**ABSTRACT**
When binary black holes merge in dense star clusters, their remnants can pair up with other black holes in the cluster, forming heavier and heavier black holes in a process called hierarchical merger. The most important condition for hierarchical merger to occur is that remnants formed by mergers are retained by the host star cluster. Using the publicly available gravitational-wave event database, we infer the magnitudes of kick velocities imparted to the remnant black holes due to anisotropic emission of gravitational waves and use that to quantify the retention probability of each event as a function of the escape speed of the star cluster. Among the GWTC-2 events, GW190814 provides the tightest constraint on the kick magnitude with \( V_{\text{kick}} = 73^{+11}_{-8} \) km/s at 90% credible level. We find that star clusters with escape speeds of 500 km/s can retain about 50% of the events in the second gravitational-wave transient catalog (GWTC-2). Using the escape speed distributions of nuclear star clusters and globular clusters, we find that \(~8\) remnants of GWTC-2 may be retained by the host star cluster if all GWTC-2 events occurred in nuclear (globular) clusters. Our study demonstrates the importance of folding in kick velocity inferences in future studies of hierarchical mergers.

**Keywords:** Gravitational Waves; Astrophysics

1. **INTRODUCTION**

Several of the stellar-mass compact binary mergers observed to date could have occurred in gravitationally-bound environments, such as globular clusters (GCs) or nuclear star clusters (NSCs) (Portegies Zwart & McMillan 2000; Downing et al. 2010; Rodriguez et al. 2015, 2016, 2018; Samsing 2018; Fragione & Koels 2018; Zevin et al. 2019; Antonini & Gieles 2020; Miller & Lauburg 2009; Petrovich & Antonini 2017; Arca-Sedda & Gualandris 2018). If the star cluster is dense enough, the remnant black hole formed by a merger can subsequently pair with another black hole (BH) via dynamical interactions, merging again under gravitational-wave radiation reaction (Doctor et al. 2019; Antonini et al. 2019; Fragione & Silk 2020; Mapelli et al. 2020). This can repeat, producing increasingly more massive black holes at each step—a process called hierarchical mergers

(Fragion et al. 2018a,b). Evidence of significant numbers of black holes formed via hierarchical mergers would strongly suggest that compact object binaries form dynamically in dense star clusters. This process can also lead to the formation of intermediate mass black holes (Miller & Hamilton 2002), which could in turn seed the formation of supermassive black holes (Bellovary et al. 2019).

The presence of heavy BHs (those with masses \( > 50M_\odot \)) in the second LIGO/Virgo Collaboration (LVC) Gravitational-Wave Transient Catalog (GWTC-2) (Abbott et al. 2020) has led to detailed investigation into hierarchical mergers (Gerosa et al. 2020; Kimball et al. 2020b). Evidence of significant numbers of black holes formed via hierarchical mergers would strongly suggest that compact object binaries form dynamically in dense star clusters. This process can also lead to the formation of intermediate mass black holes (Miller & Hamilton 2002), which could in turn seed the formation of supermassive black holes (Bellovary et al. 2019).

The presence of heavy BHs (those with masses \( > 50M_\odot \)) in the second LIGO/Virgo Collaboration (LVC) Gravitational-Wave Transient Catalog (GWTC-2) (Abbott et al. 2020) has led to detailed investigation into hierarchical mergers (Gerosa et al. 2020; Kimball et al. 2020a; Tiwari & Fairhurst 2020). Recent analyses (Kimball et al. 2020b) have found evidence of hierarchical mergers in six GWTC-2 events. This inference relies on assessing the consistency of the mass and spin parameter distributions with those expected from hierarchical mergers (Gerosa & Berti 2017; Fishbach et al. 2017).

It is well known that the anisotropic emission of gravitational waves (GWs) during the end-stages of binary
coalescence carries away linear momentum and produces a recoil or “kick” of the merger remnant (Fitchett 1983; Favata et al. 2004). This plays a decisive role in the hierarchical merger process, which cannot occur if a merger remnant is ejected from its dense stellar environment. Black hole kicks can reach hundreds to thousands of kilometers per second (Campanelli et al. 2007a; Gonzalez et al. 2007b; Tichy & Marronetti 2007; Lousto & Zlochower 2011; Lousto & Healy 2019). In comparison, globular clusters have escape speeds $\sim 2-180$ km/s, and nuclear star clusters have larger escape speeds $\sim 10-1000$ km/s (Antonini & Rasio 2016). For the hierarchical merger process to operate, the BH kick should not exceed the cluster escape speed (Merritt et al. 2004).

