Abstract

Researchers are now using deep learning models to explore the emergence of language in various language games, where simulated agents interact and develop an emergent language to solve a task. Although it is quite intuitive that different types of language games posing different communicative challenges might require emergent languages which encode different levels of information, there is no existing work exploring the expressivity of the emergent languages. In this work, we propose a definition of partial order between expressivity based on the generalisation performance across different language games. We also validate the hypothesis that expressivity of emergent languages is a trade-off between the complexity and unpredictability of the context those languages are used in. Our second novel contribution is introducing contrastive loss into the implementation of referential games. We show that using our contrastive loss alleviates the collapse of message types seen using standard referential loss functions.

1 Introduction

The concept of “language game” was first introduced by [Wittgenstein (1954)] to explore the acquisition of meanings of language utterances as results of “rules” of games being played. Instantiating this concept with the signalling game design from [Lewis (1969)] enables linguists to explore the emergence of linguistic structure ([Kirby (2001); Kirby and Hurford (2002)] where artificial languages are represented as logic or symbolic systems. The great success of deep learning (DL) models on complicated cognitive tasks ([Krizhevsky et al. (2012); LeCun et al. (2015); Silver et al. (2016)] then inspired researchers to apply DL-based models to language games such that agents could invent communication protocols from scratch.

Preprint. Under review.
In language games implemented by the existing works (e.g., [Lazaridou et al., 2018; Graesser et al., 2019; Zhang et al., 2019; Lee et al., 2018; Yuan et al., 2020]), there are usually two types of agents: 1) speakers that emit messages based on their observations (e.g., a concatenation of two 5-digits-long one-hot vectors in Figure 1a); and 2) listeners that receive messages and take actions accordingly (e.g., reconstructing the input in Figure 1a or selecting the input among two samples in Figure 1b). Based on the goals for listeners, we can categorise most of the games to the following three types: 1) referential games where listeners need to select the object observed by the speaker among a set of candidates (e.g., [Lazaridou et al., 2017; Ren et al., 2020]; 2) reconstruction games where listeners need to reconstruct the speaker’s observation (e.g., [Chaabouni et al., 2020; Kharitonov et al., 2020]; and 3) navigation games where listeners need to go to the specified locations (e.g., [Lowe et al., 2017; Kajić et al., 2020]). We focus on referential and reconstruction games, illustrated in Figure 1, which have also been investigated in the linguistic community (e.g., [Winters et al., 2018; Kirby et al., 2014]).

Intuitively, the speaker’s messages must convey different levels of information for listeners to complete their task in these two different types of games. The reconstruction game requires speakers to express all the details about the original observation such that listeners can perfectly reconstruct it. Listeners in referential games, however, can differentiate the observation from distractors as long as messages from speakers encode some unique feature of it. Experiments with human participants show that emergent languages are sensitive to the requirements of the communicative tasks for which they are used, with languages developing in which only necessary information is encoded (Winters et al., 2018). Since languages are used to complete tasks (Wittgenstein, 1954), we argue that it is necessary to explore how to facilitate an emergent language that is universally helpful for completing various types of games. For the purposes of the paper, we refer to such ability to encode task-relevant information about input space (e.g., structure, dimensionality, distribution of samples) as expressivity. In this work, we are going to explore this concept under the framework of DL-based language games.

As an initial step, we first propose a definition of partial orders between expressivity of emergent languages (Section 2.3), and we also explore the determining factors for expressivity. It has been shown by Winters et al. (2015) that the predictability of the context shapes the degree of signal autonomy in human experiments, which means that the information which can be inferred out from an emergent language does not need to be encoded by speakers. Therefore, in DL-based language games, we propose the following hypothesis about the determining factors for expressivity:

The expressivity of emergent languages is a trade-off between the complexity and the unpredictability of context in language games.

Contextual complexity and unpredictability are explained in more details in Section 2.4, but informally relate to the difficulty of distinguishing the referent from the context on any one trial (complexity), and the variability of context on a series of such trials (unpredictability). Through experiments controlling the complexity and unpredictability of context in the language games, we validate the above hypothesis. Given the hypothesis, we argue that the language games should be carefully designed in order to facilitate more expressive emergent languages.

---

1 The degree of signal autonomy refers to the capacity for utterances used in a natural language to be interpreted without contextual knowledge (Wray and Grace, 2007).

2 Complexity: for instance, the reconstruction game is more complex than the referential game, since the output space in is much larger than the candidate set.

