We propose a nanoscale rotor embedded between two ferromagnetic electrodes that is driven by spin injection. The spin-rotation coupling allows this nanorotor to continuously receive angular momentum from an injected spin under steady current flow between ferromagnetic electrodes in an antiparallel magnetization configuration. We develop a quantum theory of this angular momentum transfer and show that a relaxation process from a precession state into a sleeping top state is crucial for the efficient driving of the nanorotor by solving the master equation. Our work clarifies a general strategy for efficient driving of a nanorotor.

Introduction—A century ago, Einstein and de Haas demonstrated an angular momentum conversion phenomenon from magnetization to mechanical rotation [1], known as the Einstein–de Haas (EdH) effect. It has been observed in various magnetic systems [2] in a wide frequency range [3,4]. The EdH effect has also been utilized to generate mechanical torsion using electron spin relaxation on nanoscale objects [5–8], showing its potential as a driving force for mechanical vibrations in nanoelectromechanical systems (NEMS) [9].

Recently, mechanical rotational motion becomes a topic of nanoscale research [10,11]. Nano-carbon systems would be suitable as nanorotors, since they naturally contain nanorotor structures. For instance, the inner carbon nanotubes of multi-wall carbon nanotubes [12], or encapsulated fullerenes in carbon peapods [13] may work as nanorotors while the outer nanotubes may act as the frame since the inner carbons are low friction due to the van der Waals bonded frame [14]. However, efficient driving forces for the rotational motion are still lacking [10,11].

In this Letter, we develop a quantum theory to describe the microscopic mechanism of a nanorotor driven by electron spin injection via the EdH effect. As a feasible setup, we consider the double-wall carbon nanotube rotor shown in Fig. 1(a). Such a rotor is experimentally feasible in ferromagnetic-carbon nanotube hybrid systems [15]. To induce its rotational motion by electron spin injection, the nanorotor is embedded between two half-metallic ferromagnetic electrodes in an antiparallel magnetization configuration where the source and drain electrodes are oriented to $z$ and $-z$ directions, respectively. The rotor is driven by cyclic transitions among its three electronic states, as shown in Fig. 1(b). By applying a bias voltage between the electrodes, an electron with a spin $s_z = h/2$ tunnels from the left electrode into the nanorotor. This electron cannot tunnel to the drain electrode as long as its spin state remains $s_z = h/2$ because there is no electronic state for the spin $s_z = h/2$ in the half-metallic ferromagnetic drain. Electron accumulation by additional electron tunneling is also forbidden because of the Coulomb blockade in the nanorotor that acts like a quantum dot [10]. Therefore, only spin flipping of the injected electron enables continuous current flow through the rotor. Simultaneously with the single spin flipping ($s_z = h/2 \rightarrow -h/2$), angular momentum $h$ is eventually transferred from the injected electron to the mechanical rotational motion. Therefore, the current through the nanorotor is expected to be a driving force of the rotational motion of the nanorotor in this system. To confirm the feasibility of the above idea, a concrete theory for the microscopic mechanism of angular momentum transfer in the proposed setup is the subject in this Letter. The obtained conditions for efficient driving are expected to be common to other experimental realizations.

We shall treat the mechanical rotation of the nanorotor as that of a rigid-body [17]. In the present rotor, two kinds of rigid-body motion, i.e., precession and sleeping top as observed in classical tops, are possible at low energies (see the inset of Fig. 2). Here we describe how to induce the sleeping top state, a rotational motion of the nanorotor around a principal axis ($\zeta$) with the axis aligned with an outer axis ($z$). The process of angular momentum transfer is modeled by the spin-rotation coupling [18,19]

$$H_{\text{sr}} = -s \cdot \Omega,$$

which expresses how the electron spin $s$ interacts with an effective magnetic field induced by a mechanical rotation with angular velocity $\Omega$. As discussed later, a
the confinement potential, model a bearing of the rotor shaft, we shall introduce its states of the rotor, i.e., the eigenstates of Eq. (2), are denoted as \( |L, M, k \rangle \) for given \( M \) and \( k \). The number of additional electronic states of the rotor. The number of additional electrons injected into the rotor is restricted to 0 or 1 because of the Coulomb blockade. The spin-rotation coupling is described by the Hamiltonian \(-s \cdot \Omega\), and \( \Gamma_{L\uparrow}(\Gamma_{R\downarrow}) \) is an electron transfer rate between the rotor and the left(right) electrode.

relaxation mechanism for rotational motion in which angular momentum is exchanged with a bosonic bath can be incorporated to stabilize the rotational motion to the sleeping top state.