A direct detection of the GW kicks is very challenging as it would entail measuring either the very small Doppler shift in the frequencies of the quasi-normal modes of the remnant BHs (Favata 2009; Gerosa & Moore 2016), the rich structure in the higher-order modes of gravitational waves (Calderón Bustillo et al. 2018), or tracking certain post-merger features in the gravitational waveforms (Calderón Bustillo et al. 2019). However, numerical relativity (NR) provides useful fitting formulas (Campanelli et al. 2007b), expressing the remnant kick as a function of the mass ratio and spin configuration of the binary components. This permits inference of GW kicks for a binary black hole (BBH) merger, provided there are reasonably precise measurements of the mass and spin parameters (Varma et al. 2020).

Recently, Fragione & Loeb (2020) computed the kick velocity distributions of GWTC-2 events as a function of the spins of the binary components and studied the probability of retaining these mergers as a function of spin magnitudes. They found that only nuclear star clusters with escape speeds higher than $100$ km/s could retain the GWTC-2 merger remnants even for dimensionless spins as small as 0.1. Note that binaries containing higher-spinning BHs typically experience larger kicks as compared to binaries with low-spin BHs, and can thus be more easily ejected from clusters.

Doctor et al. (2021) mapped the properties of GWTC-2 BH remnants to the statistical properties of remnant BHs in our universe. They obtained the distribution of kick velocities of GWTC-2 events using NR surrogate waveform models (Varma et al. 2019b,a) and found that globular clusters and nuclear clusters can retain $\sim 4\%$ and $45\%$ of the remnants, respectively. They assumed the escape speeds of all globular clusters to be $50$ km/s and that of all nuclear clusters to be $250$ km/s.

Our primary goal is to compute the posterior distributions of the GWTC-2 remnant kicks using NR fitting formulas and deduce the probability that remnant BHs are retained by their host star clusters. This, in turn, will help us determine if GWTC-2 remnants can facilitate hierarchical mergers.

Specifically, we develop a framework to compute the probability that a BBH merger is retained by its environment (assuming the merger takes place inside a star cluster and that dynamical N-body interactions do not play a significant role in ejecting heavy BHs). This is applied to all BBHs in the GWTC-2 catalog, obtaining their individual retention probabilities as a function of the cluster escape speed. We also discuss what the kick velocities of the GWTC-2 population imply for different types of star clusters and their efficiency to retain BH remnants.

We find that BH kicks will not be a major obstacle for hierarchical mergers if star clusters with escape speeds $\gtrsim 500$ km/s are abundant in the universe and BBHs with masses characteristic of those in GWTC-2 primarily form in such clusters. We also find that among the six GWTC-2 events identified by Kimball et al. (2020b) as systems showing evidence for hierarchical mergers, all except GW190517_055101 may be retained by their host clusters with a probability $\sim 50\%$, paving the path for participating in further binary formation, provided they merged in clusters with escape speeds larger than $\sim 700$ km/s. With our present knowledge of the escape speed distribution of star clusters, $\sim 8$ (1) of the GWTC-2 remnants may be retained by nuclear (globular) clusters. We stress the importance of using kick velocity measurements as an ingredient in future studies of hierarchical black hole formation.

2. INFERRING RETENTION PROBABILITY FROM KICK POSTERIOR DISTRIBUTION

We first discuss how we infer the kick velocity probability distribution for a given GWTC-2 event. We then compute the retention probability of each BBH event as a function of the cluster escape speed $V_{\text{esc}}$.

2.1. Kick inference

The kick imparted by the GW linear momentum loss is described by fitting formulas based on NR simulations of BBHs (Gonzalez et al. 2007b; Campanelli et al. 2007b; Gonzalez et al. 2007a; Lousto & Zlochower 2008; Lousto et al. 2012a; Lousto & Zlochower 2013). We apply the kick magnitude of Campanelli et al. (2007b), summarized in Appendix A.