3 Unpredictability: in this sense the context of referential game has higher unpredictability than reconstruction game, since the candidates constituted context would change in referential games whereas the output space for reconstruction keeps the same.
Furthermore, to overcome the technical limitations imposed by GPU memory size on large-scale games, another contribution of us is that we modify the contrastive loss function proposed by Chen et al. (2020) and apply it into referential games. We also show that our contrastive loss is equivalent to the loss function applied by most of the existing works, e.g. Havrylov and Titov (2017), Li and Bowling (2019), Ren et al. (2020), Guo et al. (2020) while its space complexity (in the algorithmic sense) is lower.

2 Methodology

All the simulation models we report here are illustrated in Figure 2. The shared elements of the method are described in Section 2.1 and the differences between the games in Section 2.2. Section 2.3 then gives our definition of expressivity in terms of this experimental paradigm, and Section 2.4 specifies our trade-off hypothesis (given informally above) with reference to this modelling framework. In Section 2.5 we illustrate the experiment used to verify the hypothesis.

2.1 Elements and Configurations of Our Games

Universal components: As shown in Figure 2 for whichever type of language game, there are 4 universally essential components: 1) input space $X$ from which the speaker’s observations are drawn, which consists of 10,000 samples, where each $x \in X$ is a concatenation of 4 one-hot vectors whose length is 10; 2) message space $M$ consists of $10^6$ 6-tokens-long sequences $m$ (called as a message) where the size of the token inventory is 10; note that the tokens are initially meaningless, and meaning emerges through the negotiation of a communication protocol between speaker and listener; 3) speaker $S$ consists of both a multi layer perceptron (MLP) for encoding the 40-digits-long input $x$ onto a 256-digits-long embedding $h^S$, and a decoder for generating a message $m$ based on long-short term memory (LSTM) network (Hochreiter and Schmidhuber, 1997); iv) listener $L$ constituted by a LSTM-based sequence encoder which encodes $m$ into a 256-digits-long embedding $h^L$, and a game-specific action module which we will define for different games in Section 2.2.

Definition of an emergent language: Following e.g., Ren et al. (2020), we define an emergent language $L$ as a mapping function from the input space $X$ to the message space $M$, i.e. $L: X \rightarrow M$, and it can be represented as $\{(x_i, L(x_i))\}_{i \in \mathbb{X}}$. Note that $L$ could be a non-injective mapping function, i.e. it is possible for two different inputs to be mapped to an identical message. To distinguish between the messages emitted by a speaker in one trial (which might recur) and the unique message instances in $M$, we refer to a unique message instance as a "message type".

Optimisation: To overcome the discrete channel issue, we apply the Gumbel-Softmax trick proposed by Jang et al. (2017) to back-propagate the gradients from $L$ to $S$, and the temperature hyper-parameter $\tau$ is set to 1.0. As for updating the parameters, we use the Adam algorithm introduced by Kingma and Ba (2014), and the learning rate is set to $10^{-4}$.

Our implementation of games bases on the framework EGG developed by Kharitonov et al. (2019) under the MIT license. The experiments cost 1,519 hours on Nvidia Tesla P100.

According to the results from Chaabouni et al. (2020), an input space containing 10,000 samples is large enough for neural models to achieve > 99% generalisation accuracy.
2.2 Different Types of Games

2.2.1 Referential Game

In addition to the four universal components, referential games (following e.g. Havrylov and Titov [2017]) include another component: a candidate set \( D \subseteq X \) consists of one target input \( x_t \) and \(|D| - 1\) distractors \( \{x_1, x_2, \ldots, x_{|D|-1}\} \) sampled uniformly at random from \( X \) without replacement. The action module of listener is a \(|D|\)-channel classifier where the probability of choosing a candidate, i.e. \( c_i \in \{1, 2, \ldots, |D|\} \), is defined by the following equation:

\[
p(c_i | x_t, m) \propto \exp E(h_m^L \cdot f(x_i)) = \exp \left( h_m^L \cdot f(x_i) \right)
\]

where \( h_m^L \) is the embedding for the message \( m \) obtained from the sequence encoder of listener \( L \), and \( f(\cdot) \) is the MLP-based encoding function of \( L \) for candidates \( x \in D \). Since the messages are interpreted together with a candidate set, we refer to the candidate sets as the context in referential games. In the same way that synonymous words have closer embeddings (Mikolov et al., 2013), if a candidate has an embedding closer to message \( m \), the probability mass for predicting it would then be higher. Hence, the precaled probability mass is inversely proportional to the distances, e.g. the dot produce in the Equation (1) above, between the embeddings of \( m \) and all candidates.

