The entanglement of charge density wave (CDW), superconductivity, and topologically nontrivial electronic structure has recently been discovered in the kagome metal AV$_3$Sb$_5$ (A = K, Rb, Cs) family. With high-resolution angle-resolved photoemission spectroscopy, we study the electronic properties of CsV$_3$Sb$_5$ deep in the CDW state. The spectra around $\bar{K}$ is found to exhibit a peak-dip-hump structure associated with two separate branches of dispersion, demonstrating the isotropic CDW gap opening. The peak-dip-hump lineshape is contributed by linearly dispersive Dirac bands in the lower branch and a dispersionless flat band close to $E_F$ in the upper branch. The Fermi surface nesting scenario can account for these CDW-related features. The high density of states at $E_F$ associated with the flat band could play an essential role in the onset of superconductivity.

Recently, exploring the mutual interactions of different correlated states, magnetism, and non-trivial band topology became of great scientific interest, where novel quantum phenomena such as quantum anomalous Hall effect [1, 2], topological superconductivity [4–8], pair density wave [9, 10], and topological Chern magnetism [11, 12] have been intensively studied both in experiment and theory. A peak-dip-hump lineshape induced by symmetry breaking or bosonic mode coupling with the fermionic quasiparticle usually arises in the single-particle spectrum of the correlated electron systems such as actinides [13], cuprates [14, 15], iron chalcogenides [16], and colossal magnetoresistive manganites [17, 18]. Comprehensive knowledge of the renormalized electronic states and the redistribution of spectral weight inside the peak-dip-hump structure is essential for uncovering the microscopic mechanism of the intertwined correlated phases.

The kagome lattice, composed of two-dimensional (2D) network of corner-sharing triangles, is characterized by the coexistence of topologically protected Dirac bands and non-dispersing or flat bands, offering a fertile playground to study the interplay of electron correlations and non-trivial band topology [19]. Recently, the vanadium-based kagome metal AV$_3$Sb$_5$ (A = K, Rb, Cs) family with a non-zero $Z_2$ topological invariant has been discovered to host both charge density wave (CDW) and superconductivity, arousing numerous interests in the community [20–22]. Scanning tunneling microscopy (STM) [32] and x-ray scattering measurements [33] have demonstrated a three-dimensional (3D) charge modulation with a $2 \times 2 \times 2$ superstructure, which associates with the CDW formation at 80–110 K [20, 21, 23, 24, 39]. Interestingly, an optical spectroscopy study suggests the CDW is driven by the Peierls instability related to Fermi surface (FS) nesting [36], in favor of the theoretical calculations [43], but the softening of acoustic phonon is absent near the CDW vector [33], and no CDW amplitude mode is identified in an ultrafast pump-probe reflectivity experiment [44], pointing to an unconventional mechanism. Another SM measurement further suggests the presence of topological $2 \times 2$ CDW in KV$_3$Sb$_5$ [25], which energetically favors a chiral flux phase [45, 46] and may explain the observed large anomalous Hall effect [22, 26].

Several angle-resolved photoemission spectroscopy (ARPES) studies have been carried out to understand the fascinating CDW state [47–50]. Temperature-induced band renormalizations and van Hove singularities have been observed in RbV$_3$Sb$_5$ and CsV$_3$Sb$_5$ [50–52]. Meanwhile, many efforts have been devoted to resolving the CDW gap in CsV$_3$Sb$_5$. Nevertheless, two helium-lamp-based measurements report strong anisotropy of CDW gap opening around $\bar{K}$ [47, 48], in sharp contrast to the nearly isotropic gap behavior around $\bar{K}$ from another synchrotron-based study [49]. In order to clarify the discrepancy and gain insight into the underlying scenario of CDW order, further ARPES measurements are desired.

In this work, we perform a high-resolution ARPES study on CsV$_3$Sb$_5$. Deep in the CDW phase, we reveal a peak-dip-hump feature around $\bar{K}$ contributed by two separate branches of dispersion, showing the isotropic CDW gap opening. Linearly dispersive Dirac bands characterize the hump structure at higher binding energy, and the peak structure exhibits a flat band close to $E_F$. The origin of these features can be well explained by the FS nesting scenario. The high density of states (DOS) at $E_F$ associated with the flat band could promote the onset of superconductivity.