The kick velocity depends on the following parameters: the mass ratio $q$ ($\leq 1$), the dimensionless spin magnitudes $\chi_i$, the angles between the spin vectors and the total orbital angular momentum $\theta_1$, the difference
between the azimuthal angles of the two spin vectors, $\phi_{12}$; plus an additional parameter $\Theta$, which is the angle between $\Delta \times \mathbf{L}$ and a fiducial infall direction of the two BHs at merger (see Appendix A for the definition of $\Delta$ and $\mathbf{L}$). Here $i = 1, 2$ labels the primary or secondary BH. Currently the posterior samples of $\theta_i$ for GWTC-2 events are not available, but the posterior samples of $\theta_{LS}$ (the angles between the spin vectors and the direction of the Newtonian angular momentum $\hat{L}_N$) are accessible. Here we use the posterior samples for $\theta_{LS}$, assuming $\mathbf{L} \approx \hat{L}_N$ and $\theta_i \approx \theta_{LS}$. This will not affect our results. Note that the kick is independent of the binary’s total mass $M$.

In addition to feeding samples of $q$, $\chi_i$, $\theta_{LS}$, and $\phi_{12}$, into the kick fitting formula, we also need to know the parameter $\Theta$. As we cannot directly infer $\Theta$ from the posterior samples, we assume it is uniformly distributed between $[0, 2\pi]$ (Gerosa & Kesden 2016; Gerosa & Sesana 2015) when computing the posteriors of the kick magnitude via Eq. (A1).

Restricting to the 47 BBHs in GWTC-2 (Abbott et al. 2020), we construct probability density functions (PDFs) for the kick magnitude, using as input the posterior PDFs for the mass ratio and spin parameters of each BBH event. (See Appendix A for additional details on constructing the kick magnitude PDFs.)

Figure 1 shows some typical examples of the resulting kick PDFs $p(V_{kick})$ for a few selected GW events. GW190814 provides the best inference of the kick and has the lowest inferred kick. The former is due to the stringent constraint on the spin of its primary ($\chi_1 \leq 0.007$), and the latter is due to the small spin magnitude. As a check on our procedure, we compared our kick posteriors with those obtained using NRsurrogate posteriors for 22 events in GWTC-2 reported in LIGO Scientific Collaboration and Virgo Collaboration (2020) and the corresponding fits using Ref. Varma et al. (2019b,a). We find excellent agreement between both methods.

As the spins for several GW events are poorly constrained, our analysis risks returning posteriors that are prior dominated. We use the Jensen-Shannon (JS) divergence (Lin 1991) to quantify how informative are the posteriors compared to the priors, considering only those events that cross a JS divergence threshold of 0.007. This leaves 42 events for further analysis. See Appendix B for further discussion.

Given a posterior PDF $p(V_{kick})$ for the kick magnitude of each event, the corresponding cumulative distribution function (CDF) $F(v_*) = \int_0^{v_*} p(V_{kick}) dV_{kick}$ quantifies the probability that $V_{kick} \leq v_*$. Example CDFs are shown on the right panel of Fig. 1.

2.2. Retention probability of GWTC-2 events

Operating under the assumption that all reported GWTC-2 BBHs occur in star clusters with unknown escape speeds, we want to determine the probability that a particular GWTC-2 event (labelled by the index $j$) is retained by a cluster with escape speed $V_{esc}$. We call this the retention probability of the $j$th event. We additionally assume that each GWTC-2 merger is most
likely to occur in the dense core of a star cluster, so the escape speed is understood to be the speed to escape from the center of the cluster. Given these assumptions, the retention probability $P_{\text{ret},j}(V_{\text{esc}})$ of the $j$th event in a cluster with escape speed $V_{\text{esc}}$ is simply found by replacing $v_s \rightarrow V_{\text{esc}}$ in the CDF; i.e., $P_{\text{ret},j}(V_{\text{esc}}) = F(V_{\text{esc}})$.