By comparing the observation above with the contrastive loss function proposed by Hadsell et al. (2006), we find that the aim of the embeddings in referential games is the same as with contrastive loss, i.e. to make the distance between positive pairs (targets and their corresponding messages) closer while keeping the embeddings for negative pairs (distractors and the messages) as far apart as possible. To effectively validate our hypothesis about the determining factors of expressivity, we need to include the whole input space \( X \) as the candidates set \( D \) in which case the data would become too large to be stored in GPU memory using an implementation like (Havrylov and Titov, 2017) when the batch size is large. To overcome these memory issues, based on the analogy between conventional referential game implementation and contrastive loss, we apply a contrastive loss similar to (Chen et al., 2020) in referential games. Suppose that we have a batch of input samples \( B = \{x_1, x_2, \ldots, x_i, \ldots, x_{|B|}\} \) and the corresponding messages from the speaker are \( \{m_1, m_2, \ldots, m_i, \ldots, m_{|B|}\} \) which would be further encoded into \( \{h_{m_1}^L, h_{m_2}^L, \ldots, h_{m_i}^L, \ldots, h_{m_{|B|}}^L\} \) by the listener \( L \). Then the loss function for a sample \( x_t \) is defined based on a Softmax function:

\[
\ell_t = - \log \frac{\exp \left( h_{m_t}^L \cdot f^L(x_t) \right)}{\sum_{j=1}^{|B|} \exp \left( h_{m_j}^L \cdot f^L(x_t) \right)}
\]

where \( f^L(\cdot) \) is the encoding function of listener \( L \) for candidates. In this way, the number of candidates \(|D|\) is exactly the batch size \(|B|\) during training.

2.2.2 Reconstruction Game

The reconstruction game is constituted by only the four universal components introduced in Section 2.1. Although there is also an LSTM-based sequence encoder in the listener \( L \) in reconstruction game, the action module is a generator instead of a classifier, as shown in Figure 2. In this work, since our inputs \( x \) are all 40-digits-long binary vectors, the action module is set to be an MLP whose output layer consists of 40 neurons, thus the reconstructed \( \hat{x} \) is a vector consisting of 40 digits whose values are all in the range \((0,1)\). The binary cross entropy loss function for \( \hat{x} \) is then calculated as:

\[
\ell = \frac{1}{40} \sum_{k=1}^{K=40} x^k \log(\hat{x}^k) + (1 - x^k) \log(1 - \hat{x}^k)
\]

where \( \hat{x}_k = \sigma(g^k(h_x^L)) \), \( \sigma \) is the Sigmoid function, and \( g(\cdot) \) represents the MLP for reconstruction inside \( L \) where \( g^k(\cdot) \) is the \( k \)-th dimension of its output. Since the messages are interpreted within the whole output space, we refer to the space of all possible outputs (\( \mathcal{O} \)) as the context in reconstruction game.

[6]The space complexity of referential loss given by Havrylov and Titov (2017) is \( \mathcal{O}(|D|^2) \).
2.3 Definition of Expressivity in Language Games

Following the intuition that the different types of games require messages to convey different amount of information about input space $\mathcal{X}$, mutual information (MI) may seem to be a good measurement for it. We, however, argue in this work that even for two emergent languages that are both deterministic and bijective mapping functions, i.e. they have the same MI value $\log(|\mathcal{X}|)$, their expressivity could still be different. Further discussion about MI can be found in Appendix C.

Since it is more challenging to directly measure the expressivity of emergent languages, we instead focus on the partial orders between them in this work. Inspired by a common practice in the transfer learning community [Pan and Yang, 2009], where models are trained on a source domain but evaluated on different domains, here we propose a definition of the partial order between the expressivity of two emergent languages $\mathcal{L}_A$ and $\mathcal{L}_B$, i.e. $\mathcal{E}_{\mathcal{L}_A}$ and $\mathcal{E}_{\mathcal{L}_B}$:

