 0 and 1 (inclusive of 0 and 1). States can either be discrete or continuous. Similarly, actions can also be either discrete or continuous. An RL problem is expressed in terms of a Markov Decision Process (MDP), which has five components. We illustrate each of them using the game of chess.

- **State space** $S$, which are states an agent might explore. In chess, these are the 64 squares that an agent can move to.
- **Action space** $A$, which are the possible actions an agent can take. These might be restricted based on the current state. In chess, the actions depend on the game pieces like a king, queen or pawns, and the given position on the chessboard. The action space is the union of all possible actions.
- **Transition function** $T$ which given the current state and action, find the new state that the agent will transition to, e.g., moving the pawn by 1 unit north end up putting the agent in the state that is one unit north of its current state. Transition functions can be deterministic or stochastic (see Section 3).
- **Reward function** $R$ passes the reward to the agent given the action, the current state, and the new state. This reward signal is the main factor that the agent uses to learn a good policy, e.g., winning a game would pass a positive reward, and losing the game would send a negative reward to the agent.
- **Discount factor** $\gamma$ is associated with the nature of the problem at hand. This is used to decide the trade-off between immediate and long-term rewards.

Many algorithms have been developed to efficiently learn an agent, given the environment like value iteration, policy iteration, policy gradient, actor-critic methods [57].

### B Related Work

Literature in counterfactual explanations for ML is relatively recent, with the first proposed algorithm in 2017. Wachter et al. [65] proposed finding counterfactuals as a constrained optimization problem where the goal is to find the minimum change in the features such that the new datapoint has the desired label. This approach was gradient-based, did not consider actionability among features, did not adhere to data manifold or respect causal relations, and the optimization problem needed to be solved for generating a CFE for each input datapoint. Other desiderata mentioned in Section 2 were proposed by other papers: 1) approaches that generate multiple, diverse counterfactuals for a single input datapoint [39, 7, 36, 26, 55, 49], 2) approaches that generate counterfactual for black-box models and are model-agnostic [33, 34, 20, 19, 55, 46, 66, 44, 30, 7], 3) approaches that generate CFEs adhering to data manifold [10, 11, 24, 62, 36, 40, 30, 35, 7, 25], 4) approaches that generate CFEs that respect causal relations [36, 28, 29], 5) approaches that generate fast counterfactuals [36]. Only Mahajan et al. [36] proposed an approach that can generate multiple CFEs for many datapoints, after optimizing once, therefore fast counterfactuals, but their approach is gradient-based and therefore works only for differentiable models and it not black-box. Our approach overcomes this limitation and generates both fast and model-agnostic CFEs, which adhere to data manifold and respect causal relations. Out of the previous approaches that respect causal relations, only Mahajan et al. [36] works with partial SCM, while others require complete causal graph or complete SCM [28, 29], which are mostly unavailable in the real world. Our approach also works with a partial SCM.

All the previous works give a single-shot solution for getting to a counterfactual state from an input datapoint. Our approach overcomes this limitation by proposing a novel algorithm that generates sequential CFEs.

Verma et al. [64] and Karimi et al. [27] have collected and summarized recent works in counterfactual explainability. We point the readers to these surveys for an excellent in-depth review of the research landscape in this area.

### C Illustrative examples

This section gives the remaining examples of translating a CFE problem into an MDP.
Example 1: Let us now consider the example where one of the two features is age (denoted by feature \( \text{a} \)). This adds a constraint because age cannot decrease. Therefore, any change which decreases age is not allowed. This is captured by the transition function. In Figure 2 we see that the edges which act on feature \( \text{a} \) have now become unidirectional implying that the value of feature \( \text{a} \) cannot decrease. Taking the action \( \text{a}-1 \) at any state ends up being in the same state, albeit with a cost of 1.

Example 2: Let us now consider a dataset with three features, out of which one is immutable, e.g., race (denoted by feature \( \text{r} \)). Feature \( \text{a} \) still represents age and carries its non-decreasing constraint. Such a feature cannot be changed using any action, and this is encoded in the transition function by returning the same state if this action is taken. The state space in this MDP will consist of 3 values, one for each feature. Figure 3 shows the transition function for the MDP representing the CFE problem using this dataset. As we already saw, \( \text{a} \) which represents age is non-decreasing. Also, none of the actions affect the value of feature \( \text{r} \) as it remains constant (shown by the constant ‘\( \text{r} \)’ in the diagram). The reward function is similar to the first example: a constant cost to take any action and a high reward for reaching the terminal state where the first two features are (2,2). This state follows into a dummy state where any action ends up in the same dummy state.