To illustrate this, consider the CDF of GW190814 (Fig. 1 inset). Suppose a particular cluster has an escape speed $V_{\text{esc}} = 73$ km/s. Because the CDF for the GW190814 kick distribution indicates that there is $\approx 50\%$ probability that $V_{\text{kick}} < 73$ km/s, this implies that a cluster with $V_{\text{esc}} = 73$ km/s would retain this binary with $\approx 50\%$ probability. The kick CDF $F(v_s)$ for event $j$ is hence naturally mapped to the retention probability $P_{\text{ret},j}(V_{\text{esc}})$ of event $j$.

We apply this observation to the 42 BBHs in GWTC-2 with informative kick posteriors, mapping the kick magnitude CDFs to their retention probabilities. This result is shown in Fig. 2 for a selected sample of the 42 GWTC-2 events. (The 4 events highlighted in thick colored lines are representative examples of the range of kick velocity distributions; the thin gray curves are discussed below.) These retention probabilities help quantify, as a function of the cluster escape speed, the ability of these events to take part in future BBH mergers.

It is evident that GW190814 has the highest retention probability among the GWTC-2 events with informative kick posteriors. It would almost surely be retained by a cluster with an escape speed as low as 80 km/s. The lowest retention probability is for GW190517_055101, which would be retained at 50% probability by clusters with an escape speed of $\sim 1000$ km/s.

As these conclusions depend only weakly on the details of the clusters, our method provides a powerful diagnostic of the ability of star clusters to retain the BBH merger remnants. Retaining these remnants is an important prerequisite if they are to participate in subsequent BBH mergers.

### 2.3. Retention of likely hierarchical merger events

We now assess the retention probabilities of the six events reported in Kimball et al. (2020b) (and discussed earlier). Using the method of the previous section, we compute the kick PDFs for these six events and determine their retention probabilities $P_{\text{ret},j}(V_{\text{esc}})$ as a function of cluster escape speed. The result is shown in Fig. 2, where the grey lines represent five out of the six events that Kimball et al. (2020b) indicate as likely to be hierarchical in origin. The sixth event (GW190517_055101) is shown in dotted red and has the lowest retention probability (30% for a cluster with escape speed 600 km/s). The highest retention probability is for GW190602_175927: its remnant is retained with 60% probability if the cluster has an escape speed of 600 km/s. GW190521, the most massive BBH detected to date, also has a significant retention probability. A dense star cluster with escape speed $\sim 700$ km/s will be able to retain GW190521 with 50% probability, potentially allowing for the future formation of an intermediate mass BBH.

We note that our method complements that of Kimball et al. (2020b). While their approach determines the hierarchical merger history of the binary constituents by measuring the masses and spins, our method projects these systems into the future and quantifies their ability to further participate in such mergers.

### 3. CHARACTERIZING CLUSTERS VIA THEIR RETENTION OF BH MERGER REMNANTS

Having examined the retention probability of a given GWTC-2 event $j$, we now extend our results to the entire population of 42 informative GWTC-2 events \( \{j = 1, \ldots, 42\} \). Let us suppose that these 42 events
are characteristic of the population of BBHs that merge in a single star cluster that is solely parametrized by its escape speed $V_{\text{esc}}$. Over time this entire population merges in this cluster, and individual merger remnants are retained if $V_{\text{kick}} < V_{\text{esc}}$. If the escape speed of the cluster $V_{\text{esc}}$ is large compared to typical values of $\{V_{\text{kick}}\}$, a large fraction of the population is retained and can go on to seed the next generation of mergers. If not, then clusters with a particular value of $V_{\text{esc}}$ (or lower) are likely to be poor sites for subsequent generations of BBH mergers. Assuming that the informative GWTC-2 events (which obviously do not all arise from a single cluster) are reflective of the cluster BBH population, we now attempt to characterize if a particular cluster with escape speed $V_{\text{esc}}$ is a good site for subsequent BBH mergers.

It is a strong assumption that the GWTC-2 BBHs form a sample reflective of the BBH population in a typical cluster parametrized only by its escape speed, and this assumption needs to be informed by future GW observations and cluster modeling. However, because the kick velocity does not depend on the binary total mass $M$, our model assumptions will hold even if the true BBH mass distribution in clusters differs from our sample of 42 events, provided that our sample accurately reflects the true distribution of mass ratios, spins, and spin orientations (the quantities that primarily determine the kick magnitude).