High-quality single crystals of CsV$_3$Sb$_5$ were grown by the self-flux method [39]. Detailed experimental methods can be...
To further unravel the underlying band structure, we record the ARPES spectra along the $\Gamma - \bar{K}$, and two of them ($\alpha$ and $\gamma$) could be degenerate near $E_F$. To study the CDW-related gap opening along the $\Gamma - \bar{K}$ direction, we use the photon energy of 50 eV, for the balance between intensity plots and corresponding second derivative plots are shown in Fig. 2. The overall band structure agrees with previous ARPES studies and theoretical calculations. As presented in Figs. 2(a) and 2(b), multiple linear band dispersions exist around $\bar{K}$, we denote them by $\alpha$, $\kappa$, and $\gamma$ as that in Figs. 1(d)-1(f). The intensity of $\kappa$ and $\gamma$ bands near $E_F$ is weak in the first BZ, consistent with the FS mapping result in Fig. 1(d). By extrapolating the branch of $\kappa$ band at higher binding energies and tracing the $\gamma$ band in the second BZ, we can expect three Dirac-like crossings around $\bar{K}$, which is further demonstrated by the band structure in the second BZ studied in Fig. 3. The $\alpha$ and $\kappa$ bands cross at $\sim$-0.20 eV, the $\kappa$ and $\gamma$ bands could be degenerate near $E_F$, and the crossing of two branches of $\gamma$ band locates at $\sim$-0.30 eV. When changing the energy from 0 to -0.10 eV, the $\kappa$ and $\gamma$ bands are non-degenerate, then define the middle and inner constant-energy sheets around $\bar{K}$, respectively [Fig. 1(e)]. After further decreasing the energy to -0.42 eV, which corresponds to the lower branches of the Dirac-cone structures, the $\alpha$ and $\kappa$ bands evolve into the middle and outer contours, respectively, while the $\gamma$ band still describes the inner pocket around $\bar{K}$ [Fig. 1(f)].

As suggested by the theoretical calculations in the CDW phase, which is found to favor the inverse Star of David distortion energetically, the band structure is strongly modified around $\bar{K}$ as compared to that in the pristine phase. The most prominent reconstruction is a large gap opening at the Dirac-like crossing located above $E_F$ along the $\bar{K} - \bar{M}$ direction. By comparing our experimental data with the calculations, the crossing corresponds to the one between the $\kappa$ and $\gamma$ bands. The zero-field resistivity exhibits metallic behavior above the superconducting transition temperature ($T_c \sim 2.5$ K) except a distinct kink at $\sim 92$ K, indicating the onset of CDW transition.

The constant-energy ARPES images at binding energies of 0, -0.10, and -0.42 eV are displayed in Figs. 1(d)-1(f), respectively, exhibiting the hexagonal symmetry and network topology with corner-sharing triangles expected from the kagome lattice. Focusing on the FS around $\bar{K}$, with monotonically decreasing the energy, the two Fermi contours ($\alpha$ and $\beta$) gradually evolve into three sheets ($\alpha$, $\kappa$, and $\gamma$). The evolution behavior indicates that there are three bands dispersing around $\bar{K}$, and two of them ($\kappa$ and $\gamma$) could be degenerate near $E_F$. To study the underlying band structure, we record the ARPES spectra along the $\Gamma - \bar{K} - \bar{M}$ and $\Gamma - \bar{M}$ directions. The

In the inset, with 50-eV photons. Besides the cut #1 (close to \(E_{\text{CsV}}\), where the black dots are determined from the EDCs in (b). Inset: Sketches of the inner FS around \(K\) with pristine BZ. (b)-(d) EDC plots of (a) taken at \(T = 1.4, 5,\) and 23 K, respectively. (e)-(h) Same as (a)-(d) recorded along cut #2, which is illustrated by the white arrow in the inset of (e).

To further determine how the energy gap and the peak-dip-hump feature are uniformly distributed around \(F\). Consequently, these CDW-related features of EDCs, we can determine the detailed band dispersions. In order to quantitatively examine the band structure and gap opening, the corresponding energy distribution curve (EDC) plot is presented in Fig. 3(b). By tracing the peak positions of EDCs, we can determine the detailed band dispersions. Indicated by the black curve, a distinct energy gap of \(\sim 30\) meV is resolved between the \(\beta\) band (\(-0.02\) eV below \(E_{F}\)) and the \(\kappa/\gamma\) band, where the degeneracy occurs at \(-0.05\) eV below \(E_{F}\). Intriguingly, we observe a peak-dip-hump feature around the energy gap, and the lineshape is contributed by the dispersionless \(\beta\) band close to \(E_{F}\) (peak) and the linearly dispersive \(\kappa/\gamma\) band at higher binding energy (hump).