**Definition 2.1** ($\mathcal{E}_{\mathcal{L}_A}^g > \mathcal{E}_{\mathcal{L}_B}^g$). Let $g$ be an instance of language game, and $\mathcal{G}$ be a set of language game instances. Then, given $\mathcal{G}$, if the generalisation performance of $\mathcal{L}_A$ is better than $\mathcal{L}_B$ on some language games $\mathcal{G}'$, i.e. $\forall g \in \mathcal{G}', \mathcal{E}_{\mathcal{L}_A}^g > \mathcal{E}_{\mathcal{L}_B}^g$, where $\emptyset \subset \mathcal{G}' \subseteq \mathcal{G}$ and $\mathcal{G}$ denotes the generalisation performance, while there is no statistically significant difference between the converged generalisation performance of $\mathcal{L}_A$ and $\mathcal{L}_B$ on the remaining games, i.e. $\mathcal{E}_{\mathcal{L}_A}^g \approx \mathcal{E}_{\mathcal{L}_B}^g \forall g \in \mathcal{G}'$, we then say that expressivity of $\mathcal{L}_A$ is higher than $\mathcal{L}_B$ on $\mathcal{G}$, i.e. $\mathcal{E}_{\mathcal{L}_A} > \mathcal{E}_{\mathcal{L}_B}$. The metric of generalisation performance could be varied according to different types of games.

Briefly speaking, if one language performs better than the other on some games while they perform approximately the same on all games, we then say the expressivity of that language is higher than the other. Following this definition, there are several possible relationships between the expressivity of two languages $\mathcal{L}_A$ and $\mathcal{L}_B$: i) $\mathcal{E}_{\mathcal{L}_A} > \mathcal{E}_{\mathcal{L}_B}$, defined as above; ii) $\mathcal{E}_{\mathcal{L}_A} = \mathcal{E}_{\mathcal{L}_B}$, if $\mathcal{E}_{\mathcal{L}_A} \approx \mathcal{E}_{\mathcal{L}_B} \forall g \in \mathcal{G}$; iii) $\mathcal{E}_{\mathcal{L}_A} < \mathcal{E}_{\mathcal{L}_B}$, defined as above; iv) $\mathcal{E}_{\mathcal{L}_A}$ is not comparable to $\mathcal{E}_{\mathcal{L}_B}$ ($\mathcal{E}_{\mathcal{L}_A} \neq \mathcal{E}_{\mathcal{L}_B}$), if propositions $\exists g' \in \mathcal{G}$, s.t. $\mathcal{E}_{\mathcal{L}_A}^{g'} > \mathcal{E}_{\mathcal{L}_B}^{g'}$ and $\exists g'' \in \mathcal{G}$, s.t. $\mathcal{E}_{\mathcal{L}_B}^{g''} > \mathcal{E}_{\mathcal{L}_A}^{g''}$ are both true.

2.4 Trade-off Hypothesis of Expressivity

As illustrated in Section 2.2.1 and 2.2.2, in this work we restrict the concept of context to: i) the candidate set $D$ for listeners in referential games; and ii) space of all possible outputs, i.e. $\mathcal{O} = \{o_1, o_2, \ldots, o_{|\mathcal{O}|}\}$, for listeners in reconstruction game. For referential games, it is then straightforward to observe that both complexity and unpredictability of context can be related to the size of candidate set $|D|$, following: i) the fact that it requires less information to select $x_t$ from $\{x_t, x_d\}$ than $\{x_t, x_{d1}, x_{d2}, \ldots, x_{d4099}\}$, as it is more probable that the latter set contains an $x_d$ that is more similar to $x_t$, i.e. the complexity is a monotonously increasing function of $|D|$; and ii) the fact that an $x_d$ is more probable to appear again in the next round of game since the sampling procedure of distractors follows a Bernoulli distribution whose mean is $\frac{|D|}{|X|}$, i.e. unpredictability of context is a monotonously decreasing function of $|D|$. As for reconstruction game, although its context’s complexity is very high, i.e. $|\mathcal{O}| = 2^{40}$, the predictability of its context is also very high since the inputs $\mathcal{X}$ are identical in every epoch. Note that although the inputs are also identical for every epoch in referential games, the listener would face different context in every batch since the candidates are randomly sampled.

Following the references of contextual complexity and unpredictability above as well as Definition 2.1 proposed in Section 2.3, given our hypothesis we can expect a $|D| \in (2, |\mathcal{X}|) \subset \mathbb{Z}^+$ such that a referential game with $|D|$ candidates can facilitate an emergent language whose expressivity is higher than the ones from the reconstruction game or referential games with most complex ($|D| = |\mathcal{X}|$) or most unpredictable ($|D| = 2$) context.