Given the above assumption, we characterize a particular cluster’s suitability as a site of future hierarchical growth via its median retention probability. For a cluster with escape speed $V_{\text{esc}}$, Sec. 2 showed that a given event $j$ has a retention probability $P_{\text{ret},j}(V_{\text{esc}})$ (which, e.g., could be read off from Fig. 2). If we consider that the entire set $\{j = 1, \ldots, 42\}$ of informative GWTC-2 events is in a single cluster with $V_{\text{esc}}$, and that the set is representative of the cluster’s BBH population, then the median retention probability for that cluster is given by $\text{median}[P_{\text{ret},j}(V_{\text{esc}}), j = 1, \ldots, 42]$. This defines our median retention probability, which is readily calculated from data like that shown in Fig. 2.

Using our calculated values for $P_{\text{ret},j}(V_{\text{esc}})$, we proceed to calculate the median retention probability as a function of the cluster escape speed. In doing so, we make no assumption about the nature of the cluster. The result is shown in Fig. 3. We see that clusters with escape speeds of 200 km/s and 500 km/s can retain, roughly, 18% and 50% of the informative GWTC-2 population, while a cluster with an escape speed of about 1000 km/s can retain 80% of the remnants.

Our estimates can be compared with those in Doctor et al. (2021), which obtained retention fractions of 4% and 40% for clusters with escape speeds of 50 km/s and 250 km/s. This broadly agrees with our numbers, though the retention probability in Doctor et al. (2021) is quantified using the hyperparameters that describe the GWTC-2 population.

An important implication of this result concerns the role of globular clusters, which have $V_{\text{esc}} \lesssim 80 \sim 180$ km/s (with 180 km/s at the high end of the escape speed distribution and most clusters under 80 km/s; see Fig. 3 of Antonini & Rasio (2016)). These have median retention probabilities $\lesssim 15\%$. While a small subset of globular clusters could facilitate hierarchical mergers, the overall probability of globular clusters serving as major sites of hierarchical mergers is low. However, nuclear star clusters, which have escape speeds $\sim 500$ km/s, can readily host hierarchical mergers as they retain more than half of the merger remnants.

4. RETENTION PROBABILITIES OF GWTC-2 EVENTS BY GLOBULAR AND NUCLEAR STAR CLUSTERS

We now map our “agnostic cluster” curve in Fig. 3 to globular and nuclear clusters, using their expected escape speed distributions (Antonini & Rasio 2016; Mapelli et al. 2020) to determine the probability that a particular GW event can be retained by a GC or NSC. (Note that these estimates of escape speeds are from the
center of the cluster for GCs, whereas for NSCs these are defined at the half-mass radius of the cluster.)

We first construct a cluster escape speed PDF \( p_k(V_{\text{esc}}) \), where the index \( k \) denotes GC or NSC. This PDF is constructed using log-normal fits to the data in Fig. 3 of Antonini & Rasio (2016), which have means \( \langle \log_{10} \left( \frac{V_{\text{esc}}}{\text{km/s}} \right) \rangle = (1.5, 2.2) \) and standard deviations \( \sigma_{\log_{10}(V_{\text{esc}}/\text{km/s})} = (0.3, 0.36) \) for GCs and NSCs (respectively). The corresponding CDF (giving the probability that \( V_{\text{esc}} \leq v_s \)) is denoted by \( F_k(v_s) \). Then the probability for a BH with kick \( V_{\text{kick}} \) to be retained by a given cluster is \( 1 - F_k(V_{\text{kick}}) \).

Given our kick PDF \( p_j(V_{\text{kick}}) \) for GWTC-2 event \( j \), the probability that event \( j \) is retained by a cluster of type \( k \) is then

\[
P_{\text{ret},j} = \int_0^{V_{\text{max}}} p_j(V_{\text{kick}})[1 - F_k(V_{\text{kick}})] dV_{\text{kick}}. \tag{1}
\]

This simply amounts to weighting each bin of the kick PDF by the probability \( [1 - F_k(V_{\text{kick}})] \) that a cluster \( k \) retains a kicked BH with \( V_{\text{kick}} \). We set \( V_{\text{max}} = 5000 \text{ km/s} \) (any choice \( V_{\text{max}} \geq 1000 \text{ km/s} \) would make only a negligible difference).