Let \( \text{r} \) take values 0 and 1. Defined formally, here are the components for this MDP:

- States \( S = \{0,0,0\}, \{0,1,0\}, \{0,2,1\}, \{1,0,0\}, \ldots \)
- Actions \( A = \{\text{a}+1, \text{a}-1, \text{b}+1, \text{b}-1\} \)
- Transition function \( T : S \times A \rightarrow S \)
- Reward function \( R : S \times A \rightarrow \mathbb{R} \)
- Discount factor \( \gamma \in [0,1) \)

Example 3: In all the examples we visited, there was a constant cost to taking any action, and all states but one gave a 0 reward on reaching them. Consider the previous example where the dataset consisted of 3 features: age, education-level, and race. Some of the states do not appear in the training dataset used to train the classifier we are trying to generate CFEs for. Ideally, we would prefer to generate CFEs that are similar to existing data; otherwise, we might generate unrealistic and unactionable explanations. This is based on the assumption that training data is a good representation of the true distribution of features. Some of such states are:

- \((0,2,0)\) and \((0,2,1)\): intuitively this shows that it is unrealistic for an individual to be in the lowest age group (0) and have the highest education-level (1). This is true regardless of the person’s race.
Figure 3: Transition function for a dataset with 3 features, the first being age (denoted by $a$) and the third being race (denoted by $r$). Circles show all the states and edges show possible transitions. None of the actions can change the value of feature $r$ as race is immutable.

- $(2,0,1)$: it is improbable for someone belonging to the race encoded by value 1 to be in the highest age group and have the lowest possible education-level. Yet $(2,0,0)$ is not an improbable state, and this might be due to the differences in education level across different races.

We encode this information in the MDP by modifying its reward function. If we take an action that ends up in an unrealistic state, it attracts a penalty of -5 points. The dummy state still carries the +10 reward, other states reward 0, and there is a constant cost of 1 to take any action. The agent learning in this environment would ideally learn to avoid the unrealistic states and take actions that go to the terminal state. In this situation, the agent can learn not to take a shorter path because it goes through an unrealistic state. We use a $k$-Nearest Neighbour algorithm to find the appropriate penalty for landing in any state in our experiments. If a state is close to a datapoint in the training dataset or occurs in the training dataset itself, there is a low or no penalty.

**Example 4:** Reconsider the last example in which there are three features. The reward function in the last example costed the same for all features. It might be harder to change one feature than another in real life, e.g., it might be easier for someone to wait to increase their age rather than get a higher educational level. This can be accounted for by posting higher costs to change features harder to change and vice-versa for feature easier to change.

### D Counterfactual vs. Contrastive explanations

There is ongoing discussion on the exact definition of counterfactual explanation, with some researchers advocating to call it contrastive explanations. Dhurandhar and Shanmugam [9] have captured the precise difference in a recent article. They mention that the counterfactual explanations as introduced by Wachter et al. [65] are almost the same as contrastive explanations. These explanations seek to find the minimal changes to the input such that the prediction from the ML model changes. On the other hand, counterfactuals are a function of the datapoint, its prediction, the ML model, and the data generating process that created that datapoint. Pearl [41] describes three steps for generating counterfactuals:

1. Abduction: This is the process of conditioning on the exogenous variables in the data generation process.
2. Intervention: This is the process of making a sparse change on a specific observable variable.
3. Prediction: This is the process of using the exogenous variables identified in the first step and propagating the intervention to generate the counterfactual.
We agree with this framing. Therefore, counterfactual explanations amount to much more perturbing the input datapoint—as in the case of contrastive explanations, which are tied to the data generating process. Indeed, it is our belief that our proposed framework captures these concerns, if data regarding causal interactions is available.

We take note of this distinction and therefore have adherence to causal relations as a desiderata of counterfactual explanations (Section 2). Structural Causal Models (SCM) consists of the exogenous and endogenous variables involved in the data generation process. FastCFE takes as input the SCM (partial SCM is supported) of the dataset and takes it into consideration while generating CFEs. If the SCM is not provided, the explanations generated by FastCFE are basically contrastive explanations.

</table>

Table 4: Comparison of the evaluation metrics of CFEs for different value of λ hyper-parameter which determines the closeness to the training data manifold.

Table 4 shows the effect of increasing the penalty for leaving the training data manifold, which is enforced at each step of a counterfactual path. With increasing λ, the manifold distance should become smaller. Increasing λ also makes it harder for the agent to learn an effective policy, and therefore the validity could also go down. We observe both these expected trends in Table 4 above, specially for the German Credit and Credit Default datasets.