2.5 Language Transfer Experiment

To verify our hypothesis, we transfer the language which emerges in one game to the other, of which the procedure is illustrated in Experiment [1]. The results will be shown and discussed in Section 3.
Experiment 1: Procedure of the language transfer experiment

Input: A set of source game \( G_s \), a set of target game \( G_t \)

for every game \( g_i^s \) in \( G_s \) do

1. initialise a new speaker and listener for \( g_i^s \), and train them to play \( g_i^s \) with the whole \( X \);
2. after the agents converge on \( g_i^s \), record \( L = (x, m) \forall x \in X \);
3. randomly shuffle and split \( L \) into 2 disjoint sets \( L_{train} \) and \( L_{test} \) where \(|L_{train}| = 90\% \cdot |L|\);
4. for every game \( g_j^t \) in \( G_t \) do

   1. initialise a new listener for \( g_j^t \);
   2. train the listener with \( L_{train} \) to complete \( g_j^t \);
   3. record the performance of listener on \( L_{test} \) as the generalisation performance of \( g_i^s \) on \( g_j^t \);

end \( g_i^s \);
end

"refer10", "refer100", "refer1000", "refer2500", "refer7500", "refer10000"}. The emergent language whose source game is a \( g \in G \) is also named by the type of its source, e.g. "refer10 language" represents the language which emerges in referential games whose \(|D| = 10\). The language transfer procedure in our implementation is to train new listener to: i) reconstruct the inputs given only the messages; ii) select the inputs among the candidates sets given only the messages. As for the performance metrics, we use accuracy in referential games, and binary cross entropy subtracted by 1 in reconstruction game.

3 Results & Discussion

To alleviate the effect from randomness as much as possible, all the following results are obtained with 6 different random seeds. All values are averaged across the seeds, and the corresponding standard deviation (SD) are also provided.

3.1 Expressivity is a trade-off between contextual complexity and unpredictability

The raw results of language transfer experiment are given in Table 2 in Appendix A. We provide two views of these results as follows: 1) how the generalisation performance of a language from a source game changes over different target games in Figure 3 and 2) how the generalisation performance of languages from different source games change on the same target game in Figure 4.

We first illustrate the partial order between the expressivity of different languages in Figure 3. Although recon language performs consistently worse than some referential languages, e.g. ‘refer1000’ and ‘refer2500’, on referential games, its performance on reconstruction game is the best, thus its expressivity is not comparable with the others according to our definition of expressivity, as defined in Section 2.3. For referential languages, it is very clear that the ‘refer2’, ‘refer10’, and ‘refer100’ performs worse than the others on referential games with more candidates than their sources. Combining the previous fact with the fact that ‘refer7500’ and ‘refer10000’ perform worse than ‘refer1000’, ‘refer2500’, and ‘refer5000’ shows that increasing the size of candidate set \(|D|\) would not always benefit the expressivity. As for ‘refer1000’, ‘refer2500’, and ‘refer5000’, there is no statistically significant difference between their performance on the simpler referential games, and they intersect on some games, thus their expressivity are approximately the same.

As shown in Figure 4, on whichever type of game, the peak of the curves is always among ‘refer1000’, ‘refer2500’, or ‘refer5000’, which means that the best expressivity always emerges in these 3 types of games. Considering that the complexity of context in referential game is a monotonously increasing function of the \(|D|\) while the contextual unpredictability is a monotonously decreasing of it, the results shown in Figure 4 support our hypothesis, i.e. the expressivity is a trade-off between the contextual complexity and unpredictability. To be specific, although context of ‘refer2’, ‘refer10’, and ‘refer100’ have high unpredictability, their complexity is low thus the languages have lower expressivity. On the other hand, context of ‘refer7500’ and ‘refer10000’ have high complexity, but expressivity of neither
language is the highest due to the high predictability of the context in these games. We argue here that unpredictability of context could help to incentivise the agents to encode more information into the messages such that the messages could overcome the uncertainty of contexts and be interpreted in various contexts. Regarding the expressivity of reconstruction language, we argue that its expressivity suffers from a relatively low complexity, i.e. \( |X| \), thus has actually not been maximised during the training and performs worse than some referential languages on referential games. However, an important fact about ‘recon’ is that although its expected generalisation performance of recon is not as good as some referential languages, its standard deviation is quite large as shown in Table 2, which indicates that the transferring procedure of ‘recon’ to referential games is not very stable. Thus, it is possible to obtain a ‘recon’ which is more expressive than referential languages in some cases.

3.2 Degree of degeneracy affects but does not fully determine the expressivity

To further explore the determining factors for the expressivity, inspired by Kirby et al. (2015), the first factor we explore is the degree of degeneracy (i.e. the degree of ambiguity) of the languages. As a language is defined as a mapping function \( \mathcal{L} : \mathcal{X} \rightarrow \mathcal{M} \), the degree of its degeneracy could be measured by the number of distinct message types.