Applying Eq. (1), the retention probability of GWTC-2 event \( j \) by a GC or NSC is given in Table 1. The highest retention probability is for GW190814 (\( P_{\text{ret}} \approx 82\% \) for a NSC), due to the precise estimation of the low kick magnitude for this event. Four additional events have retention probabilities higher than 25\% for NSCs. Similarly, the probability that GW190814 is retained by a GC is \( \approx 11\% \), while two additional events have retention probabilities in GCs higher than 2\%.

Binning the numbers in Table 1, we construct in Fig. 4 the distribution of retention probabilities for NSCs and GCs. If all the informative GWTC-2 mergers happened in NSCs, we find that the retention probabilities of 90\% of those events would be between 0.122–0.279. Similarly, if all informative GWTC-2 events are associated with globular clusters, 90\% of them will have retention probabilities between 0.005–0.022. The outlier bump at large \( P_{\text{ret}} \) in Fig. 4 is due to GW190814; with the smallest (and best-measured) kick magnitude, it yields the largest retention probability.

The area of the two distributions in Fig. 4 (or summing the values in Table 1) gives us an estimate of the number of remnants that will be retained out of the 42 events we considered in the GWTC-2 population. There are \( \sim 8 \) (\( \sim 1 \)) events in GWTC-2 that could participate in further mergers if those events happened in nuclear (globular) clusters. These estimates are in good agreement with the projections of Mapelli et al. (2020), which indicate that roughly 15\% (0.6\%) of mergers in NSCs (GCs) would be hierarchical in nature. Note that these are present-day (\( z = 0 \)) retention probabilities; given the limited redshift reach of GWTC-2, we have not considered the redshift evolution of retention probability.

5. CONCLUSION

Formation and growth of black holes at different scales is an important open problem in astrophysics. Hierarchical mergers are one of the channels considered for black hole growth, although its efficiency is largely unknown. Observations of binary black hole mergers by LIGO/Virgo provide one of the most important tools to probe the hierarchical growth of black holes at the stellar mass scale. Predicted mass and spin distributions from hierarchical mergers were compared with GWTC-2 events in Kimball et al. (2020b) to assess the presence of hierarchical mergers. We discussed another approach for evaluating the prospects of hierarchical growth, by computing the probability that GWTC-2 merger remnants are retained by cluster environments—a necessary condition for hierarchical growth. This involved computing the gravitational-wave kick probability distribution for each GWTC-2 event and comparing with cluster escape speeds. Among the GWTC-2 merger remnants, we find about 8 remnants are expected to be retained by their host-clusters if they all merged in a nuclear star cluster, or about 1 event if all GWTC-2 mergers occurred in globular clusters. These retained remnants could po-
Table 1. Probability of retention for all informative GWTC-2 events by GCs or NSCs. This uses Eq. (1) to compute the probability that a BH merger remnant is retained by a cluster, given the distribution of cluster escape speeds and the inferred kick posterior distribution for each GWTC-2 event.

potentially participate in a subsequent generation of binary black hole mergers, provided favorable circumstances for binary formation exist near these black hole remnants. As hierarchical mergers are assisted by larger cluster escape speeds and a higher frequency of in-cluster mergers, understanding the redshift evolution of these two quantities will be important in determining the efficiency of hierarchical mergers as a function of cosmic time.

Our conclusions assume that all GWTC-2 mergers happened in star clusters and not in galactic fields, and this is hard to verify at present. As enhanced detector sensitivities allow the discovery of more binary black holes with improved parameter accuracy and precision, the methods discussed here will provide a unique probe of the hierarchical growth of stellar-mass black holes.