Model—Let \((\xi, \eta, \zeta)\) be the principal axes of inertia and \((x, y, z)\) be the laboratory coordinates. The moments of inertia of the corresponding principal axes are denoted as \( I_\xi, I_\eta, \) and \( I_\zeta \), respectively. We assume that the rotor is a symmetric top with \( I_\xi = I_\eta \). The rotational motion of the rotor is expressed by the following Hamiltonian \[ \text{(2)} \]

\[
H_R = \frac{1}{2I_\xi}L^2 + \frac{1}{2} \left( \frac{1}{I_\zeta} - \frac{1}{I_\xi} \right) L^2_\zeta,
\]

where \( L \) is the angular momentum operator of the rotor, and \( L_{\zeta} \) is the \( \zeta \) component of \( L \). The Hamiltonian \[ \text{(2)} \]

simply expresses free rotational motion. The quantum states of the rotor, i.e., the eigenstates of Eq. \[ \text{(2)} \], are denoted as \( |L, M, k \rangle \), which is specified by three quantum numbers, the amplitude of angular momentum \( L \), its \( z \) component \( M \), and the \( \zeta \) component \( k \) \[ \text{(2)} \]. To model a bearing of the rotor shaft, we shall introduce the confinement potential,

\[
H_{\text{pot}} = \frac{V}{2} (1 - \cos \theta),
\]

where \( V > 0 \) is a system-dependent value; we may choose \( V \) to be much larger than the typical energy scale of the rotation, as discussed later. The potential term has a minimum value at \( \theta = 0 \), where \( \theta \) is the angle between the \( \zeta \)- and \( z \)-axes. In the presence of the \( H_{\text{pot}} \), \( L \) is no longer a conserved quantity. In the following, we use \( I_\xi = I_\eta = 8.71 \times 10^4 \text{meV} \cdot \text{ps}^2 \) and \( I_\zeta = 4.29 \times 10^3 \text{meV} \cdot \text{ps}^2 \), which are the values for an open-ended carbon nanotube defined by the two integers \[ \text{(16)} \] \((n, m) = (6, 3)\) where the length \( L_{\text{NT}} = 4.75 \text{nm} \), and the potential \( V = 1000 \text{meV} \).

The eigenstates and eigenenergies of the rotor under the potential can be calculated by diagonalizing the Hamiltonian matrices for \( H_R + H_{\text{pot}} \) constructed from the basis states \( |L, M, k \rangle \) by utilizing the relations of the angular momentum operators and the states \[ \text{(21)} \] in each \((M, k)\) subspace. To obtain the energy spectrum, it is convenient to consider an approximation taking the leading-order terms around \( \theta = 0 \) in the Hamiltonian. The problem can then be mapped to that of a two-dimensional harmonic oscillator with the angular frequency \( \omega = (V/2I_\zeta)^{1/2} \) \[ \text{(22)} \]. Therefore, the analytical expression of the energy is given by,

\[
\varepsilon_{M,k,n} = (2n + |M - k| + 1) \hbar \omega + \frac{\hbar^2 k^2}{2I_\zeta}
\]

where \( n = 0, 1, 2, \cdots \) expresses the excitation in the harmonic oscillator for given \( M \) and \( k \). The eigenenergies in Eq. \[ \text{(1)} \] are shown as solid curves in Fig. \[ \text{2} \]. The lowest branch \( (M - k, n) = (0, 0) \) corresponds to the motion of sleeping top, stable rotation around the \( \zeta \)-axis with the \( \zeta \)-axis aligned to the \( z \)-axis. The upper branches shown in Fig. \[ \text{2} \] correspond to the precession state \( (M - k, n) = (\pm 1, 0) \) in which the angle between the \( z \)- and \( \zeta \)-axes is kept constant \[ \text{(23)} \]. When \( \omega \propto \sqrt{V} \)
is sufficiently large, each branch is energetically well separated.