As shown in the Table 1 in referential languages, the degeneracy degree decreases rapidly with the increase of the contextual complexity of the source games, and reaches a ceiling around \( |D| \geq 1,000 \). There is a positive correlation between the number of message types and expressivity for the languages with low complexity, which indicates that degree of degeneracy influences the expressivity of these languages. However, the fact that the average number of message types on refer10000 is higher than refer1000, while the expressivity of ‘refer10000’ is higher than ‘refer1000’, i.e. emergent languages having lower level of degeneracy does not necessarily have higher expressivity, indicates that degeneracy degree of one language cannot fully determine its expressivity.

\[ |X| \leq \frac{|\mathcal{O}|}{|\mathcal{X}|} \times \frac{|\mathcal{X}|}{|\mathcal{X}|}, \text{ where } |\mathcal{O}| = 2^{40}, \ |\mathcal{X}| = 10000, \text{ and } |\mathcal{D}| \in [2, 10000]. \]
Figure 4: Generalisation performance of language from different source games on the same target game. Each line represents a kind of target game, and x-axis indicates the type of source games. The two y-axis have the same meaning as the ones in Figure 3. Note that when target game is recon, i.e. the red line, the values should be read from the right y-axis. In all target games except ‘recon’, the best generalisation performance is always from ‘refer1000’, ‘refer2500’ or ‘refer5000’, but not the most predictable or complex games.

Table 1: Mean, 25th-percentile, and 75th-percentile of the distributions of message types numbers from different types of source game.

It is interesting that the degeneracy degree of ‘recon’ is similar to ‘refer100’, and is obviously lower than the more complicated referential languages, while its expressivity is the best when the target game is a reconstruction game. However, like its language transfer performance, reconstruction language’s degeneracy degree also has a higher variance, which is indicated by its 25/75-th percentiles in Table 1. One possible explanation to both phenomena is that the relatively low complexity (|X| = 10^4) makes the training procedure on reconstruction game more flexible thus suffers from high variance.

Our results also indicate that it is necessary to establish a referential game with candidate sets containing enough many distractors to guarantee that the emergent language could be as unambiguous as possible. As far as we know, the existing works do not investigate the effects of the size of candidate sets, e.g. [Lee et al. (2018)] set |D| = 2, [Li and Bowling (2019)] set |D| = 5, and |D| ≤ 20 is used by [Lazaridou et al. (2018)]. Given our results, our heuristic is that |D| should be higher than either 1000 for large input spaces or 1/10|X| for smaller ones.

### 3.3 Structure degree of mappings of different languages

Since the degenerate degree is not the only factor determining expressivity, another factor to be considered is how the mappings of a language L structured after the training procedure of agents on source games. According to the cardinality of the mappings of L, we can divide them into two disjoint sets: i) one-to-one mappings, i.e. an input is mapped to a unique message; and ii) many-to-one mappings (a.k.a degenerate components), i.e. several inputs are mapped to the same message instance. In this work, we only focus on the many-to-one mappings.

Given the objectives of games, for the degenerate components in an emergent language, a message m being mapped to several closely-related inputs could imply that it captures common features among these inputs. Suppose that several inputs X_K = {x_1, ..., x_K} are mapped to the same message m in a converged language L, we hypothesise that the average distances between every pair of messages, e.g. \[ \frac{1}{|X_K|^2} \sum_{i,j \in \{1, ..., K\}} d(x_i, x_j), \] would become smaller after training, compared with their random initial values. Therefore, we compare the averaged distances between meanings of
degenerate components as well as the frequency of degenerate components at the beginning and end of training. Results on ‘recon’ and ‘refer1000’ are shown in Figure 5.

![Figure 5](image_url)

**Figure 5**: Average distances between the meanings and statistics about frequency of Top-10 degenerate components at the beginning/end of training on ‘refer1000’ and ‘recon’. The bars indicate the number of meanings one message type corresponds to, i.e. the frequency of degenerate components, and the black lines indicate the corresponding SD. The numbers on the top of bars, however, are the mean distances between those meanings with their SD.