To further determine how the energy gap and the peak-dip-hump structure distribute in momentum space, we perform a similar measurement along cut #2, illustrated by the white arrow in the inset of Fig. 3(e). The gap opening of \(\sim 30\) meV and the peak-dip-hump lineshape exhibit little change, as shown in Figs. 3(e) and 3(f). Consequently, these CDW-related features are uniformly distributed around \(K\) (momentum cuts along other directions around \(K\) show similar behaviors, not shown here). Then we carry out the temperature-dependent study of the band structure along cuts #1 \([\text{Figs. 3(b)-3(d)}]\) and #2 \([\text{Figs. 3(f)-3(h)}]\). As the temperature is increased from 1.4 K to 23 K, one can obtain that the energy gap remains unchanged, while the peak structure close to \(E_{F}\) becomes less prominent and the spectral weight in the dip structure gradually increases. The redistribution of spectral weight upon temperature may be due to the thermal peak broadening, showing that the peak-dip-hump structure is temperature sensitive and only visible deep in the CDW state.

The origin of the peak-dip-hump feature and flat band close to \(E_{F}\) can be well accounted for by the FS nesting scenario. From a Peierls perspective, the electronic susceptibility would develop a logarithmic divergence singularity at some well nested FS sheets, hence results in a CDW transition [54]. In this picture, the in-plane \(2 \times 2\) charge ordering wave vector \(q_{\text{CDW}} = (\pi, 0)\) of CsV\(_3\)Sb\(_5\) can connect the electronic states at neighboring \(M\) points, then the inter-band scattering would cause CDW [43]. To examine the nesting property of the overall FS topology, we sketch the FS above \(T_{\text{CDW}}\), and fold it by two representative \(q_{\text{CDW}}\) as shown in Fig. 4(a). One can obtain that nearly perfect nestings exist between the original \(\gamma^*\) and folded \(\alpha^*\) as well as the original \(\alpha^*\) and folded \(\gamma^*\). Consequently, upon entering the CDW phase, the interactions between nested bands result in gap opening and reconstructed FS in the CDW BZ as schematically shown in Fig. 4(b). However, since the modulation potential of CDW is weak in CsV\(_3\)Sb\(_5\) [44], such reconstructions in the small CDW BZs are not observed [thin dashed curves in Fig. 4(b)]. The pristine and CDW phases host similar FS topologies [thick solid curves in Figs. 4(a) and 4(b)], this is further supported by the spectral weight in the dip structure gradually increases. The redistribution of spectral weight upon temperature may be due to the thermal peak broadening, showing that the peak-dip-hump structure is temperature sensitive and only visible deep in the CDW state.

The origin of the peak-dip-hump feature and flat band close to \(E_{F}\) can be well accounted for by the FS nesting scenario. From a Peierls perspective, the electronic susceptibility would develop a logarithmic divergence singularity at some well nested FS sheets, hence results in a CDW transition [54]. In this picture, the in-plane \(2 \times 2\) charge ordering wave vector \(q_{\text{CDW}} = (\pi, 0)\) of CsV\(_3\)Sb\(_5\) can connect the electronic states at neighboring \(M\) points, then the inter-band scattering would cause CDW [43]. To examine the nesting property of the overall FS topology, we sketch the FS above \(T_{\text{CDW}}\), and fold it by two representative \(q_{\text{CDW}}\) as shown in Fig. 4(a). One can obtain that nearly perfect nestings exist between the original \(\gamma^*\) and folded \(\alpha^*\) as well as the original \(\alpha^*\) and folded \(\gamma^*\). Consequently, upon entering the CDW phase, the interactions between nested bands result in gap opening and reconstructed FS in the CDW BZ as schematically shown in Fig. 4(b). However, since the modulation potential of CDW is weak in CsV\(_3\)Sb\(_5\) [44], such reconstructions in the small CDW BZs are not observed [thin dashed curves in Fig. 4(b)]. The pristine and CDW phases host similar FS topologies [thick solid curves in Figs. 4(a) and 4(b)], this is further supported by the
similar FS in the pristine phase reported in Ref. [50]. Thus, the charge compensation in the pristine phase is little affected by the band folding effect associated with CDW due to the sizes of original FS components do not change significantly.