We thank Fabio Antonini for reading the manuscript and providing useful comments. We also thank J. Bustillo and V. Varma for comments on the paper, S. Chatterjee for valuable discussions and pointers to important references, and S. Datta, P. Saini, P. Ajith, S. Kapadia, A. Vijayakumar and M. A. Shaikh for useful discussions. K.G.A. acknowledges the Swarnajayanti grant DST/SJF/PSA-01/2017-18 of the Department of Science and Technology, India. K.G.A and P.M. acknowledge the support of the Core Research Grant EMR/2016/005594 of the Science and Engineering Research Board of India and a grant from Infosys foundation. This material is based upon work supported by the NSF’s LIGO Laboratory which is a major facility fully funded by the National Science Foundation. We also acknowledge NSF support via NSF CAREER award PHY-1653374 to M. F. and NSF award AST-2006384 to B.S.S. This research has made use of data obtained from the Gravitational Wave Open Science Center (www.gw-openscience.org), a service of LIGO Laboratory, the LIGO Scientific Collaboration and the Virgo Collaboration. Virgo is funded by the French Centre National de Recherche Scientifique (CNRS), the Italian Istituto Nazionale della Fisica Nucleare (INFN) and the Dutch Nikhef, with contributions by Polish and Hungarian institutes. This has the LIGO preprint number P2100188.
APPENDIX

A. KICK FITTING FORMULA

Here we summarize the employed model for inferring the magnitude of the kick velocity. We directly apply fitting formulas based on numerical relativity simulations of binary black holes (Gonzalez et al. 2007b; Campanelli et al. 2007b; Gonzalez et al. 2007a; Lousto & Zlochower 2008; Lousto et al. 2012a; Lousto & Zlochower 2013). Following Campanelli et al. (2007b), the kick velocity magnitude is decomposed as

\[ V_{\text{kick}} = \sqrt{\frac{V_m^2 + 2V_mV_s \cos \xi + V_s^2 + V_{s \parallel}^2}{1 + q}}, \]

where \( V_m, V_s, V_{s \parallel} \) are expressed in terms of (Lousto et al. 2012a; Lousto & Zlochower 2013; Gerosa & Kesden 2016)

\[ \Delta = \frac{\chi_1 - q\chi_2}{1 + q}, \]
\[ \tilde{X} = \frac{q^2\chi_2 + \chi_1}{(1 + q)^2}, \]

where \( q \leq 1 \) is the mass ratio of the binary and \( \chi_{1,2} \) are the dimensionless spin vectors of the progenitor BHs. Contributions to the kick velocity listed in Eq. (A1) are given by (Lousto et al. 2012a; Lousto & Zlochower 2013):

\[ V_m = A \eta^2 \frac{1 - q}{1 + q} (1 + B \eta), \]
\[ V_s = H \eta^2 \Delta, \]
\[ V_{s \parallel} = 16 \eta^2 \Delta \Delta (V_{11} + 2V_A \tilde{X}_{\parallel} + 4V_B \tilde{X}_{\parallel}^2 + 8V_C \tilde{X}_{\parallel}^3) + 2 \tilde{X}_{\parallel} \Delta \Delta (C_2 + 2C_3 \tilde{X}_{\parallel}) \cos \Theta, \]

where

\[ \eta = \frac{q}{(1 + q)^2}, \]
\[ \Delta = |\Delta \cdot \hat{L}| = \frac{\chi_1 \cos \theta_1 - q\chi_2 \cos \theta_2}{1 + q}, \]
\[ \Delta = |\Delta \times \hat{L}| = \frac{1}{1 + q} [\chi_1^2 \sin^2 \theta_1 + q^2 \chi_2^2 \sin^2 \theta_2 - 2q\chi_1 \chi_2 \sin \theta_1 \sin \theta_2 \cos \phi_{12}]^{1/2}, \]
\[ \tilde{X}_{\parallel} = \tilde{X} \cdot \hat{L} = \frac{\chi_1 \cos \theta_1 + q^2 \chi_2 \cos \theta_2}{(1 + q)^2}, \]
\[ \tilde{X}_{\parallel} = |\chi \times \hat{L}| = \frac{1}{(1 + q)^2} [\chi_1^2 \sin^2 \theta_1 + q^4 \chi_2^2 \sin^2 \theta_2 + 2q^2 \chi_1 \chi_2 \sin \theta_1 \sin \theta_2 \cos \phi_{12}]^{1/2}. \]