By comparing the data of beginning and end of training in Figure 5, we can easily observe that the averaged distance decreased a lot (shown by the small numbers on red bars) throughout the training in both games, which indicates that the degenerate components actually became more although not fully structured. Furthermore, it can also be observed that the averaged distances at the end of training on ‘recon’ is smaller than on ‘refer1000’, while ‘recon’ has a higher degree of degeneracy (shown by that bars in Figure 5b are higher than the ones in Figure 5a). Combining this observation with the result from Section 3.2, it is reasonable to hypothesise that reconstruction game requires more structured mappings. Another observation we have limited understanding of is that ‘refer1000’ becomes more ambiguous after training, although its accuracy does improve to 100%.

### 3.4 Contrastive loss alleviates the collapse of message types

As we use our contrastive loss instead of the conventional referential loss applied by (e.g. Havrylov and Titov 2017; Ren et al. 2020), we also compare the behaviours of both loss functions on $G = \{ \text{‘recon’, ‘refer2’, ‘refer10’, ‘refer100’} \}$. We observe that contrastive loss is more efficient on removing degenerate components in large-scale games (where $|D| \geq 100$), and can better avoid the collapse of the number of message types. To be specific, as shown in Figure 6b, the numbers of message types collapses to less than 500 on both reconstruction and referential games with conventional referential loss. They, however, would only decrease to roughly 5000 on ‘refer10’ and ‘refer1000’ with contrastive loss as shown in Figure 6a. The contrastive loss can also make the training of referential game more stable, as illustrated by the smaller variance in Figure 6a.

**Figure 6**: How number of message types change over training epochs with different loss functions. The lines are the means over 6 runs and shadow areas indicate the corresponding standard deviation.
4 Conclusion & Future Work

According to our knowledge, this is the first work exploring the expressivity of emergent languages from different types of language games involving DL-based agents. We first defined the partial order between expressivity of different emergent languages based on the generalisation performance across a set of games, and proposed a hypothesis about the factors influencing the expressivity of emergent languages. Through a series of experiments on a reconstruction game and referential games with varying numbers of candidates, we then validated that the expressivity at first increases and then decreases as a function of the size of candidate sets, which indicates that expressivity is indeed a trade-off between the complexity and unpredictability of context in language games. After analysing the data on various target games, we also pointed out that the contextual complexity of language games, especially referential games, should be large enough such that we could facilitate more expressive languages. We further explored the degeneracy and structure degree of the mappings constituting different languages, and found that both degree are influenced by the types of games. To overcome the memory inefficiency issue caused by the conventional referential loss function, we introduced a contrastive loss into our implementation, and showed its effectiveness at avoiding the collapse of number of message types.

Since this is a step towards defining and understanding the expressivity of emergent languages, there are still some questions unanswered by this work. For example, although we show that neither of complexity nor unpredictability can fully determine the expressivity of emergent languages. We still do not understand how they affect the expressivity, and there is no quantitative measurement for such effects. More importantly, we lack understanding of the structure of mappings constituting a language, especially when the languages are generated or encoded by neural networks. Last but not least, since harder tasks don’t always lead to higher expressivity, it may imply that we need to carefully design: i) the pretraining task for neural language models in order to facilitate the best performance of models on downstream tasks; ii) curriculum learning for multi-agent reinforcement learning algorithms enhanced by emergent communication techniques (e.g. Evtimova et al. 2018). We argue that the expressivity of languages in the above scenarios still needs further exploration in order to maximise the performance of the aforementioned systems.

Table 2: Mean and standard deviation σ of generalisation performance of language games on each other.

B Message-meaning mappings before and after training

Although we show the average distances between the meanings of top-10 degenerate components in different games in Figure 5, we here provide some further visualisation to illustrate it. We first map all the meanings in X to a 2D space by t-SNE proposed by Van der Maaten and Hinton (2008). Then, for the meanings corresponding to the top-10 degenerate messages, we plot them with the same colour. Limited to the space, we choose the most typical language games, i.e. ‘recon’ (the only reconstruction language), ‘refer2’ (most ambiguous one), and ‘refer1000’ (most expressive referential language), and the results are shown in Figure 7.

The distances at the beginning and end of the training are given in the left and right column respectively. By carefully observing the distances between the dots with same colour, we can see that they become closer to each other after the training procedure. Among the three types of languages, number of dots in ‘refer2’ is the most, which indicates that it is the most ambiguous language, and number of dots in ‘refer1000’ is the least, which indicates that it is the most unambiguous language. This also matches with the quantitative results we show in Table 1. Furthermore, we can also see that the distances between the same coloured dots in ‘recon’-end is the least, which also matches our result shown in Figure 5.