Since the band folding by $q_{\text{CDW}}$ is equivalent to that along the $\Gamma-\bar{K}$ direction with respect to the momentum cut connecting neighboring $\bar{M}$ points, we show the band structure cartoons along the $\Gamma-\bar{K}$ direction to clarify the detailed mechanism. We reconstruct the band structure ($\alpha^*, \kappa^*$, and $\gamma^*$) above $T_{\text{CDW}}$ in Fig. 4(c) and plot them in Fig. 4(d) together with the folded bands ($\alpha, \kappa^*, \gamma^*$) expected to emerge due to CDW order. It is seen that $\alpha^*$ will interact with $\gamma^*$ just below $E_F$, resulting in the CDW gap opening which leads to the flat band $\beta$ and peak-dip-hump lineshape. The $\kappa^*$ band does not have a “partner” to interact with in the CDW state and therefore remains as is, smearing out the peak-dip-hump lineshape at lower momentum values. Thus, the $\kappa$ feature in Fig. 4(e) actually represents a superposition of $\kappa^*$ and $\alpha^*$. Analogous peak-dip-hump structure is not resolved at equivalent momentum [$-0.4 \text{Å}^{-1}$ in Figs. 3(a) and 3(e)] where $\alpha^*$ should interact with $\gamma^*$, because the intensity of the former is very strong and the latter, being folded of $\gamma^*$, is vanishingly weak. Most of the folded bands are hardly observed in CsV$_3$Sb$_5$ because strongest features (e.g. $\alpha^*$) nearly overlap with already existing ones (e.g. $\kappa^*$) and the modulation potential appears to be weak [44]. The formation of the CDW gap can explain the band reconstructions reported in a recent ARPES study on CsV$_3$Sb$_5$ [50]. The gap size of ~30 meV is comparable with that in previous STM [25] and ARPES studies [49], but smaller than that determined by an optical spectroscopy measurement [36]. Note that theory predicts also a spin-orbit coupling (SOC) induced gap at the crossing of $\kappa^*$ and $\gamma^*$ in the pristine phase [43]. Existing ARPES data imply that this SOC gap is centered only slightly above $E_F$ at $T > T_{\text{CDW}}$ [50]. As schematically illustrated in Fig. S1 [53], the $\beta$ feature appears to be flattened by both gaps – from SOC gap above and from CDW gap below. However, since weaker features are not clearly resolved in our spectra, we leave only most pronounced of them in Fig. 4(e). Our data, together with earlier observations [25] [49] [50], suggest that the theory may overestimate both the energy position of SOC gap and the size of CDW gap.

Before closing, we discuss the implication of our results on the underlying superconductivity. Our observation of the CDW gap opening below $T_c$ demonstrates the coexistence of CDW and superconductivity in CsV$_3$Sb$_5$. We further make an attempt to detect the superconducting gap in the small CDW BZ. As presented in Fig. S2 [53], a leading edge shift of ~0.3-0.4 meV is observed on the electron FS at BZ center when going across $T_c$, showing the signature of superconducting gap opening. The gap size is consistent with that in recent STM studies [34] [42]. In a Bilbro-McMillan partial gaping scenario, the CDW would strongly compete with superconductivity for the FS [53]. However, the electronic states at $E_F$ are not depleted by the CDW order here. Instead, the formation of CDW seems to prepare the system for superconductivity by creating the flat band feature close to $E_F$. The occurrence of this CDW-related flat band is also energetically favorable as illustrated in Fig. S3 [53]. As is the case for most known superconductors, the near-$E_F$ DOS boosted by a saddle point or an extended flat region of the dispersion could play an important role in the superconductivity [56] [57]. We believe that the onset of superconductivity in CsV$_3$Sb$_5$ is closely related to the enhanced DOS associated with the flat band, which defines majority of the FS in the CDW state.

In summary, we demonstrate a peak-dip-hump lineshape related to the isotropic CDW gap opening around $\bar{K}$ deep in the CDW state of CsV$_3$Sb$_5$. We observe that linearly dispersive Dirac bands contribute to the hump structure, and the peak structure corresponds to a dispersionless flat band close to $E_F$. These spectral features arise from the nearly perfect FS nestings and the flat band provides high DOS promoting the onset of superconductivity. Our results put strong constraints on the theoretical model for solving the origin of CDW and superconductivity in A$\alpha$V$_3$Sb$_5$ compounds.