In the setup of electron transport, the nanorotor functions as a quantum dot. The number of electrons in the nanorotor changes one by one. We shall model the electronic states in the nanorotor that contribute to transport with no \( n_d = 0 \) and a single electron \( n_d = 1 \). These states can be represented with the spin index, i.e., \( |s⟩ \), where \( s = 0 \) for \( n_d = 0 \) and \( s = ±1/2 \) for \( n_d = 1 \) (see Fig. 1(b)). The Hamiltonian of the electronic states is then written as \( H_s = \sum \epsilon|n_d(s)|s⟩⟨s| \). We shall choose \( \epsilon_0 = 0 \) to represent the resonant tunneling condition.

In the nanorotor, an electron spin interacts with the mechanical rotational motion via the spin-rotation coupling, Eq. (1). The quantum states of the nanorotor with a single electron are exactly obtained by diagonalizing the Hamiltonian matrices for \( H_R + H_{\text{pot}} + H_s + H_{\text{rt}} \). The eigenenergies are plotted in Fig. 2, which shows a small splitting of the energies between the spin up and down states as a result of the interaction. Note that the Hamiltonian conserves both \( M + s \) and \( k \). Therefore, the spin-rotation coupling can mix the states in \( (M, s) \) and \( (M + 2s, -s) \) subspaces. That is, the interaction exchanges the \( z \) component of the angular momentum between the electron and the mechanical rotation, but not the \( \zeta \) component in the present setup for the symmetric top. The angular-momentum exchange processes are diagrammatically shown in Fig. 2 with the arrow between (A) and (B). Note that the spin-rotation coupling can induce only the precession states. To drive sleeping top motion efficiently, we will consider a relaxation process from the higher to the lowest branches \((B) \) to \((C)\) in Fig. 2 in the later discussion.

**Rotational motion induced by spin injection** — The effect of the electrodes on the rotor states is accounted for by the following Hamiltonian

\[
H_e = \sum_{q,R,L} \epsilon_{rqs} c_{rqs}^\dagger c_{rqs} + \sum_{q,R,L} V_{rqs} c_{rqs}^\dagger d_s + \text{H.c.} \quad (5)
\]

The time evolution of the probability of the rotor states, \( w_i \), is described by the master equation,

\[
\frac{dw_i}{dt} = \sum_j \Gamma_{ij} w_j - \sum_j \Gamma_{ji} w_i, \quad (6)
\]

where \( i \) specifies an eigenstate of the rotor system including electronic states described by \( H_R + H_{\text{pot}} + H_s + H_{\text{rt}} \).

As is often observed in macroscopic systems, relaxation processes would exist that lower the energy of the rotational motion and stabilize the motion. To account for such processes, we explicitly consider a coupling to a bosonic bath modeled by the following Hamiltonian,

\[
H_B = \sum_q \hbar \omega_q b_q^\dagger b_q + \sum_q g_q \left( b_{-q}^\dagger + b_q \right) L_{+}^{(c)} + \text{H.c.} \quad (7)
\]

where \( L_{+}^{(c)}(L_{-}^{(c)}) \) is the angular momentum operator ascending (descending) the \( k \) states,

\[
L_{+}^{(c)} |L, M, k⟩ = \sqrt{L(L + 1) - k(k ± 1)} |L, M, k ± 1⟩, \quad (8)
\]

and the relaxation ratio is assumed to be \( \gamma^{(b)}(\varepsilon) = 2\pi\hbar g^2 \varepsilon \Theta(\varepsilon) \) for an Ohmic bath. As will be shown later, the process modeled by Eq. (7) induces a relaxation from the precession state to the sleeping top state. The effect of the relaxation expressed by Eq. (7) was clarified in a numerical simulation.

**Numerical simulation** — The time evolution of the rotational motion is calculated by solving the differential equation in Eq. (6). The temperature is set to \( T = 10 \) mK and the thermal equilibrium state of the rotor is chosen as the initial state. The tunnel couplings are chosen as \( \Gamma_{L+} = \Gamma_{R+} = 5 \times 10^{-5} \) meV, \( \Gamma_{L-} = \Gamma_{R-} = 0 \) to represent the ferromagnetic electrodes. The bias voltages are switched on at \( t = 0 \) and the expected values \( ⟨M⟩ \) and \( ⟨k⟩ \) are calculated as a function of time.