C Mutual information is insufficient

In Section 2.3 we mentioned that MI cannot completely reflect the expressivity of an emergent language. Here, we provide more detailed explanations. On one hand, higher MI value does
Figure 7: Visualisation of the distances between meanings of same messages by t-SNE. The left column is the beginning of training, and the right column is the end of training. The messages are given in the legend, and meanings of same message are plotted in the same colour.

not necessarily mean more task-relevant information, e.g. encoding the colours in messages is unnecessary for tasks involving only the shapes of inputs although it provides more information. On the other hand, not only the determinacy of the mappings matters for generalising them, but also
the structures, e.g. it would be easier for humans to extrapolate compositional languages to novel concepts than holistic ones although they are both unambiguous. In the following paragraphs, we will give more reasoning and empirical evidence to support our claim.

Following the mapping function definition of emergent languages illustrated in Section 2.1, suppose that we get a message type collection \( M \in \mathcal{M} \) in some training epoch, the calculation of the mutual information between \( M \) and \( \mathcal{X} \) is given as follows:

\[
I(M|\mathcal{X}) = \sum_{x \in \mathcal{X}} \sum_{m \in M} p(x, m) \log \frac{p(x, m)}{p(x)p(m)} = \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \sum_{m \in M} \frac{1}{|M|} \log \frac{p(x, m)}{p(x)p(m)}
\]

\[
= \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \sum_{m \in M} \log \frac{p(x, m)}{p(x)p(m)} = \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \sum_{m \in M} \left( \log p(x, m) - \log p(x) - \log p(m) \right)
\]

\[
= - \sum_{m \in M} \log p(m) - \sum_{m \in M} \log f(m) = - \sum_{m \in M} \left( \log f(m) - \log |M| \right)
\]

\[
= \sum_{m \in M} \left( \log |M| - \log f(m) \right)
\]

(4)

where \( p(x) = \frac{1}{|\mathcal{X}|} \) as \( x \) follows a uniform distribution over the input space, and \( p(x, m) = \frac{1}{|M|} \) since every \( x \) is mapped to a message.

By observing the above equation, it is straightforward to see that the MI value is decided by the number of message types and the degeneracy degree of the ambiguous messages. Therefore, if two emergent languages have approximately the same number of messages types (as shown in Table 1) and degeneracy degree, the MI values for these two languages should also be the same. However, as we illustrate in Section 3.2 that degree of degeneracy cannot fully determine the expressivity of emergent languages, we can then deduce that MI cannot fully measure the expressivity of emergent languages.

To provide more empirical evidence to support our claim, we tracked the MI values over training epochs, and the results are shown in the following Figure 8. As we can see, there is no statistically significant difference between the MI values of 'referX' (where \( X \geq 1,000 \)) while we can show that their expressivity is different in Section 2.5.

Table 3: Converged MI values of different types of games. Both mean and standard deviation (\( \sigma \)) are given.

D Varying the capacity of channel and network

To verify that our findings are robust to the capacity of the communication channel and agents, we also run some extra experiments on the following different configurations of referential games:

1. **larger channel capacity**: set the length of messages to 8 and size of token inventory to 20, thus the size of message space becomes \( 20^8 \);
2. **larger agent capacity**: set the hidden layer size to 128, thus the capacity of both speaker and listener become larger than the original setting (256);
3. **larger channel&agent capacity**: do the above two changes at the same time.

Since our key findings are about the generalisation performance between recon1000, recon2500, and recon10000, we just run these extra experiments on a game set \( G_{extra} = \)
Figure 8: Mutual information curves over training epochs in different types of games. The converged values are provided in Table 3.

{‘recon1000’, ‘recon2500’, ‘recon10000’) with multiple runs. The results of configuration 1, 2, and 3 are given in Figure 9, 10, and 11 respectively. It can be observed in all figures that ‘recon1000’ or ‘recon2500’ would always perform better than ‘recon10000’ on all kinds of target games, i.e. ‘recon1000’ or ‘recon2500’ always perform better than ‘recon10000’ on all of the above configurations. Therefore, we believe the key observation from Figure 3 hold for varying configurations of communication channel and capacity of agents, which means that our conclusions are robust to the configuration of language games.

Figure 9: Results of language transfer with larger channel capacity. Error bars indicate the standard deviation of the mean values.
Figure 10: Results of language transfer with larger agent capacity. Error bars indicate the standard deviation of the mean values.

Figure 11: Results of language transfer with larger channel and agent capacity. Error bars indicate the standard deviation of the mean values.