In the above \( \hat{L} \) is the unit vector along the total orbital angular momentum, \( \theta_{1,2} \) are the angles between \( \hat{L} \) and \( \chi_{1,2}, \phi_{12} \) is the difference between the azimuthal angles of the two spin vectors, and \( \chi_{1,2} \) are the spin magnitudes. The values of the different numerical fitting coefficients are: \( A = 1.2 \times 10^4 \text{ km/s}, B = -0.93 \) (Gonzalez et al. 2007b), \( H = 6.9 \times 10^3 \text{ km/s} \) (Lousto & Zlochower 2008), \( V_{11} = 3677.76 \text{ km/s}, V_A = 2481.21 \text{ km/s}, V_B = 1792.45 \text{ km/s}, V_C = 1506.52 \text{ km/s} \) (Lousto et al. 2012b), \( C_2 = 1140 \text{ km/s}, C_3 = 2481 \text{ km/s} \) (Lousto & Zlochower 2013). The angle \( \xi \sim 145^\circ \) for a wide range of quasi-circular configurations (Lousto & Zlochower 2008), whereas \( \Theta \) is defined as the angle between \( \Delta \times \hat{L} \) and a fiducial infall direction of the two holes at merger. (See Gerosa & Kesden (2016) for a more precise definition of \( \Theta \), which depends on orbital phase of the binary at an arbitrary reference time.)
Table 2. JS divergence between the posterior and prior distributions of the kick magnitude for different events in GWTC-2. Higher values of the JS divergence imply more informative posteriors, with GW190814 being the most informative one in GWTC-2. Following Abbott et al. (2020), a threshold of 0.007 on the JS divergence is imposed, and only those events that pass the threshold are presented in the Table. For a Gaussian distribution, this threshold corresponds to a 20% shift in its mean.

</table>

Since the spin vectors can evolve considerably throughout the binary inspiral, the kick velocity fitting formula can only be employed close to the merger, at separations $\sim 10M$ where NR simulations typically start [see Barausse & Rezzolla (2009) and Sec. 2.1 of Gerosa & Sesana (2015)]. To account for this, we evolve the posterior samples (which are specified at a reference frequency of 20 Hz) to a separation of 10$M$ using orbit-averaged post-Newtonian equations of motion (Apostolatos et al. 1994; Kidder 1995; Racine 2008; Schnittman 2004) contained in the LALSimulation libraries of LALSuite (LIGO Scientific Collaboration 2018). (For GW190521, the reference frequency is chosen to be 11 Hz.)

For BBHs from the first two observing runs (GWTC-1), we use the posterior samples produced by the Bayesian inference package Bilby (Ashton et al. 2019; Romero-Shaw et al. 2020) using the IMRPhenomPv2 waveform model (Hannam et al. 2014). For events observed during the first half of the third observing run (reported in GWTC-2), posterior samples are drawn from the GWTC-2 Data Release (LIGO Scientific Collaboration and Virgo Collaboration 2020) corresponding to PrecessingSpinIMRHM (i.e., using combined samples from the analysis that applied waveform families accounting for precession and higher modes).

B. JENSEN-SHANNON DIVERGENCE FOR THE KICK POSTERIORS

The issue of prior-dominated posteriors in the context of kick magnitude inference was pointed out by Varma et al. (2020) while inferring the kicks for GW150914 and GW170729. Priors on the kick magnitude are constructed by combining priors on the mass ratio and spin parameters with relevant NR fitting formulas for the kick. It was specifically noted that the difference between the inferred kick posteriors and the corresponding priors is very small, as evidenced by the Kullback–Leibler (KL) divergence (Kullback & Leibler 1951) between them. This was attributed to the lack of stringent constraints on the spin parameters of the binary. Here, in order to assess the information content of our kick posteriors relative to our priors, we employ a similar measure, the Jensen–Shannon (JS) divergence (Lin 1991). This is a symmetric (with respect to the two distributions that are being compared) version of the KL divergence and always has a finite value. We set a threshold of 0.007 for the JS divergence [the same threshold used in Abbott et al. (2020) for comparing posterior distributions between different waveform approximants]; above this threshold we consider the posteriors to be informative. For technical details of JS divergence, see Appendix A of Abbott et al. (2020).

This criterion reduces our GWTC-2 sample to 42 (informative) binaries. We restrict to these informative events in this study. Table 2 lists the JS divergence for the events that crossed the 0.007 threshold. GW190814 has the highest JS divergence and also has the most informative kick posterior in the entire GWTC-2 catalog.