The time evolutions of the rotational motion in the absence of a relaxation \( (g = 0) \) and in the presence of a relaxation \( (g = 10^{-5}, g = 10^{-7}) \) are shown in Fig. 3(a)–(c). In the absence of the relaxation, \( ⟨M⟩ \) increases almost linearly with respect to time, keeping \( ⟨k⟩ \) almost zero. This means that the precession motion schematically represented in the upper inset of Fig. 2 develops. In contrast, in the presence of the relaxation, \( ⟨k⟩ \) increases with \( ⟨M⟩ \). That is, the rotation in the sleeping top state...
$M = k$ that is schematically represented in the lower inset of Fig. 2 (b) develops. Note that the relaxation process indeed lowers the total energy by making a transition to the lowest branch. These results clearly show the role of the relaxation in stabilizing the rotation to the sleeping top state.

As shown in Fig. 3 (c), $⟨k⟩$ develops linearly over a long time scale when the relaxation is present. We shall define a rotatability $R$ as the slope of $⟨k⟩$ in time as follows:

$$R ≡ \left( \frac{⟨k⟩}{t_∞} \right),$$

where $t_∞$ is taken to be a sufficiently long time after applying the bias voltage through which the time evolution develops linearly in time. $R$ can be used as an index for the ease of inducing the sleeping top rotation.

Figure 3 (d) shows the calculated $R$ for wide range of source and drain bias voltages for $g = 10^{-7}$ and $t_∞ = 10 \, \mu$s. Since the symmetry relation $R(\mu_L, \mu_R) = -R(\mu_R, \mu_L)$ holds, let us focus on the positive bias regime ($\mu_L > \mu_R$). It is clear that there is a contribution to rotatability in the low bias regime, $-0.05 \, \text{meV} < \mu_R < 0$, and it becomes large around the border $\mu_R \simeq -0.05 \, \text{meV}$. These behaviors can be understood as reflecting the number of current channels. An electron with $s = 1/2$ first tunnels from the left lead to the rotor, and the angular momentum transfer occurs because of the spin-rotation coupling: $(M, k, 1/2) \rightarrow (M + 1, k, -1/2)$. The resultant state is shown in Fig. 4 (a). In the lower bias regime, the following process mainly contributes to the current flow, as shown by channel 1 in Fig. 4: (i) Relaxation $(M + 1, k, -1/2) \rightarrow (M + 1, k + 1, -1/2)$ and (ii) the spin-flipped electron (with $s = -1/2$) tunnels from the rotor to the right lead. In addition to channel 1, channel 2 shown in Fig. 4 also opens when the bias of the right electrode $\mu_R$ is smaller than $-\hbar \omega$, which corresponds to the energy difference between the sleeping top and precession states.

**Summary** — We have proposed a nanoscale rotor embedded between two ferromagnetic electrodes that is driven by injected spins via the EdH effect. As a feasible example, we considered a double-wall carbon nanotube rotor and developed a microscopic theory, in which the nanorotor is modeled as an axisymmetric rigid-body. By solving the master equation, we found that the relaxation process from a precession state into a sleeping top state is crucial for efficient driving of the nanorotor.

The mechanism discussed in the Letter is not restricted to carbon nanotubes; it applies to other materials as well. Further, there could exist other angular momentum transfer processes from that of electron spin, such as spin-orbit and electron-phonon interactions, as well as nuclear spin interactions. The locally deformed structure would eventually relax into rotational motion. The process discussed in the Letter would be a minimal model for the momentum transfer from an electron to rotor that effectively includes the other possible processes. The present results offer a general strategy for the efficiently driving nanorotors in spin-based NEMS.

[17] Such a treatment is justified for nanoscaled objects such as a carbon nanotube in which the typical energy scale of lattice deformation (∼ meV) is much higher than that of the rotational motion.

[22] The coordinate \( \theta \) corresponds to the radial component of the mapped two-dimensional harmonic oscillator.

[23] The higher branches that are not shown in Fig. 2 include the nutation state in which \( \theta \) fluctuates around an average angle \( \bar{\theta} = \sqrt{\hbar|M-k|/I\omega} \).
